The order of the structure of mesoporous materials was investigated by X-ray diffraction (XRD) using nickel filtered Cu Kα radiation. XRD patterns were recorded in the 2θ range from 1 to 10 degrees. Specific surface area was determined by nitrogen adsorption. In order to investigate the local structure around zirconium, the extended X-ray absorption fine structure (EXAFS) spectra at Zr K-edge (18.0 keV) of the catalysts were measured using a Si(111) double-crystal monochromator at BL-12C of KEK-PF. Data analysis was performed by UWXAFS package [9] and the backscattering amplitudes and phase shifts

*e-mail : aritomo@rs.noda.tus.ac.jp

were calculated with FEFF8 code [10]. The k^3-weighted EXAFS functions were Fourier transformed and fitted in R space. The k range of the Fourier transformation of EXAFS data was 30–150 nm^{-1} and the fitting R range was 0.13–0.38 nm. The spectra were fitted by two shells at most; Zr-O and Zr-(O)-Zr. The fitting parameters were coordination number, interatomic distance and Debye-Waller factors for each shell, and a correction of the threshold energy (ΔE_0). The value was determined so that the average residual factor got minimum. The number of free parameters should be smaller than the number of independent parameters calculated from the Niquest law.

Catalytic activities of Zr-MCM-41 for the peroxidative bromination of phenolsulfonephthalein (phenol red) were studied. In the reaction, 3 ml of an aqueous solution containing 0.2 mM phenol red, 0.1 M potassium bromide, and 10 mM hydrogen peroxide in HEPES buffer (pH 6.5) was stirred in the presence of 7.2 mg of the catalyst [8], to give 3′,3″,5′,5″-tetrabromophenolsulfonephthalein (bromophenol blue). Phenol red and bromophenol blue have an absorption peak at 450 and 589 nm, respectively, and the reaction was analyzed with a UV-vis spectrometer.

3. Results and discussion

3.1. *Characterization by XRD, TEM and nitrogen adsorption*

The XRD patterns of pure silica MCM-41 and Zr-MCM-41(mix) exhibited four distinguishable peaks before calcination, due to the hexagonal phase MCM-41. After calcination, the hexagonal structure of the MCM-41 and Zr-MCM-41(mix) samples was found to be retained, though the structural order decreased as evidenced by the weaker XRD peak. We investigated the unit cell parameters (***a***) obtained from XRD patterns and the specific surface areas derived from nitrogen adsorption technique. The calcination in air at 773 K caused 14 and 12% lattice contraction for pure silica MCM-41 and Zr-MCM-41(mix), respectively. Impregnation with ethanolic $ZrCl_4$ solution reduced the XRD peak for Zr-MCM-41-393(imp).

The XRD peaks for Zr-MCM-41-393(imp), Zr-MCM-41-573(imp), Zr-MCM-41-773(imp), and Zr-MCM-41-1273(imp) at $2\theta \sim 2.8$ (100 reflection line) revealed that Zr-MCM-41(imp) retained its structure after calcination at 573 and 773 K, whereas the structure of Zr-MCM-41(imp) completely collapsed after calcination at 1273 K. The specific surface areas of Zr-MCM-41(mix) and Zr-MCM-41-393(imp) were 676 and 831 $m^2\,g^{-1}$, respectively, in almost agreement with the value in the literature [11].

TEM images of MCM-41 and Zr-MCM-41-393(imp) also showed that they had ordered mesoporous structures.

3.2. *EXAFS analysis*

Figure 1 shows the Fourier transformed k^3-weighted EXAFS functions (phase shift uncorrected) for Zr-MCM-41(mix), Zr-MCM-41-393(imp), and a reference sample ZrO_2, together with the calculated functions derived from the curve fitting analysis. Two peaks were observed at 0.16 and 0.29 nm in Fig. 1 (a) for Zr-MCM-41(mix), distances similar to those corresponding to the peaks for ZrO_2, and were assigned to Zr-O and Zr-(O)-Zr contributions, respectively. Zirconium species in Zr-MCM-41(mix) aggregated each other and formed Zr-O-Zr bonds. XRD pattern in the 2θ range of 20–80 degrees for Zr-MCM-41(mix) did not show the peaks of ZrO_2 crystal indicating that Zr species

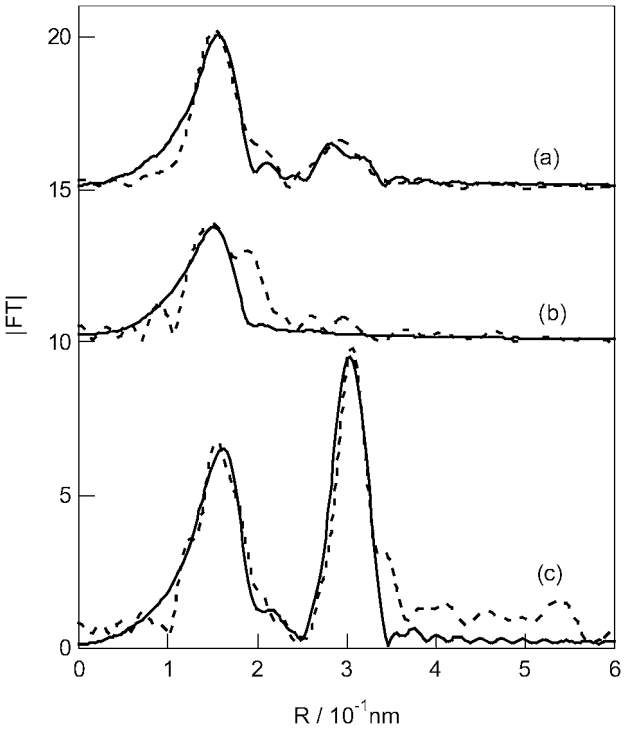

Fig. 1. Fourier transformed k^3-weighted EXAFS functions (·····) for (a) Zr-MCM-41(mix), (b) Zr-MCM-41-393(imp) and (c) reference sample ZrO_2, together with the results of curve fitting (———).

for Zr-MCM-41(mix) aggregated each other at amorphous phase. The higher shells in Fig. 1 (a) are different from those in Fig. 1 (c) because Zr species in Fig. 1 (a) and (c) are amorphous and crystal ZrO_2, respectively. As Zr species at amorphous phase does not have long-range order, the higher shells of Fourier transformed function decrease or disappear. Zr-MCM-41-393(imp) showed two peaks at 0.16 and 0.20 nm in Fig. 1 (b), which were assigned to Zr-O and long Zr-O contributions, respectively. Zr species in Zr-MCM-41-393(imp) were highly dispersed because no Zr-(O)-Zr bond was observed. Figure 2 shows the Fourier transformed k^3-weighted EXAFS functions (phase shift uncorrected) for Zr-MCM-41-573(imp), Zr-MCM-41-773(imp), and Zr-MCM-41-1273(imp), together with the calculated functions derived from the curve fitting analysis. The Fourier transform peaks at 0.29 nm in Fig. 1 (a) and Fig. 2 were fitted by Zr-(O)-Zr rather than Zr-(O)-Si, exhibiting better fits in the region, which indicated that zirconium were not incorporated in the Si framework of MCM-41 and that Zr species aggregated each other.

3.3. *Catalytic activity*

The catalytic activity of pure silica MCM-41 for the peroxidative bromination of phenol red was studied using spectral changes in UV-vis absorption. The peak at 440 nm did not decrease, which indicated that the concentration of phenol red did not change and MCM-41 without zirconium was inactive in the peroxidative bromination of phenol red. We investigated changes in the UV-vis spectrum during the reaction in the presence of Zr-MCM-41(mix) and Zr-MCM-41-393(imp). The peak at 440 nm decreased and that at 589 nm increased, a fact indicating that the reaction (phenol red changed to bromophenol blue) occurred and Zr-MCM-41(mix) and Zr-MCM-41-393(imp) showed catalytic activity in the reaction. Zirconium species in MCM-41 formed active sites for the peroxidative bromination reaction of phenol red. ZrO_2 crystal was inactive in the reaction. Zr-MCM-41-393(imp) had an activity

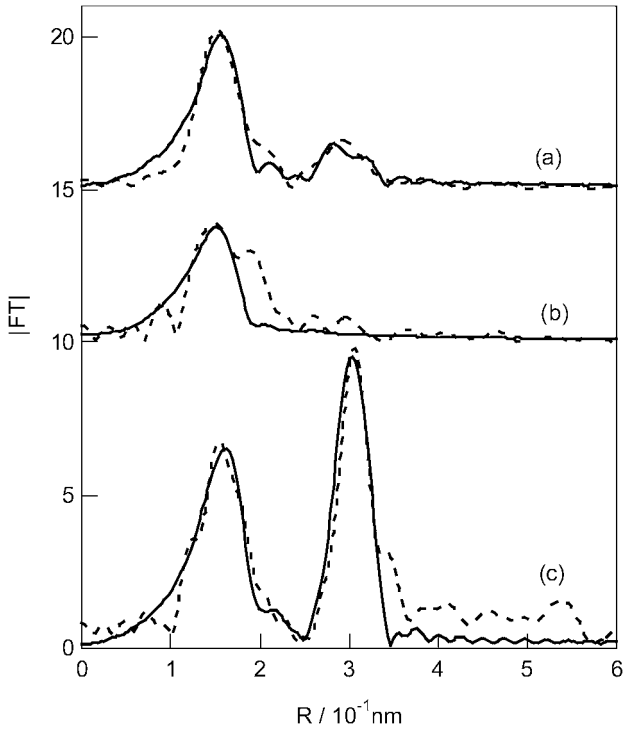

Fig. 2. Fourier transformed k^3-weighted EXAFS functions (· · · · · · · · ·) for (a) Zr-MCM-41-573(imp), (b) Zr-MCM-41-773(imp) and (c) Zr-MCM-41-1273(imp), together with the results of curve fitting (———).

higher than that for Zr-MCM-41(mix). Aggregation of zirconium species was observed in Zr-MCM-41(mix) as suggested by the results of EXAFS analysis, while zirconium species was found to be highly dispersed on the mesopore silica wall in Zr-MCM-41-393(imp), thus suggesting that the number of active site is relatively large. Zr-MCM-41-573(imp) has lower activity for the peroxidative bromination reaction of phenol red than that of Zr-MCM-41-393(imp) and that the activity for the reaction decreases with calcination temperature. As revealed in the results of EXAFS analysis, zirconium species aggregate each other by calcination at 573 K. The aggregation of zirconium species caused reduces the catalytic activity for the reaction.

Acknowledgement

The EXAFS measurements were done by the approval of the PAC committee (proposal No: 2001G298).

Abstract

X-ray absorption spectroscopy has been used to optimize the synthesis of Ni nano particles between thin layers of AlO_x in an Al matrix. Al deposition is used to reduce previously oxidized Ni clusters. Ex-situ characterization shows absence of Ni/Al intermixing and of Ni oxidation for a wide range of Ni thickness and exposures to dry air. The system shows new magnetic properties reported here for the first time.

1. Introduction

Al or AlO_x coating of ferromagnetic metals (FM) or anti-ferromagnetic oxides is a step of the fabrication of magnetic tunnel junctions. In this step mixing can occur at the interface between Al and the ferromagnetic metal or incomplete oxidation of the AlO_x barrier can reduce a part of the underlying anti-ferromagnetic oxide.

Recently, Egelhoff *et al.* suggested employing oxygen to suppress intermixing at the Al/*FM* interface [1]. The authors showed by X-ray reflectometry that oxidation of the first atomic layers of the ferromagnetic metal is sufficient to stop intermixing with Al in the case of $X = $ Co, Ni and $Ni_{80}Fe_{20}$ for stacks of the type SiO_2\10 nm X\4 nm Al. The same authors reported that Al is able to reduce the first few atomic layers of the ferromagnetic metal (*FM* = Ni, Co or Fe) and form an AlO_x diffusion barrier. R. Schad *et al.* [2] observed the stability of the AlO_x barrier and its capacity to protect the *FM* metal from oxidation even at an AlO_x thickness of about 0.6 nm. The authors employed reflectometry or X-ray photo-emission spectroscopy (XPS), but no detailed structural data are available by these techniques. Room temperature spontaneous mixing at the Al/Ni interface has already been successfully characterized by combining XAS and magnetic measurements (SQUID). Ni/Al (111) bi-layers [3] as well as Ni/Al multilayers [4] have been investigated. Ni and Al quickly react and below a thickness of 8 ML, Ni is fully mixed with Al, thus non-magnetic [5, 6].

We have studied stacks of the type SiO_2\Al*FM* t(nm)\Al produced by metal vapor deposition (MVD) in high vacuum (HV). After the deposition of each Ni or Al film, samples are exposed in-situ to a dry synthetic air flux. When optimal exposure time and pressures are found, no sign of FM\Al intermixing or of FM oxidation can be detected for t_{Ni} as low as 0.7 nm, even if exposure to oxygen is by two orders of magnitude larger than that reported by Egelhoff *et al.* [1].

XAS is sensitive both to oxidation state and local structure, it proves to be a unique tool to optimize the synthesis conditions: stopping intermixing and prevent oxidation of the thin ferromagnetic layer. We have been able to make *FM* clusters at the scale of a few nm or less in Al/AlO_x.

Grazing incidence small angle X-ray scattering (GISAXS) and transmission electron microscopy sustain XAS observations and provide upper limits for cluster size and cluster-cluster distances.

Finally, first magnetic results are shown. Peculiar magnetic properties are found and the possible origin of these features will be shortly discussed.

2. Experimental

Samples of the type SiO_2/Al 20 nm (p_{air})/Ni t(nm) (p_{air})/Al 20 nm were prepared in a HV chamber by metal vapor evaporation on a room temperature substrate. Maximum pressure during evaporation of the metals is in the low 10^{-7} mbar range. After the deposition of each different layer of the film, we raise the pressure in the chamber with a flux of synthetic air: nitrogen is necessary to avoid damages to the turbo pump. The pressure is kept for 5′ and then it is lowered back to the base value in almost the same time. The values of air pressure (20% O_2) are reported in Tab. I and discussed in section 3 with the results. Al and Ni thicknesses have been measured by a calibrated quartz micro-balance during deposition. Growth speeds are 10^{-2} and 10^{-1} nm s^{-1} for Ni and Al, respectively.

XANES (in Fig. 1) and EXAFS (not shown) spectra have been recorded at beam line D42 LURE with Si111 channel cut monochromator; a ionization chamber filled with air was used to monitor the incoming monochromatic beam and spectra were collected in the conversion electron yield (CEY) mode at liquid nitrogen temperature (LNT). The CEY cryostat employed is described in [7]. Spectra have been analyzed towards

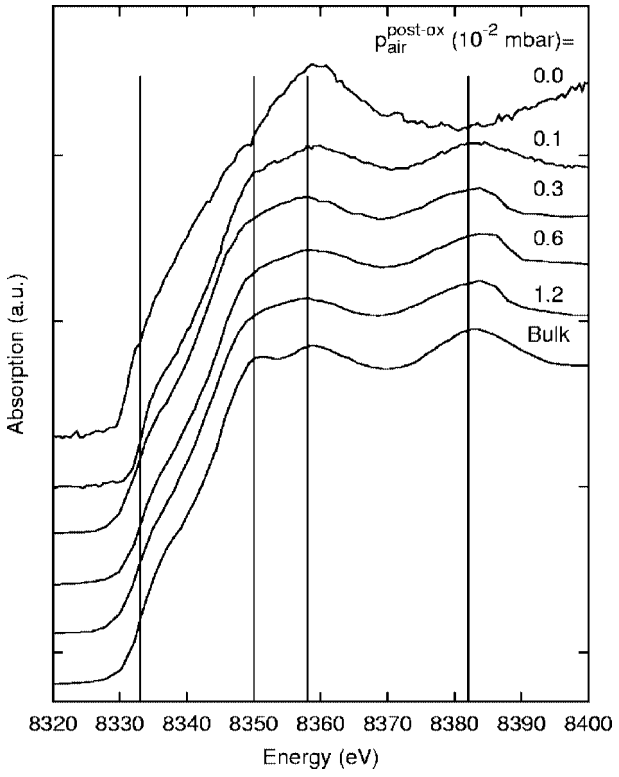

Fig. 1. XANES spectra at the Ni K-edge on samples SiO_2/Al 20 nm/Ni 1.5 nm/Al 20 nm versus different exposures to synthetic air (20% O_2/80% N_2). Exposure time is constant, 300 s. See Section 2. experimental for details.

theoretical standards obtained with code Feff8.1 [8] and self consistent MS calculations. EXAFS extraction and refinements have been performed by Autobk [9] and IFeffit codes [10], respectively.

The morphology and arrangement of the clusters was investigated by grazing incidence small-angle X-ray scattering (GISAXS) [11]. Measurements were carried out on DW31B LURE beam-line at a wavelength of 0.168 nm. GISAXS spectra are not shown.

The microstructure of the films was investigated by a JEOL 3010 high resolution transmission electron microscope (HRTEM) operating at 300 kV. A cross section of the sample with $t_{Ni} = 1.5$ nm and $p_{air} = 10^{-3}$ mbar is shown in Fig. 2.

Magnetization cycles have been measured with a superconducting quantum interference device (SQUID) at different temperatures and are reported in Fig. 3 and 4. Diamagnetic background coming from the thick SiO_2 substrate has been removed by a linear fit of the magnetization at high negative fields. A magnetization measurement of a blank SiO_2 substrate has been used to check the procedure and ensure background linearity.

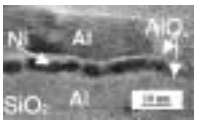

Fig. 2. Transmission electron microscopy image on a cross section of sample SiO_2/Al 20 nm/Ni 1.5 nm/Al 20 nm with $p = 3.0 \cdot 10^{-3}$ mbar. Ni clusters are in black at the center embedded in a thin layer of amorphous AlO_x.

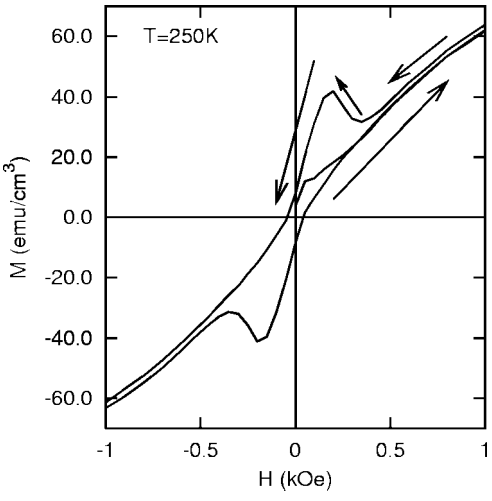

Fig. 4. An expanded view of the magnetization-demagnetization cycle at $T = 250$ K of sample SiO_2/Al 20 nm/[Ni 1.5 nm/Al 8.3 nm]$_3$ with $p = 10^{-3}$ mbar. The arrows indicate the magnetization path.

3. Results

3.1. *X-ray absorption spectroscopy*

XANES spectra in Fig. 1 well describe how XAS is effective in detecting Ni/Al intermixing and in driving synthesis optimization: when no air is introduced in the chamber after the deposition (in Fig. 1. $p_{air} = 0.0$ mbar), Ni and Al diffuse and XANES is typical of a disordered Ni aluminide like AlNi, Al_3Ni or Al_3Ni_2 [3, 4]. At pressures above $p_{air} = 10^{-3}$ mbar spectra are similar to bulk Ni, but smeared. This can be due to disorder or size distribution and small size of the particles. At $p_{air} = 10^{-3}$ mbar XANES is similar to bulk Ni, but the peak above 8358 eV is displaced at higher energy and is broader. This is simply due to the presence of a small Ni aluminide fraction that contributes to XANES [4]. The analysis of EXAFS spectra (not shown here)

Table II. *Thickness dependence of the structure and size of Ni clusters.*

Ni thickness t (nm)		N	R (nm)	σ^2 (10^{-5} nm^{-2})	Average Particle Diameter (nm)
0.7	Al	3(1)	2.41(2)	12(8)	
	Ni	4.9(7)	2.482(6)	5(1)	0.63(9)
1.5	Ni	8.9(6)	0.2478(3)	5.4(5)	1.5(3)
3.0	Ni	10.4(4)	0.2482(2)	4.8(3)	2.8(7)
6.0	Ni	11.3(6)	0.2481(3)	4.4(4)	>4
12.0	Ni	11.9(4)	0.2485(2)	4.6(2)	/
20.0	Ni	12.1(4)	0.2487(2)	4.4(2)	/
Bulk	Ni	12.0(5)	0.2478(2)	3.1(3)	/

gives a more quantitative description of the system. Results for samples at different oxidation pressures and $t_{Ni} = 1.5$ nm are shown in Tab. I. In agreement with XANES qualitative perusal, sample labeled $p_{air} = 0.0$ mbar contains a diluted Ni aluminide, while rising the pressure to $p_{air} = 10^{-3}$ mbar separates Ni and Al except for a small fraction. At higher pressures the local structure contains only contributions of a small Ni cluster and it does not change significantly from sample to sample. From the diminished Ni-Ni coordination number we can estimate the average particle size that is 1.5(5) nm.

EXAFS analysis results on samples obtained with variable Ni thickness and $p_{air} = 3 \cdot 10^{-3}$ are shown in Tab. II. The Ni-Ni coordination number increases as t_{Ni} and the average particles size obtained is close to the layer thickness. Disorder decreases in the series as we move from a fine particulate system to an almost continuous film. Ni-Ni distance marginally changes, but there is no clear trend in its evolution. In the case of $t_{Ni} = 0.7$ nm (about 3 Ni atomic layers), instead of a Ni-O contribution a Ni-Al signal is found. Assuming that it comes from the particles interfaces, we can deduce an average particle size of 0.63(9) nm.

3.2. *GISAXS*

GISAXS results (Tab. III) are of difficult interpretation for Ni thickness above 1.5 nm, since the system is almost coalescent. In Tab. III, numerical results for samples obtained with $p_{air} = 3 \cdot 10^{-3}$ mbar are shown. For $t_{Ni} = 0.7$ and 1.5 nm two small nonspecular diffuse peaks appear along the q_y axis. Integration of narrow stripes in the q_z and q_y directions provides information on vertical and horizontal particle sizes and average inter particle distance.

Actually, at $t_{Ni} = 1.5$ nm (and both p_{air}) half of the matter is apparently lost and it could be in the form of smaller particles or in a quasi continuous layer. This point will be discussed later.

Table III. *GISAXS results for $p_{air} = 3 \cdot 10^{-3}$ mbar.*

t_{Ni} (nm)	p_{air} (mbar)	Particle size (nm × nm)	Particle-Particle Distance (nm)
0.7	$3 \cdot 10^{-3}$	3.0 × 1.7	4.9
1.5	$3 \cdot 10^{-3}$	3.0 × 1.5	5.6
1.5	$1 \cdot 10^{-3}$	3.0 × 2.0	6.0

3.3. *Electron Microscopy*

A cross section of sample $p_{air} = 3 \cdot 10^{-3}$ mbar and $t_{Ni} = 1.5$ nm is shown in Fig. 2. Clusters are visible as dark objects in the central layer. Around them, a thin film is observable in light contrast. This is most likely AlO_x as will be discussed in the next section. Then, lower and upper Al films are visible; in the upper film there is a Al grain oriented as such to diffract the electrons and reveal interference fringes.

3.4. *Magnetometry*

Up to now, only sample (SiO_2/Al 20 nm/[Ni 1.5 nm/Al 8.3 nm]$_3$, $p_{air} = 1 \cdot 10^{-3}$ mbar) has been investigated. Magnetization cycles are shown in Fig. 3 for temperatures below and above the blocking (T_B) and Curie (T_C) temperature. Blocking temperature is about 50 K at 100 Oe and Curie temperature at about 250 K (corresponding zero-field-cooled/field-cooled cycles are not shown here). Lowering of the saturation magnetization ($M_S = -250$ emu/cm^3 at $T = 250$ K and 1 kOe) and increase of the coercitive field (H_C about 240 Oe at 5 K) with respect to bulk ($M_S = 484$ emu/cm^3, $H_C = 6$ Oe) are observed.

Another important feature appears at H about 1 kOe: the total magnetization drops of about 40% and at higher field it increases again, but at slower rate. This happens at 1 kOe at 5 K and at lower fields at higher temperatures.

A more detailed view of the magnetization cycle at 250 K is shown in Fig. 4 and reveals a second feature. The path it is not reversible and the total magnetization increases in a narrow region at low field while decreasing applied field. To our knowledge, these two features have never been described before in the literature.

4. Discussion

X-ray absorption data give direct and indirect information on the Ni structure. The first important information is that Ni oxide is not found in all samples within the sensitivity of XAS (a few %). Sample $t_{Ni} = 0.7$ nm should be the more sensitive, since it has the most important surface to bulk ratio; in this sample Ni-Al contributions are found instead of Ni-O. This finding is in accordance with the more negative potential for the oxidation of Al than that of Ni, then Ni and Al mixing is favorable in thermodynamic terms and occurs spontaneously at room temperature [3, 4] Al deposited on the top of oxidized Ni completely reduces it, thus Ni is surrounded by AlO_x.

The size of the particles as evaluated by XAS, GISAXS and observed by TEM is quite different. XAS results indicate a dense packing of particles with an average diameter close to the layer thickness for $t_{Ni} < 3$ nm. Actually, for values of t_{Ni} equal to or larger than 3 nm, it is not appropriate to speak in terms of particles, since GISAXS shows that particles are coalescent and no more nonspecular peaks are visible.

On the other hand, if we restrain our discussion to values of t_{Ni} equal to or smaller than 1.5 nm, GISAXS estimate does not take into account a large part of matter. Larger, well ordered particles contribute much more to the nonspecular signal than smaller particles. This justifies that the Ni amount calculated on the basis of GISAXS for sample $t_{Ni} = 1.5$ nm is less than half of the real Ni quantity even considering a compact packing in the plane. Thus, EXAFS average can be retained, but GISAXS gives a good estimate of the larger particles. This is in part confirmed by TEM cross section in which largest particles are almost 2–3 nm in

size, while particle-particle distance cannot be easily determined since we are observing the projection in the plane of the particles at different depths.

Magnetic properties of embedded nano particles are quite complex, since they are dominated by competing factors. While small size should favor an increased magnetic moment of the surface particles as observed in free particles [12], the interaction with the matrix can induce a loss [4, 13] or an increase [14] of the magnetization or more complicate exchange effects [15]. In addition, inter particle interactions play a role when the distance between particles is comparable to their size, as it is the case here.

This complexity makes difficult to find a model to explain magnetization cycles reported in Fig. 3 and 4. The irreversible path in Fig. 4 can be partially explained by the nucleation of vortex and its propagation during magnetization reversal as described by Guslienko *et al.* [16]. Actually, the authors described the vortex inside a particle and its propagation in an array of particles, but the same scheme could be applied to a vortex structure of magnetically interacting particles.

The drop of magnetization observed at all temperatures could be caused by a partial antiferromagnetic (AF) coupling of particles or of the particle shell. The origin of this coupling is at present undetermined. While the presence of a significant fraction of Ni oxide, which is AF, has been excluded and it has been demonstrated that Ni should be in contact with Al rather oxygen, this point is open and it is the subject of our active research.

5. Conclusions

A dense layer of Ni clusters with sizes below 3 nm can be produced in a thin AlO_x cage embedded in Al. XAS shows to be the best method to characterize the clusters and optimize the synthesis for particle sizes of a few nanometers.

Magnetization measurements reveal new properties of these systems that are reported here for the first time. The work to understand them is currently in progress.

Abstract

Both XAFS and XRD techniques have been used to investigate the effects of boron and phosphorous in nano-amorphous Ni-B and Ni-P alloys annealed at various temperatures. The XAFS and XRD results indicate that the initial Ni-B and Ni-P samples are amorphous alloys with large disorder. The static disorder factor (σ_S) of the nearest Ni-Ni sub-shell is 0.33 and 0.28 Å for the initial Ni-B and Ni-P alloys, respectively. Under an annealing temperature of 573 K, the nano-amorphous Ni-B alloy is crystallized into mixed phases of a crystalline Ni_3B and a metastable intermediate with smaller grain size and metallic Ni-like structure whose average grain size is about 30 nm, and the nano-amorphous Ni-P alloy forms two phases of crystalline Ni and Ni_3P with an average grain size of about 120 nm. It means that boron can retard the growth of Ni-B alloy into particles with larger size, in comparison with phosphorous. When the annealing temperature is increased to 773 K, most of the nano-crystalline Ni_3B is decomposed into crystalline Ni with larger grain size, but crystalline Ni_3P is rather stable. The XAFS results further show that the local structure around Ni atoms in the NiB sample annealed at 773 K is almost the same as that of Ni foil. However, the static disorder σ_S (0.125 Å) of the Ni-P sample annealed at 773 K is still much larger, which is attributed to the existence of some amount of crystalline Ni_3P. These results suggest that there is a great difference in the crystallization mechanism between nano-amorphous Ni-B and Ni-P alloys.

1. Introduction

Recently, much attention has been paid to the industrial applications of catalytic hydrogenation of nano-amorphous metal-metalloid Ni-B (P) alloy powders prepared by chemical reduction, since they have shown much higher activity and selectivity in the hydrogenation of furfural, cyclopentadiene and benzene as compared to the conventional industrial catalyst of Raney Ni [4–9]. In order to well understand and modify the catalytic nature of nano-amorphous Ni-B and Ni-P alloys, it is essential to study the effect on their structures of boron and phosphorous.

A lot of studies have been performed to elucidate the roles of boron and phosphorous in amorphous Ni-B (P) alloys. Li *et al*. [10, 11], Keong *et al*. [12] have studied the long-range structures of Ni-B and Ni-P alloys with X-ray diffraction (XRD). Their results have shown that the initial Ni-B and Ni-P samples are amorphous alloys. After annealing at 573 K, the amorphous Ni-B alloy crystallized to form a mixture of Ni, Ni_2B and Ni_3B [10, 11], and amorphous Ni-P alloy crystallized to produce a mixture of Ni, Ni_2P and Ni_3P [12]. With the annealing temperature rising to 773 K, most of the Ni_3B alloy in the Ni-B alloy decomposes into metallic Ni with a large grain size [11, 13, 16], while the crystalline Ni_3P in the NiP alloy kept its stability [12, 14, 15]. Although Li *et al*. have studied the structure of Ni-B and Ni-P with XAFS [10, 11, 14, 15], they only showed the radial structural functions of Ni atoms for the initial and annealed Ni-B and Ni-P alloys. Their results indicate that the amorphous Ni-B and Ni-P alloys are crystallized at annealing temperatures of 573 or 773 K. However, they have not performed a deeper and quantitative data analysis for the local structures of the amorphous Ni-B and Ni-P alloys due to the difficulty in analyzing XAFS spectra with large disorder.

In this work, both XRD and XAFS are used to study the long-range and local structures of initial and annealed nano-amorphous Ni-B and Ni-P alloys prepared by chemical reduction. We aim to investigate the influence of boron and phosphorous on the structures and the thermal stability of the nano-amorphous NiB and NiP alloys. These results are useful to understand the relationship between the structures and catalytic activity for nano-amorphous Ni-B and Ni-P alloys.

2. Experimental

Nano-amorphous Ni-P alloy powders were prepared via the following procedures: 22.5 g $NiCl_2{\cdot}6H_2O$, 20 g $NaH_2PO_2{\cdot}H_2O$ and NaAc were dissolved in water, and the volume of this mixed aqueous solution was 150 ml. The pH of this mixed solution was adjusted to 11 using 0.1 mol NaOH solution. Then, the aqueous solution was heated and kept at 313 K in a water bath for 4 hours. After the reaction had finished, the product was filtered and washed thoroughly with ammonia solution, subsequently washed by distilled water and 99.9% ethanol (EtOH) several times. The final product was kept in EtOH. The preparation of nano-amorphous Ni-B was described elsewhere [16]. Inductively coupled plasma spectrometry showed that the atomic composition of Ni-B and Ni-P powder was $Ni_{70}B_{30}$ and $Ni_{80}P_{20}$ (denoted as Ni-B and Ni-P hereafter). The crystallization process of the nano-amorphous Ni-B (or Ni-P) is described as follows. First, initial Ni-B (or Ni-P) powder of 2 g was placed in a pipe furnace, in a flow of high purity Ar gas. Second, the sample was slowly elevated to an annealing temperature designed in advance, and kept at various annealing temperatures for 2 hours. Finally, the annealed Ni-B (or Ni-P) samples were obtained after cooling naturally to room temperature.

The X-ray absorption spectra at the Ni K-edge for the initial and annealed $Ni_{70}B_{30}$ samples were measured at the beamline of U7C of the National Synchrotron Radiation Laboratory (NSRL) and 4W1B of the Beijing Synchrotron Radiation Facitlity (BSRF). The storage ring of NSRL was operated at 0.8 GeV with a maximum current of 160 mA. The hard X-ray beam was from a three-pole superconducting Wiggler with a magnetic field intensity of 6 Tesla. Fixed-exit Si(111) flat double crystals were used as a monochromator. The XAFS spectra were recorded in transmission mode with ionization chambers filled with Ar/N_2 at room temperature, using a Keithley Model 6517 Electrometer to

collect the electron charge directly. XAFS data of Ni-B and Ni-P samples were analyzed by USTCXAFS3.0 software packages compiled by Zhong and Wei according to the standard procedures [17].

The X-ray diffraction (XRD) patterns of the initial and annealed nano-amorphous NiB and NiP alloys were measured on a Y-4ϕ rotating target diffractometer (Dandong X-ray photometer Co. LTD) using Cu K_α radiation ($\lambda = 1.54056$ Å, 40 kV and 100 mA).

3. Results and Discussion

From the XRD patterns as shown in Fig. 1, it can be observed that there is a broad and weak peak located at $2\theta = 45^\circ$ in the initial nano-amorphous NiB and NiP alloys, which demonstrates that the initial Ni-B and Ni-P are typical amorphous alloys. Moreover, the peak of the initial Ni-B sample is much broader and weaker than that of the initial Ni-P sample, indicating the Ni-B sample possessing a higher amorphization than that of the Ni-P one. After annealing at 573 K, sharp peaks appear in the XRD curves of the NiB and NiP samples. By comparing with the standard XRD spectra of JCPDS-ICDD, it can be found that the crystalline Ni_3B and small amount of crystalline Ni_2B are formed for the nano-amorphous Ni-B alloy, and crystalline Ni_3P and metallic Ni are produced for the nano-amorphous Ni-P alloy. By using of the Scherrer Formula to estimate the grain size from the main peak of their XRD patterns, the average grain sizes are found to be about 30 nm and 120 nm for the Ni-B and Ni-P samples annealed at 573 K, respectively. These results indicate that boron plays a more important role in inhibiting the growth of nano-crystalline grains than phosphorous does. Our results about the grain-sizes of the annealing Ni-B and Ni-P alloys are consistent with those reported by Deng *et al*. [18] and Li *et al*. [19].

After annealing at 773 K, the strongest diffraction peak corresponding to crystalline Ni appears and the peaks associated with Ni_3B become much weaker for the Ni-B sample. This indicates that most of the Ni_3B has been decomposed to form crystalline Ni. The XRD pattern for the Ni-P sample annealed at 773 K is similar to that annealed at 573 K, except that the peaks corresponding to crystalline Ni and Ni_3P are much stronger. This means that there still remains some amount of crystalline Ni_3P in the Ni-P sample annealed at 773 K. We consider that the thermodynamic stability of nano-crystalline Ni_3P with larger grain size (120 nm) is higher than that of nano-crystalline Ni_3B with smaller grain size (30 nm).

The radial structural functions (RSF) of the nano-amorphous Ni-B and Ni-P alloys are shown in Fig. 2. In order to obtain the local structural parameters of Ni-B and NiP samples, the asymmetric pair distribution function of $G(R)_{\text{asym}}$ assumed as a convolution of Gaussian function, P_G, and exponential function, P_E, is used to fit the Ni K-edge XAFS spectra of the nano-amorphous Ni-B and Ni-P alloys. $G(R)_{\text{asym}}$ has been reported elsewhere [20, 21]. The structural parameters of the Ni-B and Ni-P samples annealed at various temperatures are summarized in Table I. In Fig. 2 only one main peak at 2.05 Å is observed for the initial Ni-B and Ni-P samples. This further shows the amorphous feature of the initial Ni-B and Ni-P alloys. The static disorder factor (σ_S) of the first nearest Ni-Ni sub-shell for the initial Ni-B alloy is 0.33 Å, which is larger than that ($\sigma_S = 0.28$ Å) of the initial Ni-P alloy. It indicates obviously that the disorder of the nano-amorphous Ni-B alloy is larger than that of the nano-amorphous Ni-P alloy. This result is consistent with that obtained from our XRD. Li *et al*. [10, 11] and Keong *et al*. [12] have reported that only one strong peak appears at the R-range of 1.3–2.8 Å, and that no peaks can be observed at longer distances.

After annealing at 573 K, the position of the first peak of the Ni-B and Ni-P samples shifts from 2.05 to 2.14 Å and its magnitude intensity increases about twice. Furthermore, it can be found that two small peaks corresponding to the second and third coordination shells appear at the positions of $R = 3.9$ Å and $R = 4.8$ Å. This result indicates that the nano-amorphous Ni-B and Ni-P alloys are crystallized at the annealing temperature of 573 K. The structural parameters in Table I have shown that the bond length R and σ_S for the Ni-Ni sub-shell undergo large changes for the Ni-B and Ni-P alloys annealed at 573 K, and decrease from 2.75 Å and 0.33 Å to 2.55 Å and 0.11 Å, and from 2.71 Å and 0.28 Å to 2.58 Å and 0.16 Å, respectively. These XAFS results are in good agreement with those from XRD. Moreover, the XAFS results indicate that two phases of nano-crystalline Ni with small grain size and crystalline Ni_3B are formed in the nano-amorphous Ni-B alloy annealed at 573 K, despite that no diffraction peaks corresponding to crystalline Ni appear in its XRD pattern [16]. Hence, we consider that boron can inhibit the nano-crystalline Ni to grow into grains with large sizes.

With the annealing temperature increasing to 773 K, the RSF curve of the Ni-B sample is almost the same as that of the metallic Ni foil. From the structural parameters of the Ni-B alloy annealed at 773 K in Table I, the coordination number N decreases from 2.6 to 0.3 for the first Ni-B sub-shell, and the bond length R and the

		Ni-P	2.25	2.19	0.6 ± 0.3	0.040	0.056	7.6
Ni foil		Ni-Ni		2.49	12.0	0.074		

*Average distance $R = R_0 + \sigma_S$, the uncertainties (or error bar) of R, σ_T and σ_S are about ±0.02 Å, ±0.005 Å, ±0.01 Å, respectively.

static disorder factor σ_S is 2.49 Å and 0.029 Å for the second Ni-Ni sub-shell, respectively. This indicates that most of the crystalline Ni_3B has decomposed. However, the intensity of the RSF first peak of the Ni-P alloy annealed at 773 K is only about half of that of metallic Ni foil, but is still similar to that of the Ni-P alloy annealed at 573 K. R and σ_S are 2.55 Å and 0.125 Å for the Ni-Ni sub-shell of Ni-P sample annealed at 773 K, respectively. Considering the XRD results, it can be believed that the thermodynamic stability of nano-crystalline Ni_3P is much higher than that of nano-crystalline Ni_3B. Hence, Ni_3P does not decompose at a temperature of 773 K.

Abstract

Photosynthetic water oxidation proceeds at a tetra-manganese complex bound to a cofactor-protein complex denoted as Photosystem II (PSII). To understand this process of fundamental importance for life on Earth, the crucial changes of the active-site occurring upon the individual transitions in the catalytic S-state cycle have been investigated by X-ray absorption spectroscopy at the Mn K-edge. For the S_2-S_3 transition, the changes in position and shape of the X-ray edge have been interpreted to be either associated with oxidation of Mn(III) to Mn(IV) or to formation of a ligand radical without manganese oxidation. Here we simulate XANES spectra of simple Mn-complexes using modern multiple-scattering code. Features of the XANES spectra are assigned to molecular orbitals by means of comparative semi-empirical calculations. It is concluded that the changes in position and shape of the edge spectra observed for the S_2-S_3 transition are explainable by the transformation of five-coordinated Mn(III) in a square-pyramidal geometry to six-coordinated Mn(IV).

1. Introduction

Photosynthetic water oxidation occurs at a manganese complex bound to a cofactor-protein complex denoted as Photosystem II (PSII). This complex contains four manganese atoms and, possibly, one calcium [1]. In the course of photosynthetic water oxidation the manganese complex of PSII acquires four distinct semi-stable oxidation states: S_0, S_1(dark-stable), S_2, and S_3. Light-driven oxidation of the S_3-complex is assumed to result in formation of S_4 which immediately is transformed to S_0, a transition coupled to the release of dioxygen. As reviewed elsewhere [2–5], by X-ray absorption spectroscopy (XAS) at the Mn K-edge changes in the arrangement of the nuclei as well as in the electronic structure (oxidation states, orbital occupancies) can be monitored as the Mn-complex of PSII advances through its catalytic S-state cycle. These changes are crucial with respect to the final goal to understand the mechanism of photosynthetic water oxidation at the atomic level.

Empirically it is found that the position of the X-ray edge shifts to higher energies upon oxidation of the X-ray absorbing transition metal (for a detailed discussion, see [5]). As shown in Fig. 1, for all oxidizing S-state transitions of the PSII manganese complex the Mn K-edge indeed shifts to higher energies [3, 6–10]. For the S_2-S_3 transition, however, the extent and especially the interpretation of the shift in the X-ray edge position is still debated. Using the inflection-point energy (zero-crossing point of the second derivative) as a marker for the edge position, Roelofs *et al.* [7] and Messinger *et al.* [9] found that the edge-shift determined for the S_2-S_3 transition is clearly smaller (by a factor of 4 to 7!!) than the ΔE_{edge} of the S_1-S_2 or S_0-S_1 transitions; they concluded that the S_2-S_3 transition does not involve manganese oxidation, but formation of a ligand radical instead. Using various alternative approaches to quantify the edge position, we determined the edge-shift to be of comparable magnitude for all oxidizing S-state transitions [3, 5, 8, 10, 11]. Consequently, we have concluded that Mn-centered oxidation is more likely than ligand-radical formation. It should be noted that the recent data of Dau *et al.* [3] and Messinger *et al.* [9] are mostly similar. We feel that the diverging conclusions are not rooted in the minor differences between these recent data sets, but in inappropriate analysis approaches (as discussed in [5]) and, especially, in an incomplete understanding of the structural and electronic factors that determine the XANES (X-ray absorption near-edge structure) spectra.

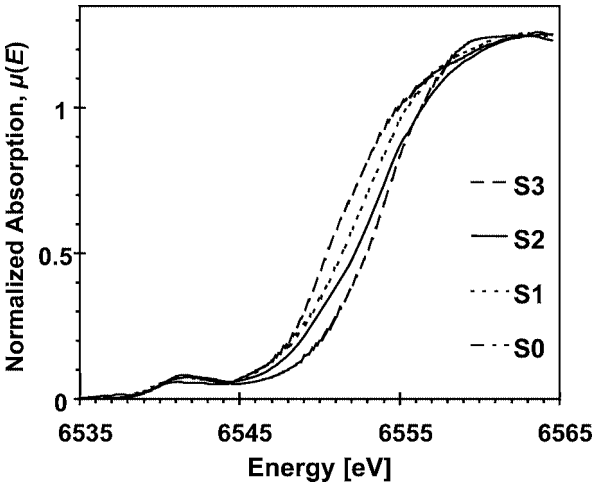

Fig. 1. XANES spectra of the PSII manganese complex for all four semi-stable intermediate states of the catalytic cycle.

In the S_2-S_3 transition the edge shape changes more pronouncedly than in the other oxidizing transitions. A particularly pronounced edge-shift is observed in the rising region of the edge (μ(E) < 0.4) which is continuously decreasing at higher energies. In clear contrast to the S_1-S_2 transition, no shift of the spectrum is observed around 6560 eV; instead an increase in the absorption is detectable (increase in the integrated area of the edge peak). Similarly pronounced changes in edge shape are not observed for the S_1-S_2 transition, which is commonly assumed to involve oxidation of Mn(III) to Mn(IV). Thus it has been argued that the edge-shape changes point towards the absence of Mn oxidation in the S_2-S_3 transition [7, 9], a conjecture which is rendered unlikely by the here presented XANES simulations.

Analysis of EXAFS (extended X-ray absorption fine-structure) spectra measured at 20 K (freeze-quench approach; [3, 4, 12]) and at room temperature [10, 13] indicate an increase in the number of di-μ-oxo bridges between Mn ions from two, in the S_1 and

*e-mail: holger.dau@physik.fu-berlin.de

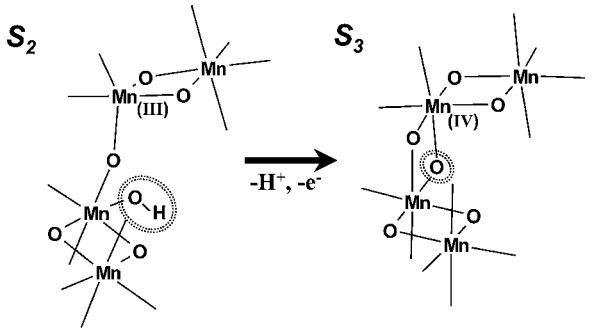

Fig. 2. Hypothesis on the structural changes of the PSII manganese complex associated with the S_2-S_3 transition [3]. The increase in the number of di-μ-oxo bridges upon the S_2-S_3 transition is strongly suggested by the analysis of EXAFS spectra collected for layered PSII membrane particles [3, 10, 12, 13]. The depicted arrangements of nuclei was chosen for clarity. The arrangement that is in best agreement with the linear dichroism in the EXAFS data of partially oriented samples [14, 15] and the structural information stemming from protein crystallography [16] differs slightly; for a more precise structural model of the PSII manganese complex in its S_1- and S_2-state, see [4, 17, 18]. The release of one proton from the manganese complex concomitant to the S_2-S_3 transition is indicated by time-resolved investigations on the proton release into the bulk phase and by analysis of electrochromic effects (Stark-shift in the spectra of nearby pigments); for review see [19]. The presence of five-coordinated Mn(III) can be energetically particularly favorable (Jahn-Teller effect) whereas Mn(IV) clearly prefers an octahedral coordination geometry. The proposed transformation of five-coordinated Mn(III) to six-coordinated Mn(IV) is confirmed by the XANES simulations discussed further below.

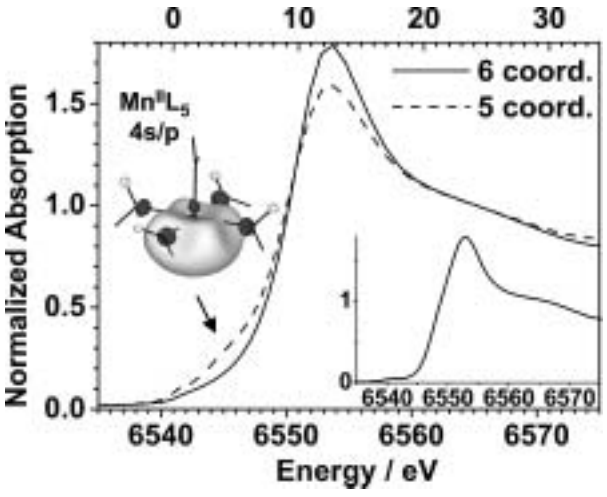

Fig. 3. XANES simulations of five-coordinated (square-pyramidal) and six-coordinated (octahedral) Mn(II). Solid line – $[Mn(H_2O)_6]^{2+}$; broken line – $[Mn(H_2O)_5]^{2+}$. For both complexes the Mn-O distance had been 2.195 Å. For comparison, the measured spectrum of $[Mn(H_2O)_6]^{2+}$ in aqueous solution is shown as an inset. The five-coordinated complex represents a purely hypothetical complex that had been obtained by omitting one of the six ligands of the six-coordinated complex. The molecular orbital (MO) is depicted that can be assigned to the shoulder-like feature in the simulated XANES spectrum of the five-coordinated complex. For the corresponding MO of the six-coordinated complex (not shown) we find that of all atomic orbitals of manganese only the 4s orbital contributes whereas in the five-coordinated complex significant s-p mixing is present (see inset). The s-p mixing facilitates the formally dipole forbidden 1s-4s transition in the five-coordinated complex. For details see [5].

S_2-state, to three, in the S_3-state. We have proposed that the μ-oxo bridge formation upon the S_2-S_3 transition is facilitated by transformation of five-coordinated Mn(III) to six-coordinated Mn(IV) [3]; a hypothetical scheme for the involved structural changes is depicted in Fig. 2. By XANES simulations it is shown that the occurrence of a transition from five-coordinated Mn(III) to six-coordinated Mn(IV) may indeed explain the distinct edge-shape changes observed upon the S_2-S_3 transition.

2. Materials and Methods

The experimental spectra shown in Fig. 1 correspond to the spectra presented in Dau *et al*. [3], but the shown spectra are renormalized such that their similarity with the data of Messinger *et al*. [9] is emphasized. For a description of experimental details, see [8].

To investigate the influence of coordination-number changes, XANES spectra were calculated using the *ab-initio* multiple-scattering code FEFF 8.2 of Rehr and coworkers (self-consistent potentials, full-multiple scattering calculations [20], for further details see [5]). Features of the XANES spectrum were assigned to molecular orbitals (MOs) by means of comparative semi-empirical MO-calculations [21] using the rationale described in Dau *et al*. [5].

3. Results and Discussion

In Figure 3, XANES spectra simulated for the Mn-hexaquo complex are shown; the simulated spectrum compares favorably well with measured spectra (inset in Fig. 3). By omission of one of the six water ligands a hypothetical five-coordinated complex (square-pyramidal coordination) is obtained which is characterized by a distinctly different XANES spectrum: (1) an additional shoulder is present in the rising part of the edge, and (2) the area of the principal absorption peak is diminished. Oscillator strength seems to shift from the edge peak towards the region of the initial edge rise.

The principal absorption maximum can be assigned to transition of the 1s core electron (of Mn) to unoccupied anti-bonding MOs with strong contributions of the 4p-orbitals of the X-ray absorbing manganese [5]. The energy level of the Mn 4s-orbital is in the rising part of the edge (∼7 eV above the onset of the pre-edge peak). In the six-coordinated complex the 1s-4s transition is dipole forbidden. In the five-coordinated complex, however, the corresponding molecular orbital gains significant p-character (see inset in Fig. 3). Due to this s-p mixing, a shoulder in the rising part of the spectrum is predicted for the five-coordinated complex. For a more complete discussion, see [5].

In the above considerations the Mn-ligand distances were assumed to be identical in the five-coordinated and in the six-coordinated Mn(II)-complex. To obtain spectra more closely related to the S_2-S_3 transition, we carried out XANES simulations for five-coordinated and six-coordinated Mn(III) and Mn(IV) ions using distances between manganese and its oxygen ligands that are typical for the respective oxidation-state/coordination-number combination.

As shown in Fig. 4, the transformation of Mn(III)L_6 to Mn(IV)L_6 is accompanied by an edge shift that (a) is relatively small in the region of the initial rise of the edge ($\mu(E) < 0.4$) and (b) continuously increases up to the edge maximum; the height of the edge maximum remains essentially unchanged. Upon the transition from five-coordinated Mn(III) to six-coordinated Mn(IV), however, the edge shift (1) is maximal in the region of the initial rise and minimal at the edge maximum; and (2) a clear increase in the area of the edge peak is observed.

In comparison to the simulated spectra of Fig. 4, in PSII (Fig. 1) the edge peak is clearly broader and lower, an observation easily explained by the pronounced spread of Mn-ligand distances [5] as

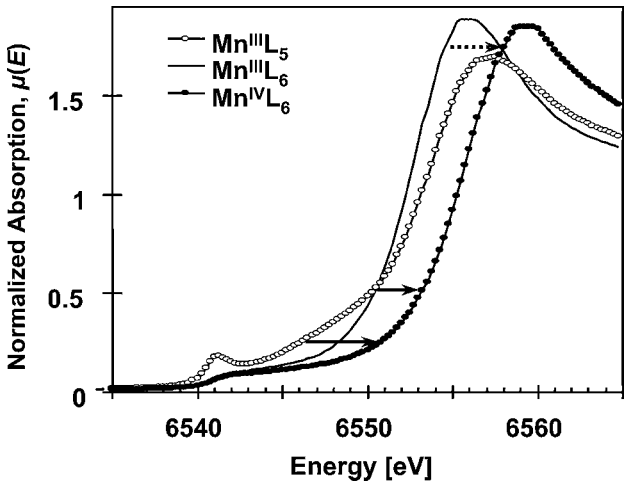

Fig. 4. XANES simulations for five- and six-coordinated Mn(III), and for six-coordinated Mn(IV). Open circles: $Mn(H_2O)_2(OH)_3$, Mn-O distance of 1.95 Å, square-pyramidal geometry. Solid line: $Mn(H_2O)_3(OH)_3$, Mn-O distance of 2.02 Å, octahedral geometry. Black circles: $Mn(H_2O)_2(OH)_4$, Mn-O distance of 1.90 Å, octahedral geometry.

it is encountered in the PSII manganese complex (see, e.g. [15]); the lower symmetry of the Mn coordination environment in PSII likely also contributes. The pre-edge peak is not appropriately simulated for two reasons: (*i*) The used multiple-scattering simulations can be anticipated to be of relatively low accuracy for low-lying bound states. (*ii*) The pre-edge peak depends strongly on details of the ligand environment (enhancement by broken inversion symmetry). The presence of di-μ-oxo bridges, e.g., leads to a significantly enhanced pre-edge magnitude. Such structural details, however, have not been considered in the shown XANES simulations. The most apparent difference between experimental spectra (Fig. 1) and simulated spectra (Fig. 4) is the magnitude of the edge shift that is roughly by a factor of four greater in the simulations. However, since in the tetra-manganese complex of PSII only one out of four Mn-ions is oxidized on each individual S-state transition, the magnitude of the observed edge shifts are anticipated to be by a factor of four smaller than in the simulations of Fig. 4.

Keeping in mind the above considerations, the comparison of the experimental spectra shown in Fig. 1 and of the simulated spectra shown in Fig. 4 can be approached. We find that the changes in the edge spectra detected for the S_1-S_2 transition resemble qualitatively the predicted changes for transformation of a Mn(III)L_6 complex to a Mn(IV)L_6 complex (see above, (a) and (b)). Most importantly, however, the major characteristics of the changes in the XANES spectra upon the S_2-S_3 transition are remarkably well modeled by simulating a transition from a square-pyramidal Mn(III)L_5 complex to an octahedral Mn(IV)L_6 complex (see above, (1) and (2)).

In the simulations described above we used the most simple structures (single Mn ion, all 5 or 6 Mn ligands at the same distance, idealized coordination geometries) that allow for a qualitatively correct description of the edge-shape changes. By XANES simulations on basis of clearly more sophisticated structural models of the tetra-manganese complex of PSII, a closer similarity between experimental and simulated spectra can be achieved (data not shown; see also contribution of Liebisch *et al.* in this volume), but the changes in the XANES spectra upon changes in the Mn oxidation and/or coordination geometry are similar to the here described edge-shape changes. To illustrate the principal effect and to facilitate a qualitative understanding of the underlying reasons for the edge-shape changes (in terms of molecular orbitals), we have deliberately chosen particularly simple structures.

In conclusion, the changes in the shape of the edge spectra observed for the S_2-S_3 transition are explainable by the transformation from five-coordinated Mn(III) to six-coordinated Mn(IV). That these changes in the edge spectra are associated with oxidation of a manganese ligand is a supposition we consider to be unlikely.

Abstract

The tetra-manganese complex of photosystem II is the site of the production of most of the atmospheric dioxygen. To understand its function, an atomic-resolution structural model is required. X-ray absorption spectroscopy and protein crystallography yielded models for the arrangement of the four Mn atoms. The location of the functionally essential calcium cofactor within the complex, however, is still debated. To dwell on this point, XAS was performed at the Ca K-edge. Simulations of Ca EXAFS spectra reveal that at least two Mn atoms are located at a distance of ~3.3 Å to one Ca ion. Ca bound to the complex seems not to be fully hydrated. On basis of the complementary structural information derived from XAS at the Mn and Ca K-edge, a model of the Mn_4/Ca complex in its S_1-state is proposed which predicts intimate links between the Ca ion and Mn, possibly by bridging substrate-water molecules.

1. Introduction

Photosynthetic water oxidation is accomplished at a tetra-nuclear manganese complex bound to the lumenal side of the D1 subunit of photosystem II (PSII). Driven by light energy, from two water molecules, presumably bound to the Mn complex, dioxygen is produced in a five-stepped catalytic cycle. This biologically most important reaction generates the atmospheric oxygen [1, 2]. It has been shown that, besides of the Mn atoms, calcium is essential for the functioning of water oxidation [2]. Specifically, one Ca ion has been proposed to be in close vicinity to the Mn atoms [3–5] but this interpretation has been questioned [6].

Based on X-ray absorption spectroscopy (XAS) studies on all semistable oxidation states and on the crystallographic structure at 3.8 Å resolution [7, 8], we have previously proposed an atomic-resolution model of the Mn complex in its S_1-state [5, 9–11] with the following features: The four Mn atoms are arranged in two di-μ-oxo bridged pairs (Mn-Mn distance ~2.7 Å), the Mn-Mn vectors are about perpendicular to the membrane normal, and two Mn atoms of the dimers are separated by ~3.1 Å. The precise location and coordination of calcium has remained an open question. XAS data have been interpreted as indicating its location at about 3.3 Å from Mn [3–5, 11]; this attribution allowing for several positions of Ca with respect to the Mn atoms.

In this work we studied the coordination of Ca by XAS at the Ca K-edge on PSII preparations which contain about two Ca atoms per PSII center (one is supposedly close to Mn, the other one may be bound to an antenna protein [2]). It is shown that Ca is not fully hydrated and located at ~3.3 Å from minimally two Mn atoms which possibly belong to the same Mn dimer.

2. Materials and Methods

Highly active PSII membrane fragments (~1200–1400 μmol O_2/mg chlorophyll (Chl) × h at 28 °C) and partially dehydrated multilayer samples for XAS were prepared with betaine (0.5 M) in all media as a stabilizing agent as detailed in [11]; multilayers were deposited on Ca-free Mylar tape as a support; a pre-flash procedure was employed to quantitatively populate the S_1-state of the Mn complex [12]. Depletion of bulk Ca was achieved by gentle stirring of a solution of PSII membrane fragments (0.5 mg Chl/ml) with Chelex-100 (1.5 g/mg chl.) at 4 °C for 60 min at pH 6.5 and in darkness. Afterwards, Chelex was removed by filtration and then centrifugation. Pellets were resuspended in a buffer containing 25 mM MES, pH 6.5, 15 mM NaCl, and 1 M betaine, aliquots were taken for O_2-assays and AAS (atomic absorption spectroscopy) and samples were immediately used for preparation of multilayers.

AAS measurements were employed to quantify the Mn and Ca contents of the samples. Samples used for XAS contained 2 ± 1.5 Ca atoms per 4 Mn atoms. Chelex-treated samples possessed at least 90% of the oxygen-evolution activity of untreated controls.

XAS at the Ca K-edge was performed at the ESRF (Grenoble, France) at undulator beamline ID26 [13]. A newly constructed cryostat was used; samples were mounted on a helium-cooled turnable coldfinger. Samples were rapidly frozen to 50 K under evacuation of the cryostat; vacuum (~10^{-5} mbar) was maintained throughout the measurements. XAS spectra were collected in fluorescence mode using a large-area photodiode as a detector mounted within the cryostat (the angle between the electric field vector of the X-ray beam and the sample normal was 45°). A Ca-free, 150 nm thick Si-nitrite window was used for I_0 detection; no other foils were passed by the incident X-ray beam (spot size ~1 mm^2) or the X-ray fluorescence prior to detection. XAS spectra were measured using the rapid-scan mode of ID26 within 30 s (scan range 3900–4500 eV); only one scan was performed per sample spot. Measurements of reference substances revealed that the energy axis was stable by ±0.2 eV during the scans. Raw XAS spectra were normalized and EXAFS oscillations were extracted as previously described [5, 13]. Simulations of EXAFS spectra were carried out with the in-house software SimX [14] using an E_0 of 4030 eV (E_0 was allowed to refine by ±1.5 eV in the simulations) and phases calculated by FEFF 7 (J. Rehr and coworkers, Univ. of Washington). Fourier transforms were calculated from unfiltered EXAFS oscillations ranging over 23–400 eV above E_0 using cosine windows extending over 10% at both sides of the k-space. Backtransforms were calculated from 0–5 Å of reduced distance. EXAFS simulations were performed solely on unfiltered k^3-weighted oscillations (~30 scans averaged, k = 2.3–10.2 $Å^{-1}$, ${S_0}^2 = 0.9$).

Upper trace: tentative pure spectrum of the Ca within the Mn complex. Solid lines, experimental data; dashes, simulations (Table I; bottom, fit I; middle, fit IV; top, fit VI).

3. Results and Discussion

Figure 1 compares the XANES spectra at the Ca K-edge of PSII multilayer samples which contained ~80 Ca per four Mn ions (Ca was added as $CaCl_2$ to the buffer) (dashed line) and of a preparation where the Ca content was reduced to ~2 Ca/4 Mn by Chelex-treatment (solid line). Subtle but reproducible differences in the XANES are observed. A higher pre-edge peak (enhancement of dipole-forbidden $1s \rightarrow 3d$ transitions, inset in Fig. 1), a by 0.3 eV reduced edge energy ($E_{edge} = 4032.5$ eV vs. 4032.8 eV at 50% of normalized intensity), and a lower principal maximum are likely indicative of a lower coordination number and/or lower symmetry of Ca bound to PSII in Chelex-treated samples compared to its more symmetric coordination by 7–8 oxygens from water molecules in the bulk [15].

It has been shown by XAS measurements at the Mn K-edge that photoreduction of the Mn complex ("radiation damage") occurs within minutes at photon fluxes of $\sim 10^{13}\,s^{-1}$ even at cryogenic temperatures [13, 16–18]. This process produces Mn(II) which is released, presumably together with Ca, from its binding site [5, 13]. The problem may be even more severe in XAS measurements at the Ca K-edge where the X-ray absorption of the low-Z atoms of the samples is increased. To address the question whether radiation damage occurs, we employed the difference in the Ca K-edge magnitudes (most pronounced at 4038 eV, arrow in Fig. 1) of Ca bound to PSII or hydrated in the bulk. At an excitation energy of 4038 eV the X-ray fluorescence was recorded as function of time [17, 18] with Chelex-treated samples. Indeed, an increase of the fluorescence intensity is observed (Fig. 2) which likely indicates the release of specifically bound Ca (and Mn) from their binding sites into the bulk. At 50 K, Ca release seemed to occur within ~400 s. However, within the duration of the XAS scans (30 s) the fluorescence intensity at 4038 eV and, hence, the Ca K-edge magnitude remained about unchanged (Fig. 2, arrow). We conclude that Ca stayed bound to the Mn complex during the XAS scans; it is likely that also photoreduction was negligible and that the Mn complex was kept in its S_1-state.

Figure 3 shows the respective Fourier-transforms (FTs) of EXAFS oscillations (inset) of the ~80 Ca/4 Mn and the Chelex-treated samples. The spectrum of the high-Ca sample (lower traces) is well simulated using a single Ca-O shell with a coordination number of 7–8 and an average bond length of ~2.4 Å (Table I, fit I), parameters which are anticipated for hydrated Ca [15]. Thus, Ca is mainly present in its fully hydrated form in this sample, as expected. The FT of the EXAFS oscillations of the Chelex-treated sample is distinctly different (Fig. 3, middle traces). The magnitude of the main peak at ~2 Å of reduced distance is significantly diminished and the peak is broadened. Furthermore, a pronounced second peak at ~2.7 Å of reduced distance emerges in the FT. Such a peak is expected if Ca-Mn interactions are present. We first simulated this EXAFS spectrum by using only two backscatterer shells, O and Mn. The result is not satisfying as the error factor (R_F) is relatively large (Table I, fit II). Involving two oxygen shells significantly improved the fit, now revealing two Ca-O vectors of ~2.26 Å and ~2.43 Å lengths with a total coordination number of about 6 (Table I, fit III). The longer distance was similar to the one found in the high-Ca sample. A significant fraction of the Ca obviously is not bound to the Mn complex but present in a coordination which resembles the one of Ca in bulk water. The total coordination

(Ca in the Mn complex)		Ca-Mn	2.00*	3.27	9.3	

number of the Ca-O vectors was close to 6. This implies that the Ca bound to the Mn complex is not fully hydrated but coordinated by presumably only 5–6 oxygens, in line with the changes in the XANES spectrum. In both fit approaches, the number of Mn atoms as "seen" by the absorber, Ca, is well above unity, close to 1.5. If exactly two Ca atoms are present per 4 Mn atoms and only one is bound to the Mn complex, one would expect that the coordination number of the Ca-Mn vector is unity if one Ca is located at the same distance from two Mn ions. The found coordination number of the Ca-Mn vector of ~1.5 thus may mean that the average Ca : Mn stoichiometry in the Chelex-treated sample is truly 1.5 : 4 (compatible with the error in Ca quantification by AAS), or, alternatively, that three Mn ions are close to the Ca. The results of simulations on basis of the latter two possibilities (further assuming 7-coordinated Ca not bound to Mn and 5-coordinated Ca bound to Mn) are listed in Table I (fit IV, Ca : Mn = 1.5 : 4, 2 Mn-Ca vectors; fit V, Ca : Mn = 2 : 4, 3 Ca-Mn vectors). Both approaches yield reasonable fit qualities; two Ca-Mn vectors being slightly better. In summary, Ca is at about the same distance, ~3.3 Å, from minimally two Mn atoms. We tentatively deconvoluted the XAS spectrum of the Chelex-treated sample on basis of fit IV (by subtraction of 33% of the spectrum from the high-Ca sample). For the deconvoluted XAS spectra see Fig. 1 (dashed line) and Fig. 3 (upper trace). The EXAFS oscillations now attributed to Ca in the Mn complex are well simulated using only two backscatterer shells, Ca-O with $N = 5$ and Ca-Mn with $N = 2$ (two Ca-Mn vectors, Table I).

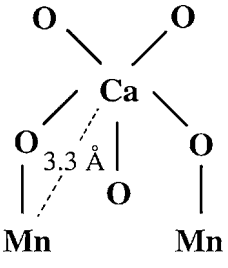

Fig. 4. The possible coordination of calcium within the Mn complex on basis of Ca XAS data.

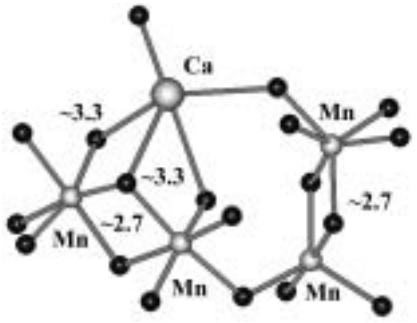

Fig. 5. Tentative model of the Mn_4/Ca complex in its S_1-state. Black dots, oxygens; two di-μ-oxo and one mono-μ-oxo bridge between Mn atoms are depicted (the model has been rotated with respect to previous drawings [10, 11]). Distances are given in Å.

On basis of the Ca XAS results we construct a model for the coordination of Ca in the Mn complex. It is shown in Fig. 4. Each distance between Ca and Mn is compatible with the presence of an intervening oxygen. The Mn complex in its S_1-state likely consists of a pair of di-μ-oxo bridged Mn dimers [5, 9, 10, 18]. If we combine the coordination of the Ca with the previously derived structural model of the Mn complex in S_1 [5, 9–11], one favored location of Ca within the complex is depicted in Fig. 5. We note that the five metal ions in this arrangement fit into the electron density of the Mn complex derived from crystallography [7, 8]. Interestingly, a Ca ion in this position would be at the same distance (~3.3 Å) from minimally the two Mn atoms of one dimer and furthermore, possibly coordinated by four oxygens that are, in turn, ligands to Mn. It is tempting to speculate that at least one of these oxygens belongs to substrate water which thereby becomes bound to both, Mn and Ca.

4. Conclusions

The location of the Ca ion within the Mn complex of PSII was investigated by XAS at the Ca K-edge. The shape of the XANES spectrum and EXAFS simulations imply that Ca is coordinated by 5–6 oxygens and that it is at ~3.3 Å distance from at least two Mn atoms. Combining information from Ca and Mn XAS we arrive at a structural model of the Mn_4/Ca complex in its S_1-state which is compatible with recent crystallographic data. The Mn atoms and the Ca in the complex may together form a binding site for the substrate water molecules. Investigations on the coordination of Ca in higher S-states of the catalytic cycle of water oxidation are underway.

Abstract

In this work, near-edge X-ray absorption fine structure spectroscopy (NEXAFS) experiment is done to obtain the chemical and structural information about the occurrence and the average orientation of unoccupied molecular orbitals within the organic films. Amino acid, such as Tyrosine and 3,4-dihydroxyphenylalanine (DOPA), is linked to a thiol through a peptide bond and is adsorbed and self-assembled to polycrystalline gold surfaces. Results from the C k-edge and O k-edge spectra serves as fingerprints to each amino acid analogues. The average orientation of the molecules relative to the gold surface is determined from the polarization effects observed as intensity changes of the peaks in the spectra when the X-ray incidence angle is varied. It is assumed that the average tilt angle of the main molecular axis of amino acid linked to short amidethiol is based on the deduced orientation of the peptide bond.

1. Introduction

Immobilizing biomolecules such as amino acid and peptide derivatives can be used as model surfaces for studying specific interactions with other molecules which is important for biomaterial and biosensor application. Amino acids with aromatic side chains are interesting to study because they play an important role in many biochemical reactions. Tyrosine is one amino acid involved in the phosphate transfer of adenosine triphosphate (ATP). Covalent phosphorylation of such amino acid induces protein conformational change [1]. Immobilizing such amino acid derivative onto surface can be used to probe specific details such as molecular conformational changes and energy transfer involved in phosphorylation. Another interesting amino acid and closely related to Tyrosine is DOPA. DOPA has a big role in mussel adhesive proteins [2, 3] and the possibility of the cross-linking process on surfaces is interesting to study. It can also serve as an electroactive ligand for indirect determination of aluminum in biological samples [4]. This molecule in the future can be used as affinity sensing molecule for coordination of Al^{3+} existing in the body [5].

A way to study these amino acids on the surface is by chemically linking them to a thiol and making use of the self-assembly technique to immobilize them on the surface. Previous studies on self-assembled monolayers (SAMs) involving aromatic thiols [6–8] serve as significant references in characterizing the model surfaces under study. NEXAFS spectroscopy (otherwise known as XANES) is one tool used to extract chemical and structural information of organic films. Several studies have recently used NEXAFS to characterize amino acids and peptides [9–12].

In this work, both Tyrosine and DOPA are linked to 3-mercaptoproprionic acid through an amide bond. The resulting molecule namely Tyrosine-terminated Propanethiol (TPT) and DOPA-terminated Propanethiol (DOPA-PT) are adsorbed on gold surface through thiol chemistry. Chemical states and molecular orientation of the adsorbates are investigated by NEXAFS. The characterized surfaces will be subjected to biomolecular interaction studies using technique such as surface plasmon resonance (SPR). Electrochemical studies will also be employed to study relevant metallic ion interactions with the surfaces.

2. Experimental

2.1. *Sample preparation*

The TPT and DOPA-PT were synthesized at the Department of Chemistry, Linköping University. The related synthetic pathway is shown elsewhere [13]. The adsorbates were prepared from ethanol solutions with a concentration of 1 mM.

The gold substrates used were prepared by electron beam evaporation of 2000 Å thick Au at a rate of 10 Å/s onto clean single-crystal Si(100) wafers. Before evaporation of the gold film, the silicon wafers were first coated with a 20–25 Å thick Ti layer at a rate of 2 Å/s. The base pressure was always $<5 \times 10^{-9}$ Torr and the evaporation pressure, $<2 \times 10^{-8}$ Torr. The thin gold film has preferred (111) with grain size of 70–300 Å and with the outer parts of these grains showing extremely flat films [14]. The gold surfaces were cleaned in a 5 : 1 : 1 mixture of MilliQ water, 25% hydrogen peroxide, and 30% ammonia for 5 min at 80 °C and then thoroughly rinsed in MilliQ water.

The gold surfaces were incubated in the solutions for the duration of more than 24 h, rinsed in deionized water and then ultrasonicated in deionized water for 5 minutes. The deionized resistance of the deionized water is 18.2 MΩ-cm. It is followed by blow-drying of the surfaces with nitrogen gas and then immediately analyzed. The DOPA-PT multilayer sample was prepared by letting a droplet of high-concentration DOPA-PT dry on a prepared monolayer on gold surface, while letting a stream of gaseous nitrogen pass over the surface.

2.2. *NEXAFS*

The NEXAFS spectra were recorded at the synchrotron storage ring MAX II at MAX–Lab in Lund, Sweden using the D1011 bending magnet beamline. The beamline is equipped with a modified SX-700 monochromator [15]. The measurements were carried out at the C1s and O1s absorption edge in the partial electron yield mode with retarding voltage of −150 V and −300 V, respectively. Linear polarized synchrotron light with a polarization factor of ∼85% was used. The energy resolution was ∼0.5 eV. The incidence angle of the synchrotron light used was 90° (*E*-vector in surface plane) and 30° or 20° (*E*-vector near surface normal) to monitor the orientation of the adsorbates. The raw NEXAFS spectra were normalized to the incident photon flux by division through a spectrum of a sputtered clean gold sample.

3. Results and Discussion

A NEXAFS spectrum reveals information about the local bonding environment around specific atoms including the chemical states

of these atoms. Determination of average orientation of the molecules can also be achieved from the polarization effects observed as intensity modulations of peaks in the spectra when X-ray incidence angles are varied. The C K-edge and O K-edge spectra of TPT and DOPA-PT on Au at selected X-ray incidence angles are shown in Figure 1 and 2, respectively. Summary of the assignments of the peaks are shown in Table I and II for C K-edge and O K-edge spectrum, respectively.

The C K-edge spectra (Fig. 1) for both DOPA-PT and TPT show three narrow peaks associated with bound resonances. The peak at about 285 eV (peak 1) is associated with the $\pi^*_{C=C}$ states of the aromatic ring. This peak can be split into two peaks upon close observation which is consistent with the phenylalanine and tyrosine amino acid, identified as a vibrational fine structure from the expected shifts of $1s \rightarrow \pi^*$ associated with different

3	540	540	$\sigma^*_{C\text{-}O}$

[a]Refer to Figure 2.

carbon sites around the ring [12]. The second band around 287 eV (peak 2) is assigned as the C1s(C-OH) $\rightarrow 1\pi^*$ transition. The assignment is consistent with Tyrosine related molecules [9, 12] and is similar to that found previously for phenols [16, 17] and hydroquinones [17]. The strong resonance about 288 eV (peak 3) arises primarily from the C 1s to π^* transition in carbonyl group present in the peptide bond. The peak position is consistent with the carbonyl C $1s \rightarrow \pi^*_{C=O}$ transition found for other molecular system such as nylon with amide motif [18], disulfide containing amide [19] and a cysteine-containing peptide tether [20]. Also at this energy, additional π^* states in the phenyl ring and Rydberg resonances in the alkyl carbon chain of the molecule contributes to the intensity [21]. Broad peaks related to shape resonances at about 293 eV (peak 4) show an excitation of C 1s electrons into σ^* (C-C) orbitals in the ring and short alkyl chain [22]. The peak at about 296 eV (peak 5) is also accounted to C-C σ^* convoluted with C-N σ^*. The broad peak at about 303 eV (peak 6) corresponds to C=C σ^* convoluted with C=O σ^* resonances.

Fingerprinting of the two closely related molecule can be based on the extent of the intensity difference between characteristic peaks. A close look at the bound resonances of C K-edge spectra shows difference in the intensity of the peaks between TPT and DOPA-PT. Apparent reduction in the intensity of the lines near 285 eV relative to the intensity of the carbonyl peak at 288 eV can be observed when DOPA-PT is compared with TPT. The reduction is due to the intensity redistribution, which is caused by hydroxyl group substitution. Similar observation between phenylalanine (Phe) and tyrosine (Tyr) innershell absorption spectra is seen. Apparent reduction in intensity of lines near 285.2 eV relative to the intensity of the carboxyl π^* peak is observed [12]. Also, the appearance of peak at 287 eV is seen for Tyr as compared with Phe [9, 12]. Similar trend applies also when TPT is compared with DOPA-PT. Increase in the intensity of peak 2 relative to peak 1 can be observed from DOPA-PT as compared to TPT. This is due to splitting of oscillator strength and transfer of intensity to the C1s(C-OH) $\rightarrow 1\pi^*$ peak. Increase in the intensity (or more pronounced peak) of C $1s \rightarrow \sigma^*_{C-C}$ around 292 eV is also observed on DOPA-PT (compared to TPT) due to the same

reason. Additional observation to DOPA-PT spectrum includes a weak feature at about 284 eV, which could be some small amount of contaminants.

The O K-edge spectrum in Figure 2 has peaks at about 532 eV, 535 eV and about 540 eV. Peak 1 is assigned to the O 1s $\rightarrow \pi^*_{C=O}$ transition in the carbonyl part of the peptide bond. The peak position is consistent with that of spectrum of Nylon having amide moiety [18]. The peak appearing as shoulder for DOPA-PT at about 535 eV is more intense for TPT. This peak is seen in the O 1s spectra of alcohols [23] and previously attributed to O 1s $\rightarrow \sigma^*_{O-H}$ transitions. A feature due to oxygen contribution of the delocalized C=C π^* around 537 eV can also be observed. This O 1s $\rightarrow \pi^*$ transition feature is supported by the Extended Huckle (EHMO) calculation results done by Francis and Hitchcock for phenols and hydroquinones [17]. The broad 540 eV peak is assigned to the σ^*(C-O) consistent with that of phenol and hydroquinone NEXAFS spectra [17].

Comparing the NEXAFS spectra acquired at different X-ray incidence angles, orientation of the molecules can be predicted based on the dependence of the intensity of the angle of light incidence. The intensity of NEXAFS resonance depends on the orientation of the polarization of light with respect to the molecular orbital that is probed [24]. The intensity is at its maximum if the direction of the electric field of radiation (E-vector) and the final state orbital is parallel with each other. Conversely, when E- vector is orthogonal to the direction of the final state orbital, the resonance is greatly attenuated. In the C K-edge spectrum for the two types of adsorbates, the aromatic π^* feature is slightly more intense at normal incidence than in grazing. The band associated with the 1s $\rightarrow \pi^*$ excitation at C atom bound to OH groups is also more intense from normal to grazing incidence. Bands assigned to C-C σ^* and C=C σ^* features are faintly more intense at grazing angle. This indicates that the molecules (particularly the aromatic molecules) on the average are oriented more "standing-up" than "lying-down". The increase in intensity of the band assigned to the C-O σ^*, which is associated with the hydroxyl groups attached to the ring, supports more the "standing up" orientation of the aromatic ring. The band at about 288 eV associated with primarily the C=O π^* feature is more intense at the grazing incidence than the normal incidence. This indicates that the peptide is positioned with the carbonyl groups almost parallel to the gold surface. This orientation is supported further by the increase in the intensity of the band assigned to the O 1s $\rightarrow \pi^*_{C=O}$ transition (see peak 1, Figure 2) at grazing incidence for TPT and more for DOPA-PT molecule.

The average tilt values of the molecule are obtained by quantitative analysis of the angular dependence of the NEXAFS resonance intensities. The calculations are based on the procedure developed by Stöhr [24]. This involves taking the area of the peak at normal and grazing photon incidence and calculating the relative ratio of the integrated intensity, I_{90}/I_{30} *(or* I_{90}/I_{20}*)*, where I_{90} is the intensity (area) of the π^* peak at normal photon incidence and I_{30} (or I_{20}) that at grazing incidence. The average tilt value is obtained from the vector-like orbital intensity ratio (I_{90}/I_{30} or I_{90}/I_{20}) as a function of the tilt angle of the π^* and σ^* orbital from the surface normal with the assumption that the polarization is ~0.85 [24]. From the small angular variation of the C=C 1π^* - intensity in the spectra, it is estimated that the ring plane of the aromatic ring for DOPA-PT exhibits a preferential orientation with an average tilt angle (α) of about 64° ± 2°. For TPT, it estimated to be about 60° ± 2° [25]. The estimations are very close to the approximation done by Lee, *et al.* [8] for tilt angle

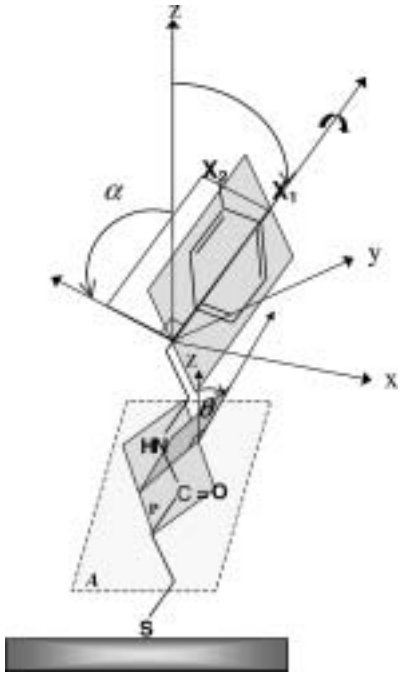

Fig. 3. Schematic structure representing the two molecules when adsorbed on gold showing angles extracted from NEXAFS used to characterize the monolayer's orientation. X_1 and X_2 represents the hydroxyl (-OH) functional groups. X_1 is only present in TPT while both X_1 and X_2 are present in DOPA-PT. The peptide plane (plane P) is assumed to be in/plane with the main molecular axis plane (plane A).

of phenyl-terminated SAMs having an even number of methylene units. The average tilt angle is close to the magic angle (55°) but larger than it. It indicates a certain degree of order (as supported by the XPS angle dependent measurement, ellipsometry and contact angle measurements) with a certain degree of disorder to be considered. The dichroism of the resonances associated with the $\pi^*_{C=C}$ states of the aromatic ring is rather small compared with dichroism of the π^* resonances for the thiol-derived aromatic SAMs on gold having average tilt angle of the aromatic chain of about 22° [26]. Also from the observed angular variation of intensity in the C K-edge NEXAFS spectrum, the tilt angle of the π^* orbital of C=O (in the peptide bond) for DOPA-PT is approximately 53° ± 2° relative to the normal of the surface. TPT has about 52° ± 2° [25] which is of the same tilt angle as that of DOPA-PT. A schematic orientation representing the two related adsorbates is shown in Figure 3. The angle, θ, is used to approximate the orientation of the main molecular axis. The C=O π^* orbital is perpendicular to the peptide (bond) plane and that the plane is assumed to be coplanar with the molecular axis of the molecule. Also, it is assumed that the amide has a trans conformation with adjacent CH chains. From the abovementioned fact and assumption, the main molecular axis of the DOPA-PT molecule is estimated to be tilting about 37° ± 2° relative to the surface normal and the molecular axis of TPT is estimated to be about 38° ± 2°. For comparison, it can be mentioned that for phenyl-terminated organic surfaces, a 46°- tilt angle of the methylene chain with respect to the surface normal has been reported [22].

4. Conclusion

Amino acid linked to short amidethiol has been studied in this work. Analogues such as TPT and DOPA-PT are adsorbed to

gold surfaces and their chemical states and molecular orientation is investigated by NEXAFS spectroscopy. The characteristic NEXAFS spectra of both TPT and DOPA-PT can be used as fingerprints of the two given amino acid derivatives. The two closely related molecule shows similar structural orientation when adsorbed on gold surface. Knowing the molecular orientation of such interesting derived biomolecules, future investigations and studies related to biosensing will be well executed and understood.

Abstract

X-ray absorption measurements were performed on Ca^{2+} and 5 Mn^{2+} regenerated purple membrane in order to obtain structural information about the cation environment. For the regenerated membrane with 5 Mn^{2+}, EXAFS analysis shows a first six-coordination sphere with two Mn-O distances (2.18 Å and 2.49 Å), whereas for the 5 Mn^{2+} regenerated bleached membrane the first shell is formed by 6 oxygen atoms at 2.17 Å. In the case of Ca^{2+}-substituted bacteriorhodopsin, *ab initio* calculations of the X-ray absorption cross section based on a full multiple scattering approach, with a best fit of the experimental data, show that the Ca^{2+} environment is composed by 6 oxygen atoms showing a distorted orthorhombic symmetry, while Ca^{2+} in water solution has a regular octahydrated first sphere of coordination. Our results provide strong direct evidence of the specific binding site of the metal cation in bacteriorhodopsin and are in good agreement with previous molecular models suggesting that there could be a high affinity cationic site in the proximity of the retinal pocket.

1. Introduction

Bacteriorhodpsin (BR) is a seven-helical transmembrane protein found in the purple membrane (PM) of *Halobacterium salinarum*. It has a retinal molecule covalently linked to Lys-216 through a protonated Schiff base. When it absorbs a photon, it undergoes a photochemical cycle during which the retinal configuration changes from *all-trans* to *13-cis*. This induces protein conformational changes that result in the translocation of a proton from the inside to the outside of the cell, returning both the retinal molecule and the protein to their initial states. In fact, bacteriorhodopsin converts the energy of light into an electrochemical proton gradient, which is used by the bacteria to produce ATP by ATP-synthases (for reviews see [1, 2]).

Native PM contains divalent cations (Ca^{2+} and Mg^{2+}) that are necessary to maintain the structure of the protein and its function [3]. Removal of these cations from the PM increases the apparent pK of the blue/purple transition from about 3.2 in water to 5.5. This change is reversible by addition of a variety of cations. The binding has been explained in terms of specific chemical binding to negatively charged groups (most probably carboxylic groups of the protein). Different affinity sites, 5 of high and medium affinity, and 5 of low affinity have been found, although their localization is not yet clear [4–6]. An alternative model suggested a non-specific binding to the Gouy-Chapman bilayer [7].

Several three-dimensional models of bacteriorhodopsin have been published [8–10], but so far none of them gives any evidence about the bound cations, perhaps because they are in part or completely lost upon crystallization. In contrast, all of these three-dimensional models show different Asp and Glu groups that in terms of geometry and bound distances are compatible with cation binding sites.

Due to the strict requirements of classical X-ray crystallography about sample preparation, and to its low sensitivity to the system dynamics, X-ray Absorption Spectroscopy (XAS) has become an important alternative and a complementary technique to obtain information about the cation environment because it allows the study of purple membrane in solution, i.e. in an environment which is much closer to its physiological state.

In this work we present two complementary analyses. In order to study the local environment of the high-affinity cation binding site of PM we have first measured XAS spectra, at the Ca K-edge, of deionised membrane regenerated with Ca^{2+}. In the second part we study the medium affinity binding sites, and the effect of the retinal in the maintenance of structure, by comparing XAS spectra of a deionised membrane regenerated with 5 Mn^{2+} per mol of protein (5 Mn/BR sample) with a deionised bleached membrane regenerated with 5 Mn^{2+} per mol of protein (5 Mn/BO sample).

2. Materials and Methods

Purple membrane was isolated from the *Halobacterium salinarum* strain S9, as described previously [11]. Cations were removed from purple membrane by an extensive dialysis in front of a cation-exchange Dowex AG-50W resin, and the regeneration was done at pH 5. Bleaching of the purple membrane was effected by its illumination in the presence of 1 M hydroxylamine and 4 M NaCl at room temperature with a 150 W lamp.

EXAFS of the Mn/BR samples were carried out at 230 K in fluorescence mode at the Mn K-edge, at the beam-line ID29 of the European Synchrotron Radiation Facility (ESRF). The final concentration of the protein was about 2–3 mM.

Measurements at the Ca K-edge were carried out at the beam line ID26 (ESRF) that is dedicated to the study of very dilute systems, requiring high photon flux ($>10^{13}$ ph/s). The samples were deposited on the sample holders and were kept overnight in a closed chamber in order to get a partially dried film by applying a mild vacuum. Monochromatic beam was obtained, in both cases, by means of a Si(111) double crystal, with an energy resolution $\Delta E/E = 1.4 \cdot 10^{-4}$. The fluorescence signal at the Ca and Mn K-edge, was detected by a multi-element Silicon-drift solid state detector. The absorption spectrum of Mn^{2+} and Ca^{2+} in water were also recorded as reference systems.

*e-mail: Francesc.Sepulcre@upc.es

In order to extract the structural/geometrical information on the Ca^{2+} first coordination shell that is contained in the fine structure just above the edge, we performed a quantitative analysis of the XANES spectrum using the MXAN code [12].

The EXAFS spectra at the Mn K-edge were analysed by a least-squares fit procedure, comparing the experimental spectrum with a theoretical signal generated by the FEFF8 code [13].

3. Results and Discussion

3.1. *The high affinity binding site*

Because the low S/N ratio of the Ca^{2+}-substituted BR sample, a standard EXAFS analysis is not relevant (i.e. the k-range experimental data for this samples is limited) and also because we attempt to make a quantitative geometrical characterization of the high-affinity binding site by comparing our experimental data with know X-ray structures. Therefore, in this case we focus our attention on the XANES region.

The XANES spectra of deionized PM after reconstitution with Ca^{2+} at a molar ratio of 1:1 (Ca^{2+} : BR), is shown in Fig. 1. It is the average of several scans taken during an overall integration time of about 12 hours, carried out moving the sample in the X-ray beam to avoid radiation damage. At this Ca concentration only the high affinity binding site should be filled. The experimental spectra of the Ca^{2+}-BR complex show a small shoulder at about 40 eV above the edge due, probably, to a multiple excitation.

Several studies have suggested that a divalent cation is located in the proximity of the retinal binding pocket [14–16] associated with Asp-85 and Asp-212. To test this hypothesis, we performed a fitting of the experimental data with a molecular model obtained from the optimized geometry described in [16] by selecting a sphere of radius 6 Å centred on the absorbing atom containing the side chains of Asp85 and Asp212, three water molecules and a part of the retinal chromophore. The starting cluster to be refined includes 6 oxygen atoms in a distorted octahedral-like configuration with Ca-O distances varying from 1.98 Å to 2.24 Å, corresponding to an average distance of 2.12 Å. The results of this analysis are shown in Fig. 1. The best fit of the experimental data, corresponds to a first coordination shell of 6 O atoms, in a quite distorted geometry, with a Ca-O average distance of 2.31 Å.

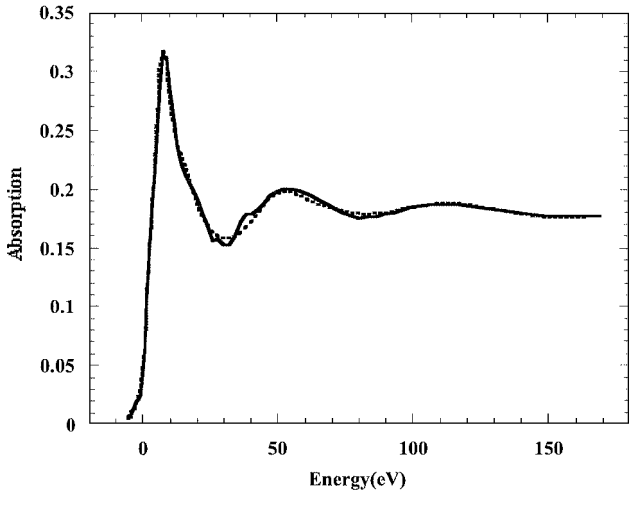

Fig. 1. Theory-vs-experiment best-fit results for Ca^{2+}-BR complex starting from Asp85-Asp212-3H_2O cluster. The O-C-O distances are correlated. The solid line correspond to the experimental data.

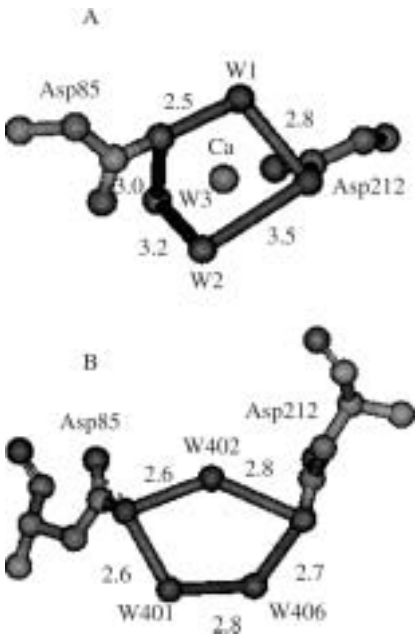

Fig. 2. A) Ca^{2+}-coordination in the vicinity of the Schiff base, corresponding to the best-fit for the Ca^{2+}-BR complex starting from the putative cluster described in [16]. B) X-ray crystallographic structure of the Schiff base region from PDB entry 1C3W [9]. The numbers are bond distances in Ångstroms.

It has to be noted that the refinement results show an increase of the average Ca-O distance, as expected due to the increased ionic radius of Ca in comparison with the Mg cation of the model [16]. The agreement between the experimental data and the fitting calculations is very good, suggesting that this internal cluster is a possible high-affinity binding site in the protein. Figure 2A shows a detailed view of the computed best fit to the Asp85-Asp212-3H_2O cluster. As it can be observed, the first sphere around the Ca^{2+} ion has a very distorted octahedral coordination formed by the O atoms of Asp212, one O atom of Asp85 and three water molecules.

The best fit curve for Ca^{2+} in water, obtained using the same starting atomic clusters as for the protein sample corresponds instead, to a regular square for the first hydration shell ($n = 8$) of the calcium atom at an average distance of 2.35 Å.

These results are consistent with our previous EXAFS work in which we found an octahedral geometry for the high-affinity Mn^{2+} binding site [17]. This similarity suggests that both cations (Mn^{2+} and Ca^{2+}) could bind to the same high-affinity binding site.

The crystallographic structures of bacteriorhodopsin have reported the location of internal water molecules near the Schiff base region, forming a pentagonal cluster [8–10]. As can be seen in Fig. 2, our results reproduce this pentagonal cluster remarkably well. The discrepancy in the O-O distances and angles between the crystallographic structures cited above and the cluster proposed in this work could be due to the fact that in the last refinement process of the crystallographic structures the Ca^{2+} cation is not included.

3.2. *The medium affinity binding sites and the effect of the retinal extraction*

ESR studies on the binding of the paramagnetic Mn^{2+} cation [4] have indicated that the apparent affinity constants for Ca^{2+} and Mn^{2+} to the deionised BR were almost identical. Therefore, and with the purpose to extrapolate the conclusions to the physiologically important cations (e.g. Ca^{2+}) we used in our experiments the same conditions used by these authors. The

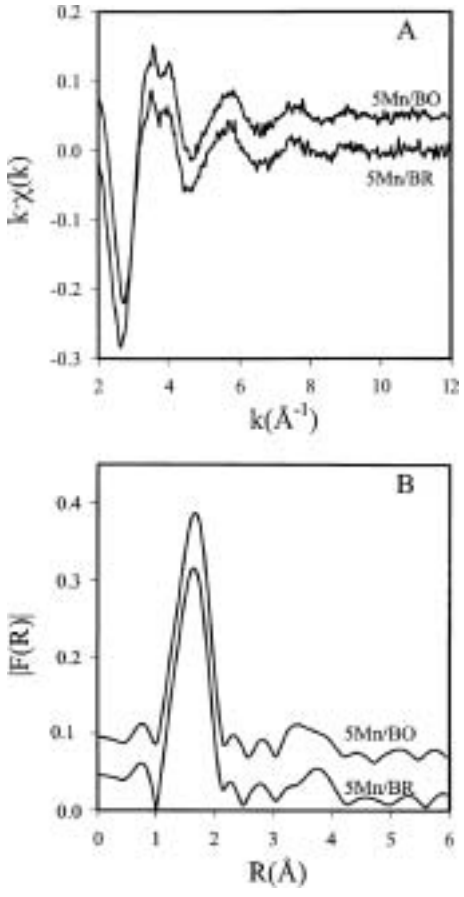

Fig. 3. A) EXAFS spectra of the 5 Mn/BR and 5 Mn/BO samples, taken at the Mn K-edge at 230 K. B) FT of the $k\cdot\chi(k)$ data, calculated in the range 2–12 Å with a Gaussian window.

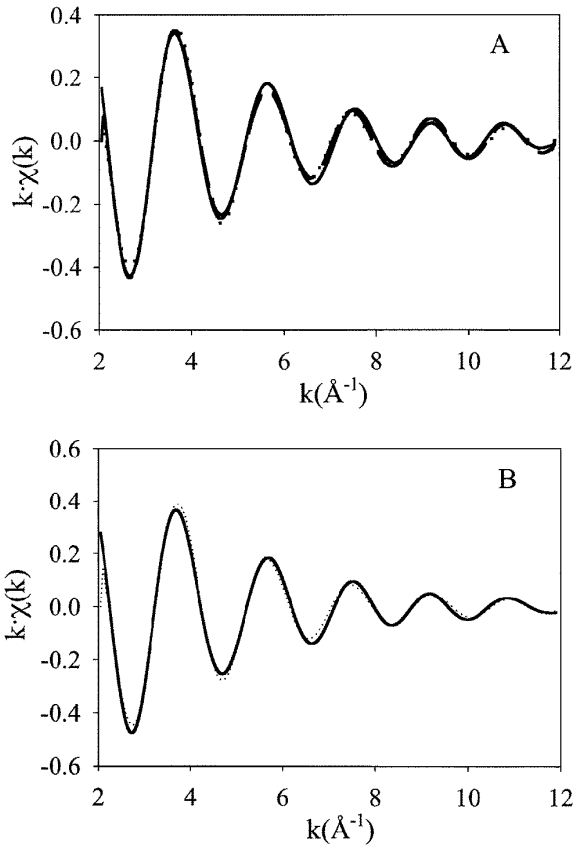

Fig. 4. (A) Single-shell best fit (dotted line), two-shells best fit (dashed line) and filtered experimental signal curve (solid line) for 5 Mn/BR. (B) Single-shell best fit (dotted line) and filtered experimental signal curve (solid line) for 5 Mn/BO.

relevance of these data is enhanced by the fact that they were obtained with different techniques [4, 5].

The raw EXAFS data of 5 Mn/BR, 5 Mn/BO and its Fourier transforms are shown in Figs. 3 and 4 respectively. The $\chi(k)$ signals of Mn^{2+} for both samples are quite close to each other. The FT of the spectra show a main peak centered at about 1.6 Å, and no appreciable contribution due to further shells is observed in any case. As we show in [17], if one of the high and/or medium affinity sites were located in the lipidic region, the Fourier transform of this spectra should show a second peak due to the next nearest neighbours, P and/or S atoms in the phospho- and sulpholipids. Therefore, cation binding is not taking place on the outer lipidic region of the membrane.

To obtain Mn^{2+}-O distances for the protein, we transformed back to k-space the first shell R-space contribution and performed a best fit procedure (Fig. 4) of the experimental data with theoretical phases and amplitudes calculated using the FEFF8 code [13]. The same theoretical signal was also used to fit the Mn^{2+} solution filtered spectrum. The results are reported in Table I. Coordination numbers, Debye-Waller factors, and interatomic distances were iterated. A distance of 2.17 ± 0.01 Å is obtained for Mn^{2+}-O in both the 5 Mn^{2+} regenerated and 5 Mn^{2+} bleached-regenerated membrane. The coordination numbers are equal to six, within the experimental error, for both samples. The Mn^{2+}-O distance found for the Mn solution sample is equal to 2.2 ± 0.01 Å, i.e. 0.03 Å longer than in the protein, demonstrating that in the protein samples the Mn^{2+} are located in the protein environment.

Further information obtained from the fit procedure was that, despite of the close similarity between the two protein samples, the best fit procedure result is different. In the case of the 5 Mn/BR data, the best fit is obtained when an extra Mn-O shell at 2.49 ± 0.02 Å is included. The fit corresponding to the sample in which the retinal has been eliminated (5 Mn/BO) only allows one distance at about 2.17 Å, suggesting that retinal extraction induces

Table I. *Best fit results for 5 Mn/BR, 5 Mn/BO and Mn^{2+} solution samples. The error on Mn-O distances are equal to 0.01 Å for the short Mn-O distance and equal to 0.02 Å for the longer Mn-O distance found for the 5 Mn/BR sample. Errors on Debye-Waller factor and coordination numbers are of about 20%.*

changes in the environment of Mn^{2+}. The loss of the heterogeneity of cation binding sites in the bleached sample suggest that the structural change produced in the protein by the retinal extraction affect the geometry of the cation binding sites. It is know that retinal extraction produces tertiary structural changes with only small alterations of the secondary structure. Therefore cations can help in the protein compactness, because the carboxylic groups that participate in cation binding are from different helices.

All these results are a strong evidence of the specific binding site of the metal cation to bacteriorhodopsin.

Simulation of XANES Spectra for Protein-Bound Metal Centers: Analysis of Linear Dichroism Data

Peter Liebisch[1], Michael Haumann and Holger Dau

Freie Universität Berlin, Fachbereich Physik, Arnimallee 14, D-14195 Berlin, Germany

Received June 26, 2003; accepted December 17, 2003

Abstract

For protein-bound transition metals, the structure of the metal site (geometric arrangement of the nuclei) and the electronic structure (oxidations state and orbital occupancy) can be investigated by X-ray absorption spectroscopy. While the extended X-ray absorption fine-structure (EXAFS) is theoretically well understood and the advantages of EXAFS spectroscopy on protein-bound metal centers have been repeatedly demonstrated, quantitative analysis of the near-edge structure (XANES) is more demanding. However, by now XANES simulations, for which a number of codes are available, may be useful to understand geometric and electronic structure effects.

For a simplified model of the manganese complex in photosystem II we simulate polarization-dependent XANES spectra using the FEFF 8.2 code [Ankudinov *et al.*, Phys Rev. B **12** (1998).], which includes self-consistent muffin-tin potentials and polarization-dependent full multiple-scattering calculations. We derive a scheme to analyze the polarization dependence of XANES data that facilitates a treatment of partially uni-directionally oriented samples. Reasonably good agreement between simulations and experiments is obtained for the chosen model of the photosystem II manganese complex and its orientation with respect to the protein-carrying membrane.

1. Introduction

X-ray absorption spectroscopy is frequently applied to collect information on geometric and electronic structure of the catalytic centers in metallo-proteins [1, 2]. While the extended fine-structure (EXAFS) is readily analyzed by least-square fits to an analytical expression to yield coordination numbers, distances and disorder parameters, no closed expression exists for the description for the near-edge region (XANES). Nevertheless, application of modern *ab-initio* computer simulations can provide insight in ligand geometry (distances and angles) and the electronic structure [1, 3, 4]. Interestingly X-ray absorption spectra depend on the angle between the electric field vector of the polarized X-rays and the anisotropic sample, an effect that has been exploited in single-crystal studies and surface science.

For biological samples where single crystals are not available, as it is the case for many membrane proteins, a frequently viable approach involves the use of non-crystalline, but uni-directionally oriented samples where the metal complex has a preferential orientation with respect to the sample normal. Photosystem II (PSII) is a protein complex embedded in the thylakoid membrane of cyanobacteria and higher plants; it contains tetra-manganese complex [5]. PSII-containing membrane fragments can be deposited onto a plane surface by paint-dry techniques or centrifugation such that the membrane plane becomes oriented preferentially parallel to the plane of the substrate surface of the macroscopic sample (for references see [5] and [2]).

For such unidirectionally ordered samples with significant disorder (mosaic spread) we have developed an approach to analyze the single-scattering EXAFS on the basis of curved-wave theory quantitatively [6]. However, this approach is not applicable to XANES spectra. To demonstrate the potential of XANES analysis we show first attempts to understand experimental results from partially oriented samples by XANES simulations.

2. Materials and Methods

Simulations were performed using the *ab-initio* full-multiple scattering (FMS) code FEFF 8.2 [3]. The simulations are performed polarization-dependent using self-consistent potential calculations (SCF) in the muffin-tin approximation with 15% overlap between the muffin tins. The radius for the SCF and the FMS calculations was chosen large enough to include all atoms in the cluster.

3. Results

In general, the normalized X-ray absorption is directly proportional to the matrix element of the transition from initial to the final state as given by Fermi's Golden Rule. For a given polarization, $\vec{\boldsymbol{\epsilon}}$, the absorption is therefore given as $\mu \sim |\vec{\boldsymbol{\epsilon}} \cdot \langle f\,|\vec{\boldsymbol{r}}|\,i\rangle|^2$ (p. 279 of [7]). Performing the quadrature after component-wise expansion of the vectorial expression yields

$$\mu(\vec{\boldsymbol{\epsilon}}) = \epsilon_x^2\mu_{xx} + \epsilon_y^2\mu_{yy} + \epsilon_z^2\mu_{zz} + 2\epsilon_x\epsilon_y\mu_{xy} + 2\,\epsilon_y\epsilon_z\mu_{yz} + 2\epsilon_z\epsilon_x\mu_{zx}. \quad (1)$$

Thus, $\mu(\vec{\boldsymbol{\epsilon}})$ is described by a second rank tensor with six independent parameters [8] which can be visualized as an absorption ellipsoid. Therefore with six independent simulations for different polarization directions an equation system can be set up and which provides the tensor components. Writing Eq. (1) as quadratic form

$$\mathbf{1} = \vec{\boldsymbol{\epsilon}}^T\mathbf{A}\vec{\boldsymbol{\epsilon}} \quad (2)$$

allows the calculation of Eigenvectors and Eigenvalues of the coefficient matrix, which to the principal axes of the absorption ellipsoid and the inverse square root of their length. We denote the principal-axes unit vectors (Eigenvectors of $\mathbf{A}$) as $\vec{\boldsymbol{v}}_1$, $\vec{\boldsymbol{v}}_2$ and $\vec{\boldsymbol{v}}_3$ and the corresponding Eigenvalues as D_1, D_2 and D_3. Then the length of each principal axis is given by: $L_i = 1/\sqrt{D_i} = \sqrt{\mu_i}$; $i = 1, 2, 3$.

Thus we can write for the X-ray absorption in the molecule system

$$\mu(E, \vec{\boldsymbol{\epsilon}}) = \sum_{i=1}^{3} \mu_i(\vec{\boldsymbol{v}}_i \cdot \vec{\boldsymbol{\epsilon}}_i)^2 = \sum_{i=1}^{3} \mu_i \cos^2 \Theta_{v_i,\epsilon_i} \quad (3)$$

For each principle axis unit vector, the absorption is proportional to the squared cosine of $\Theta_{v,\epsilon}$ rendering each term analogous to the cosine term in Eq. (2) of Dittmer and Dau [6]. In continuation of the analogy, we introduce Θ_i, the angles between the principle-axis unit vectors and the membrane normal ($\vec{\boldsymbol{N}}$), as well as Θ_E, the

[1] peter.liebisch@physik.fu-berlin.de

angle between the electric field vector and the membrane normal. Following the rationale given in [6], we finally arrive at the result

$$\mu(E, \Theta_E) = \frac{1}{3}\sum_{i=1}^{3}\mu_i + \frac{1}{6}\,(3\cos^2\Theta_E - 1)\,I_{ord}\sum_{i=1}^{3}\mu_i(3\cos^2\Theta_i - 1) \qquad (4)$$

with the order parameter, I_{ord}, which has been defined in [6] (Eq. 8) as an integral over the properly normalized distribution function of the membrane normals, $P(\alpha)$, according to:

$$I_{ord} = 2\pi^2\int_0^{\pi/2}(3\cos^2(\alpha) - 1)P(\alpha)\sin(\alpha)\,\mathrm{d}\alpha. \qquad (5)$$

The I_{ord}-value of 1 is obtained for perfect orientation, and I_{ord} is zero for an isotropic distribution.

As an example we discuss polarization-dependent simulations for the simple mixed-valent di-μ-oxo-bridged manganese dimer shown in Fig. 1. The native tetra-manganese complex of PSII may consist of two binuclear units both being similar to the complex shown in Fig. 1.

In Fig. 2 we show spectra of layered PSII membranes for angles between the X-ray electric field vector and the sample normal of 15°, 35°, 55° and 75°. Here, the edge position of the 75° spectrum is shifted by 0.7 eV to higher energies compared to the 15° spectrum; the magnitude of the pre-edge peak is maximal in the 75° spectrum and minimal for 15°.

In the simulations we use a highly simplified structural model for the water-oxidizing complex of PSII. The native manganese complex seems to consist of two di-μ-oxo bridged Mn_2-units [5]. Linear Dichroism EXAFS analysis shows that the Mn-Mn vector is at an angle of about 70° to the membrane normal and that the di-μ-oxo plane is rather parallel than perpendicular to the membrane plane [1, 2, 5, 9]. XANES analysis suggests a $Mn(III)_2Mn(IV)_2$ complex in the dark-stable S_1-state [1, 2, 5]. Here we use a single Mn(III)-(μ-O)$_2$-Mn(IV) unit assuming that the native complex consists of two such units. The oxidation state of the manganese atoms is incorporated in two ways: (1) as formal oxidation state by substitution of water ligands by (negative) hydroxyl ligands and (2) by means of the bonding distances that are typical for the respective oxidation states.

The specrta calculated separately for Mn(III) and Mn(IV) for different polarization angles are shown in Fig. 3 whereas Fig. 4 shows the average spectrum. Firstly we can state that the polarization-dependent changes in the experimental spectra are reproduced. Secondly we note, that the modeling of the oxidation states works quite well since an upshift of the edge position by about 3–4 eV is known to be typical for an oxidation state change of +1 (see [1]). However, the polarization dependence is largely overestimated by the simulations. For the following reasons this is to be anticipated: (1) the actual XAS samples are not perfectly oriented but partially disordered; (2) in the Mn_4-complex of the PSII the $Mn_2(\mu\text{-O})_2$ planes are certainly not both perfectly parallel to the membrane plane; and (3) only partial orientation exists (partially uni-directionally oriented samples).

The latter argument necessitates angle averaging. This can be performed if the absorption ellipsoid is known at each energy. Figure 5 shows the absorption ellipsoids for selected X-ray energies where μ corresponds to the square of the length of the radius vector for a given orientation (also indicated by the surface color).

Applying the result of Eq. (4) to the absorption ellipsoids calculated for each energy point we can calculate XANES spectra corresponding to a distinct degree of orientation ($I_{ord} = 0.45$) and

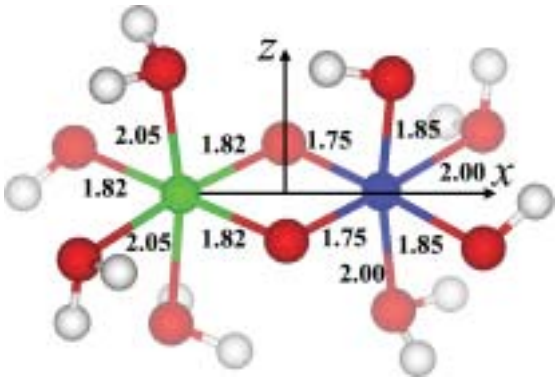

Fig. 1. Structure of a hypothetical di-μ-oxo-bridged manganese complex. Red spheres stand for oxygen atoms, white spheres for hydrogen, the green sphere for Mn(III), and the blue one for Mn(IV). The numbers indicate the bond length in Å. The axes indicate the orientation of the coordinate system selected for the simulations: The x-axis points along the Mn-Mn vector, the y-axis connects the two bridging oxygens and the z-axis is perpendicular to the $Mn_2(\mu\text{-O})_2$-plane.

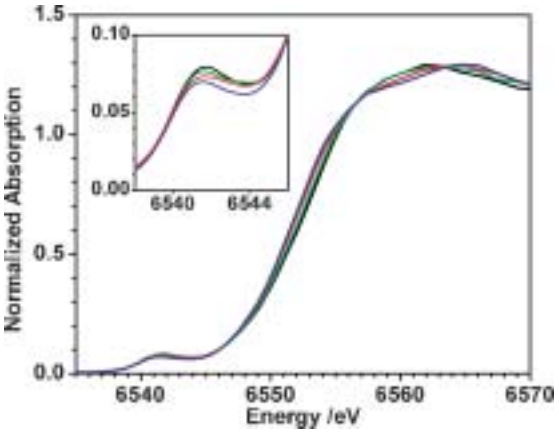

Fig. 2. XANES spectra of the PSII manganese complex measured at excitation angles of $\Theta_E = 15°$ (blue line), 35° (red line), 55° (green line) and 75° (black line) on partially oriented PSII membrane particles. The inset shows the pre-edge region on an expanded scale. Sample preparation and data collection as described in [9, 10].

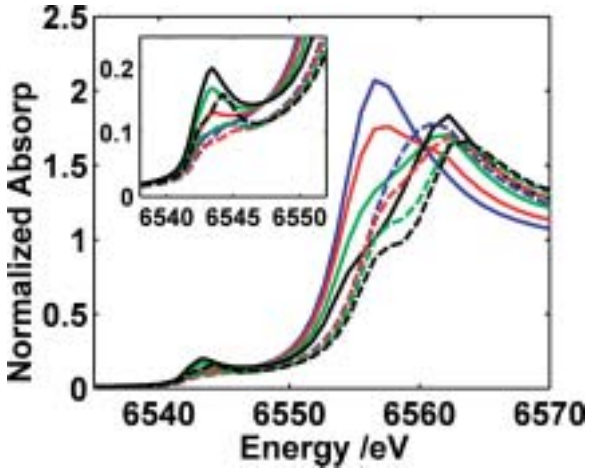

Fig. 3. Simulated polarization dependence of the XANES for the Mn(III) (solid lines) and Mn(IV) (dashed lines) in the dimer structure of Fig. 1. The polarization vector was chosen in the x-z-plane at angles with the z-axis of $\Theta_E = 15°$ (blue line), 35° (red line), 55° (green line) and 75° (black line).

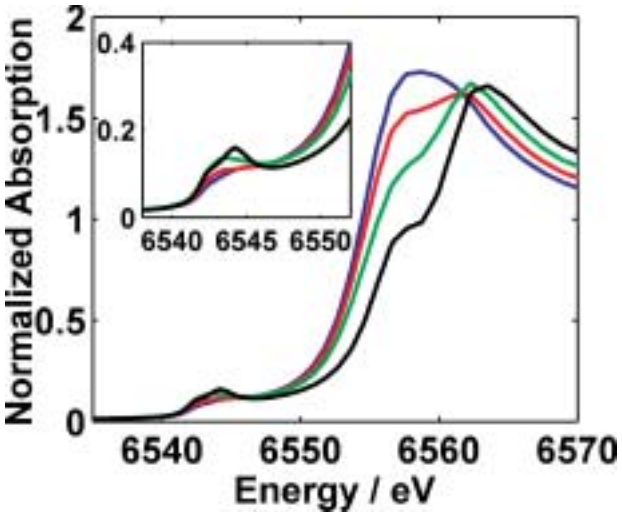

Fig. 4. XANES spectra obtained by averaging of the corresponding Mn(III) and Mn(IV) spectra of Fig. 3. $\Theta_E = 15^\circ$ (blue line), 35° (red line), 55° (green line) and 75° (black line).

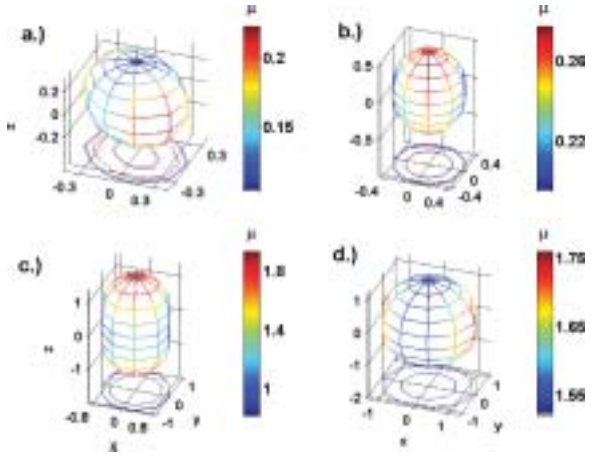

Fig. 5. Shape of the absorption ellipsoids for different energies for the Mn(IV) atom in the model structure: a.) 6544 eV, b.) 6550 eV, c.) 6555 eV and d.) 6560 eV. The axes are chosen to lie as indicated in Fig. 1, the length of a vector pointing from the origin to the ellipsoid surface at a direction $\vec{\boldsymbol{\epsilon}}$ is given by $\sqrt{\mu(\vec{\boldsymbol{\epsilon}})}$. The normalized absorption μ is also indicated by the surface color.

a distinct orientation of the molecular system with respect to the membrane normal. The spectra shown in Fig. 6 were calculated assuming that the $Mn_2(\mu\text{-}O)_2$ plane lies in the membrane plane.

We observe a polarization dependence which not only qualitatively reflects the experimental results but also is of approximately correct magnitude with respect to the edge-shift and the angle-dependence of the pre-edge magnitude. Furthermore, in the range of the shape resonance a cross-over point is found that is similar to the one in the experimental data. The second crossing is missing in the simulation which is most probably due to the grossly simplified model.

Figure 7 shows the simulated spectra under the assumption that the $Mn_2(\mu\text{-}O)_2$ plane is perpendicular to the membrane plane. Obviously, the results are not in agreement with the experiment.

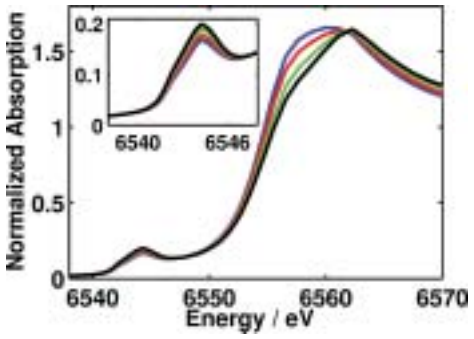

Fig. 6. Spectra resulting from angle averaging under the assumption that the $Mn_2(\mu\text{-}O)_2$-plane lies in the membrane plane ($\vec{z} \parallel \vec{N}$). Blue line, $\Theta_E = 15^\circ$; red line, $\Theta_E = 35^\circ$; green line, $\Theta_E = 55^\circ$, black line $\Theta_E = 75^\circ$.

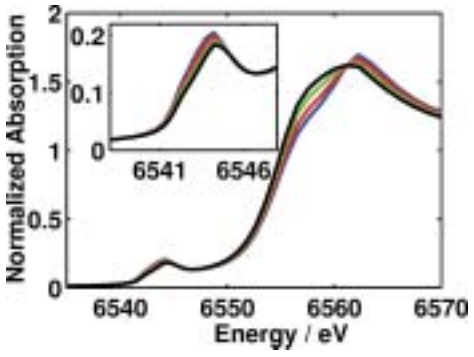

Fig. 7. Spectra resulting from angle averaging under the assumption that the $Mn_2(\mu\text{-}O)_2$-plane is perpendicular to the membrane plane ($\vec{z} \perp \vec{N}$) (same color code as in Fig. 6).

We feel that the simulation of the linear dichroism (LD) in the XANES represents a promising new approach. In the future the LD-XANES analysis may complement the LD-EXAFS analysis.

Abstract

The active site geometry of Fe(II)-bleomycin, peplomycin and its derivatives have been studied on the basis of theoretical multiple scattering simulations of the Fe K-edge X-ray absorption near edge structure. Comparisons of the experimental and theoretical spectra calculated for the different models of Fe(II)-bleomycin reveal serious distortions of the ligands nearest to Fe. This includes the presence of one ligand with a very short bond length as well as angular distortions. Reconstruction of the nearest environment of the Fe during perturbation of axial ligand was investigated for peplomycin. It was found that replacement of carbamoyl group of the mannose with solvent molecule led to a small increase of average radius (0.03 Å) of the first atomic shell around Fe ion and elongation of the shortest bond length (0.10 Å).

1. Introduction

Investigation of the non-heme active site structure of bleomycin (Blm) and its variations during ligand substitution is a key step to understand the antibiotic activity of this complex and its ability to degrade DNA with site specificity. At present there are no high-resolution crystal structure data of bleomycin or its analogues such as peplomycin. Current insight into the Fe-ligand geometry is based on NMR or optical spectroscopic data as well as on molecular dynamic results. A description of recent results in this field can be found in [1, 2]. The secondary amine of β-aminoalanine (Ala), pyrimidine (Pyr) and imidazole (Imid) rings and amine nitrogen of β-hydroxyhistidine (His) are found to be the equatorial ligands to the metal centers in all bleomycins studied to date. Nevertheless, the axial ligation of the metal center still remains unclear. Different models with the primary amine of Ala and either carbamoyl substituent of mannose (Man) or solvent molecule occupying axial positions have been proposed. Moreover, some models represent opposite chiralities of the metal center. XANES spectroscopy is a sensitive probe of metal arrangement in bio-molecules and we have applied it to clarify axial ligands and geometry in bleomycin.

2. Method of calculation

The method of XANES simulations is based on a full multiple scattering scheme in the framework of the muffin-tin approximation. It was described in detail in [3]. A cluster of 54 atoms for Blm and peplomycin (Pep) and 51 nearest to Fe atoms for iso-peplomycin (Iso-Pep) have been chosen using the criterion of spectrum convergence as a function of cluster size. The molecular muffin-tin potential was obtained by a self-consistent-field scattering waves technique within the local density approximation. To take into account the broadening of the experimental spectrum according to the core hole lifetime, the finite mean free path of the photoelectron and the experimental resolution, the theoretical spectra were convoluted with a Lorentzian function. We have used the value of 1.25 eV for the core hole bandwidth, an energy dependent function from [4] representing all inelastic processes, and a value of 1.4 eV for experimental resolution.

Within the limit of small variations of structural parameters (less than 0.15 Å if the parameter is a distance) a simple approximation to interpolate a spectrum as a function of these parameters can be used:

$$I(E, p_1 + \delta p_1, p_2 + \delta p_2, \ldots, p_n + \delta p_n) = I(E, p_1, p_2, \ldots, p_n) + \sum_{i=1}^{n} \frac{\partial I}{\partial p_i}(E)\delta p_i,$$

where

$$\frac{\partial I}{\partial p_i}(E) = \frac{I(E, p_1, p_2, \ldots, p_i + \Delta p, \ldots, p_n) - I(E, p_1, p_2, \ldots, p_n)}{\Delta p}.$$

Such an approach allows a significant reduction in computational time during the geometry optimization using a standard fitting technique (only $n + 1$ multiple scattering calculations are needed, where n is a number of parameters). Tests of approximation accuracy were performed but they are out of the scope of this paper.

3. Results and discussion

Calculations of the Fe K-edge XANES of bleomycin were performed for 7 models generated using the molecular dynamic technique [1]. All variants of axial ligation with the primary amine of Ala and different second ligands (nitrogen or oxygen of carbamoyl group of the mannose or oxygen of the solvent molecule) were tested. Models 1, 2, 5 and 6 involve only endogenous ligands. In models 1 and 5 the second axial position is occupied by the carbamoyl oxygen, while models 2 and 6 include the nitrogen of the same group. Pairs 1,5 and 2,6 represent opposite chiralities of the metal center. Models 3 and 7 were derived from models 1 and 5 respectively by substituting the carbamoyl with a solvent molecule. In these models the sugar moiety is located near the solvent molecule. In model 4 the Fe ligation is the same as that in model 7, but the sugar moiety is close to the primary amine of Ala. A more detailed description of the models can be found in [1].

*e-mail: Soldatov@rsu.ru

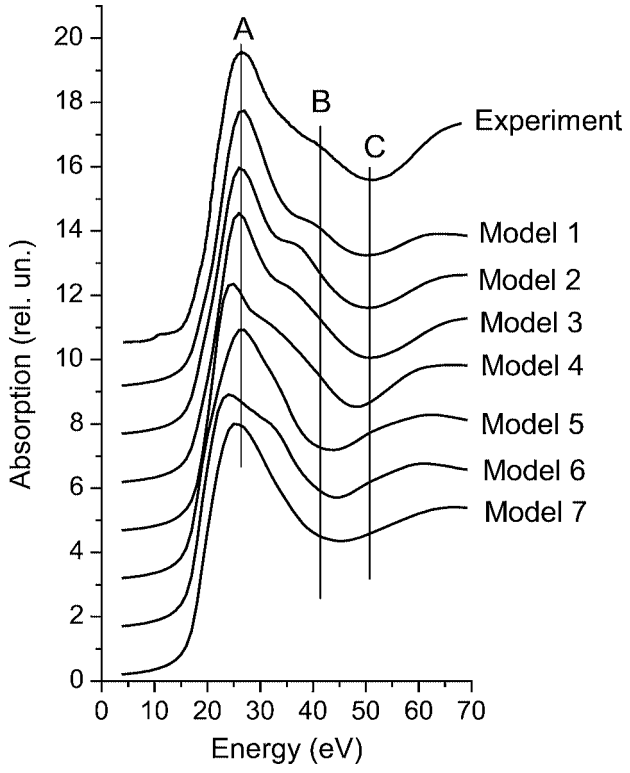

Fig. 1. Experimental and theoretical Fe K-edge XANES of bleomycin. Calculations for 7 models from [1] are presented.

A comparison of theoretical spectra with experimental spectrum in fig. 1 shows that models 1, 2, 3 and 4 correctly predict the relative energy separation between maximum A and minimum C, while this energy separation is very small for models 5–7. The shapes of spectra 1, 2 and 3 between features A and C are very similar, but the position of shoulder B depends on the model. The best agreement between the experimental and theoretical spectra is achieved for model 1 with the mannose oxygen in the second axial position. Therefore this model is the most realistic among the seven models considered. The key parameters that distinguish this model from models 2 and 3 are angular distortions of the six ligands nearest to Fe. For example primary amine of Ala-Fe-Imid angle is 67° for model 1 and 98° and 105° for models 2 and 3 respectively. Also, angles between the second axial ligand and ligands in the equatorial plain significantly different.

Subsequent simulations were performed to address the structural origin of geometry reconstruction found upon perturbation of one of the axial ligands. Active sites of Blm and Pep are expected to be very similar, because the bithiazole tail, which solely distinguishes Blm from Pep, does not participate in Fe ligation. This also correlates with the results of an EXAFS analysis [5]. In contrast, in the case of Iso-Pep, perturbation of one of the axial ligands, namely replacement of mannose carbamoyl with the 2-hydroxy group, modifies the ligand arrangement. It was shown using EXAFS and pre-edge data analysis [5], that this complex remains six-coordinate, therefore the oxygen from a solvent water molecule was proposed as a second axial ligand. This type of coordination corresponds to model 3 above. Nevertheless differences between the experimental spectra of Pep and Iso-Pep are not so severe as the differences between theoretical spectra from models 1 and 3. Experimentally, there is only an overall shift of the experimental spectra and a small increase of main peak intensity, while theoretical spectra are distinguished from each other mostly by the energy of peak B.

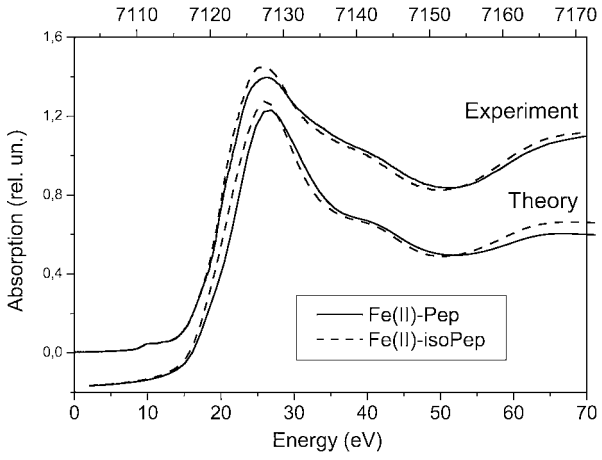

Fig. 2. Experimental and theoretical Fe K-edge XANES of peplomycin and iso-peplomycin. Calculations for model A of iso-peplomycin are presented.

Table I. *Fe-ligand bond lengths (in Å) for Fe(II)-Pep, Blm and two models of Iso-Pep.*

Ligand	Fe(II)-Pep (Blm)	Iso-Fe(II)-Pep Model A	Iso-Fe(II)-Pep Model B
Pyrimidine	2.02	1.99	2.05
Imidazole	2.06	2.07	2.09
Amide (hydroxyhistedine)	1.89	2.07	1.97
Secondary amine (aminoalanine)	2.13	2.14	2.15
Axial N (mannose)	2.03	2.05	2.06
Axial N (aminoalanine)	2.05	2.07	2.09
Average 1 shell distance	2.03	2.06	2.07

Thus, we conclude that axial ligand perturbation does not produce angular distortions of the octahedron of ligands nearest to Fe. Therefore a further refinement of the geometry was performed by optimizing the Fe-ligand bond lengths while all ligand-Fe-ligand angles remained fixed.

The results of these simulations are presented in fig. 2. Fe-ligand bond lengths are summarized in tab. I. The model of Fe(II)-Pep corresponds to model 1 reported in [1], but all Fe-ligand distances were expanded to 0.03 Å. Theoretical spectra of Iso-Pep, calculated for the models with the nearest equatorial nitrogen from Imid and amide of His are very similar (Models A and B in Table I). It is impossible to choose the best fit from these two models on the basis of XANES analysis alone. Nevertheless, the nearest ligand was assigned as Imid on the basis of results from optical spectroscopy [2]. Therefore model A of Iso-Pep is the most realistic.

Acknowledgment

We thank Prof. T. Lehmann (Instituto Venezolano de Investigaciones Cientificas (IVIC), Venezuela) for sharing with us her structural data on Fe(II)-Blm and for useful discussions.

Abstract

Metalloporphyrins (MP) are important for a wide variety of biological processes and photosynthesis and have been intensively investigated by X-ray absorption spectroscopy. The typical metal K-edge XANES spectra of the square-planar MTPP show a very sharp peak on the rising edge of the main absorption peak, which was assigned to $1s \rightarrow 4p_z$ electronic transition. We carried out a series of multiple-scattering calculations of porphyrin molecules and found that this peak can be greatly enhanced due to the π-π stacking of phenyl rings below and above the porphyrin plane. Density of state calculations confirmed that the emergence of this electronic state is due to the interaction of the $4p_z$ orbital of the metal with π orbitals of an aromatic solvent molecule with its plane parallel with the macrocycle. This XANES feature of metalloporphyrins can be used to investigate the solvent-solute interactions with presumed non-ligating solvent.

Metalloporphyrins (MP) are analogs of heme and chlorophylls that play critical roles in photosynthesis because of their intense absorption in the visible and UV regions which allows them to perform light harvesting as well as light energy conversion. Meanwhile, MP are also capable of ligating with a variety of small molecules as axial ligands, such as oxygen, which are vital in oxygen transportation of red blood cells [1, 2]. The basic unit of MP consists of a porphyrin macrocycle in an essentially planar structure, but a variety of nonplanar conformations could be induced by the metal ions in the center as well as by the peripheral substituted groups. Such a flexibility in the structure is believed to be important for its various applications, e.g., as nanoscale molecular devices [3] or selective oxidative catalysts [4]. Therefore, it is important to use XAFS technique to investigate MP structures in solvated or ligated states, the conformations of the macrocycles in catalytic reactions. X-ray absorption near-edge structure (XANES) can probe the local structures and electronic properties, regardless of the sample crystallinity. The recent development of computational methods, such as FEFF using multiple-scattering (MS) theory allows us to investigate the XANES features of MP as well as their correlation with the density of states in more quantitative ways [5–7]. Therefore, the solvent solute interactions that may affect electronic states can be analyzed.

Room temperature XANES spectra of zinc tetraphenyl-porphyrin (ZnTPP) and its copper analog, CuTPP in tolune and pyridine solutions were measured at a wiggler beamline (11ID-D) of Basic Energy Science Synchrotron Research Center, Advanced Photon Source at Argonne National Laboratory, with a Si-220 double crystal in the monochromator. All the spectra were collected in fluorescence mode using a nine element solid state detector (Canberra).

ZnTPP and CuTPP remain unligated in toluene (the inset of Fig. 1), the XANES spectra of both exhibit a sharp peak at the rising edge of absorption (peak A), as shown in Fig. 1,

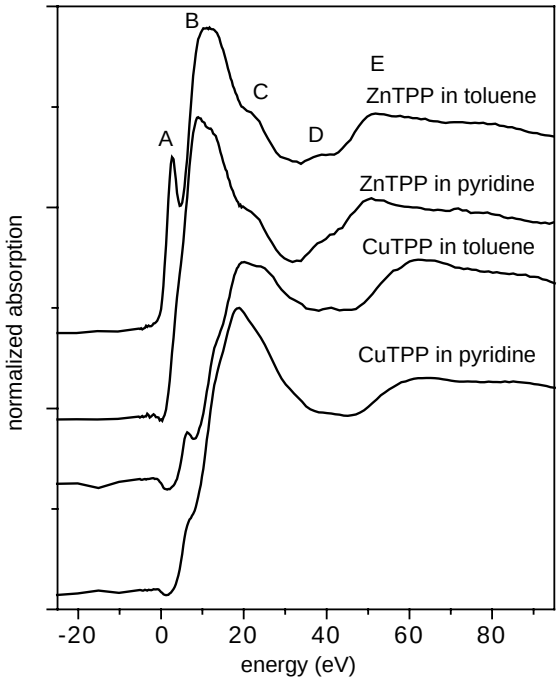

Fig. 1. XANES spectra of ZnTPP and CuTPP solutions in toluene and in pyridine.

which is assigned to the 1s to $4p_z$ transition of transition metals [8]. However, in ligating solvents, pyridine or piperidine, this peak is attenuated significantly due to the axial ligation of solvent molecules with the metal, forming a penta-coordinated square-pyramidal or a hexa-coordinated octahedral geometry. Consequently, the $4p_z$ orbital of the transition metal is less empty and delocalized due to the ligation [9].

A series of XANES and l-density of state ($l = \mathrm{s, p, d, \ldots}$, -DOS) calculations were carried out using FEFF8 programs (version 8.10) [5], a real-space full multiple-scattering approach using a self-consistent potential. The whole molecule around the central Zn atom was included to construct the self-consistent field (SCF) potential. XANES spectra were calculated using the Hedin-Lundqvist self-energy with an energy dispersion of -0.1 eV to account for the core hole lifetime and the instrumental broadening effects. Full multiple scattering (FMS) calculations were used for all calculations. The muffin-tin radii were overlapped up to 1.3 to reduce the effects of discontinuities between adjacent regions. The Debye-Waller factors were set to zero because of their negligible influence on the XANES spectra.

Figure 2 shows MS calculations for a single molecule of ZnTPP with increasing number of neighboring atoms around Zn defined by the MS radii used in the calculation. Each cluster

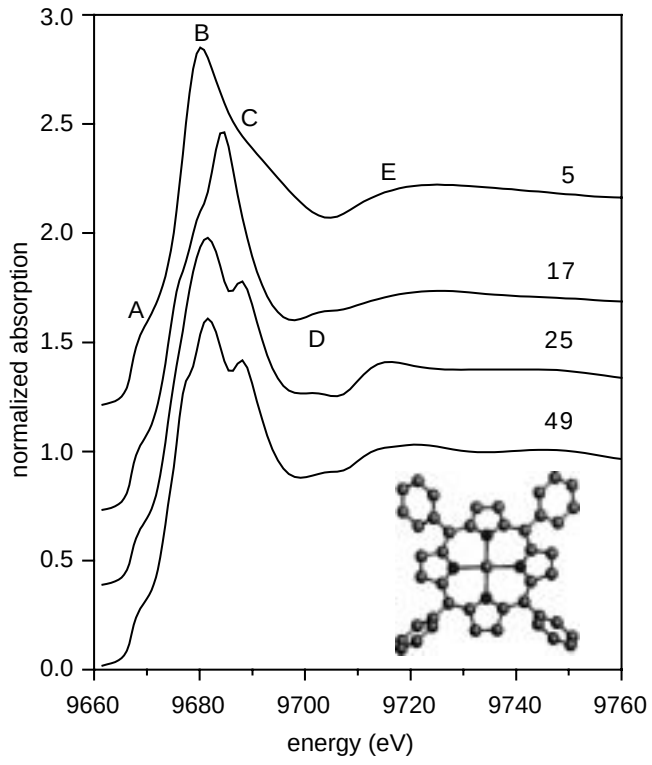

Fig. 2. MS calculations for clusters built by gradually increasing the size of the molecular around the central Zn atom; 5: ZnN_4; 17: ZnN_4C_{12}; 25: ZnN_4C_{20}; 49: ZnN_4C_{44}, the inset shows ZnTPP molecule.

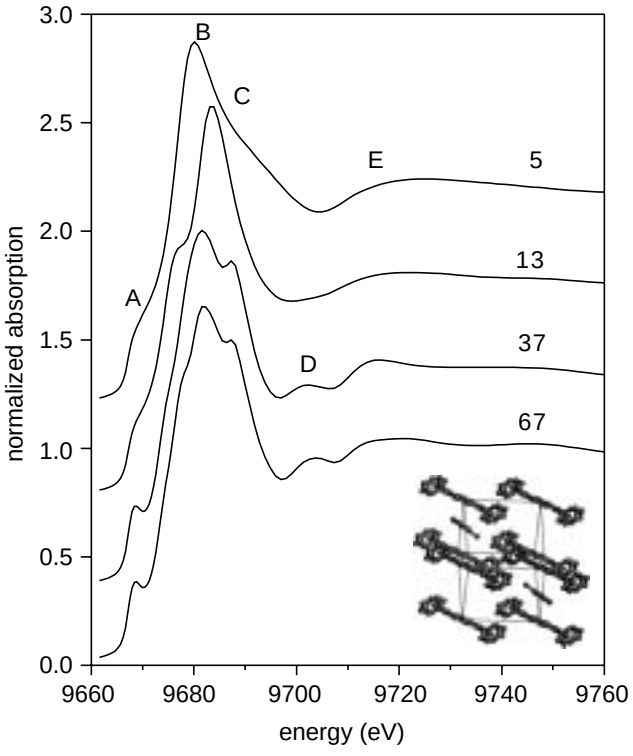

Fig. 3. MS calculations for clusters built by gradually increasing the cluster size around the central Zn atom; 5: ZnN_4; 17: ZnN_4C_{12}; 37: ZnN_4C_{22}; 67: ZnN_4C_{42}, the inset shows the triclinic crystal ZnTPP of toluene solvate.

was constructed from the ZnTPP crystal structure with solvated toluene molecules [9]. Zn-N_4 cluster displays main features A, B and E. While the calculations extend to more neighboring atoms, peak B splits into B and C, and peak D emerged. Apparently distant neighbors are responsible for the evolution of the spectra. Compared with the experimental results, the main features of B, C, D and E are produced. However, the separation of B and C is not distinct and peak A is less distinct than observed experimentally for the ZnTPP in toluene solution. One possibility of this distinction is due to the insufficient accuracy of the self-consistent field potentials [5].

In a parallel calculation that included the solvated toluene molecule (Fig. 3), the toluene molecules above and below the ZnTPP plane were included for clusters larger than 13 atoms. The two phenyl rings above and below the ZnTPP plane form a close packed cluster so that the π-π interactions of ZnTPP with the two phenyl-rings result in an enhancement of peak A.

To further demonstrate this, clusters were built by stacking two phenyl-rings above and below the ZnTPP plane and changing the spacing of the rings to the ZnTPP plane. As is clearly shown in Fig. 4, peak A develops and becomes more pronounced as the distance to the ZnTPP is reduced, meanwhile, peak B is shifted to higher energy. Figure 5 shows that the p-DOS spectra of the excited state has a new electronic state developing right above the Fermi level as the phenyl-rings approach to ZnTPP.

For comparison, MS calculations on ZnTPP·$(H_2O)_2$, crystals (tetragonal, I4/m) [10] and ZnTPC(Py) crystals (triclinc P-1, benzene solvate) [11] were also performed, but no enhancement of peak A was observed in the XANES spectra as expected [8]. In both cases, Zn forms σ-bond instead of nonbonding π-π interaction with the solvent molecules. Zn forms chemical bonds with two oxygens as axial ligands in the former case and one nitrogen in the latter. Such a σ-bonding is much stronger due to

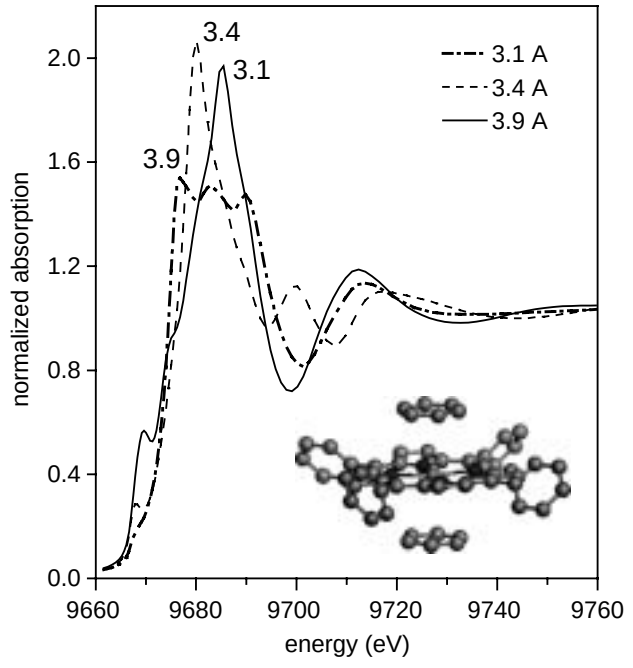

Fig. 4. XANES calculations of clusters built by placing two benzene above and below the ZnTPP plane (inset) and changing the spacing of benzene relative to the ZnTPP plane.

strong overlap between the Zn orbital in the z-direction with the solvent lone pair electrons, and is fundamentally different from the much weaker nonbonding π-π interaction where only slight electron density transfer between two parallel aromatic rings is expected.

The enhancement of the new excited electronic states is closely related to the multi-scattering paths due to atoms in

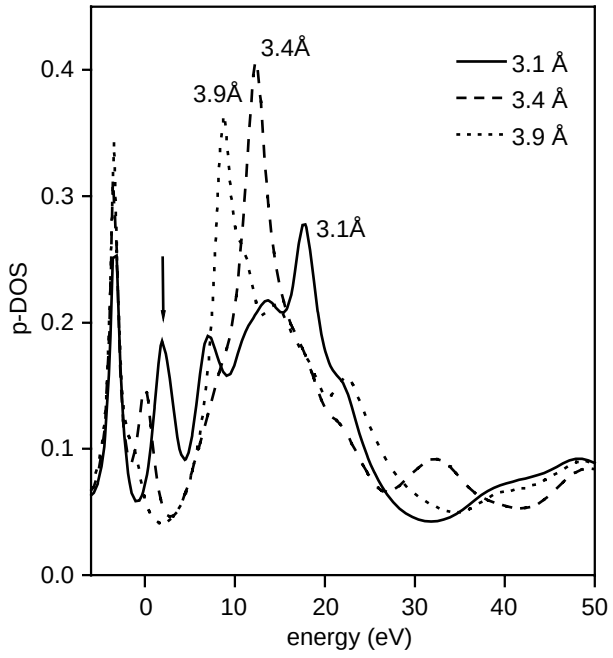

Fig. 5. p-DOS calculations of clusters built by placing two benzene above and below the ZnTPP plane (inset) and changing the spacing of benzene relative to the ZnTPP plane.

a solvent molecule simultaneously brought in the vicinity of the macrocycle, producing resonance from the interference between several scattering paths. Stacking of two phenyl rings above and below the porphyrin plane can form a close packed molecular cage. As reported previously [12], the main multiple scattering resonances in the XANES of $Fe(CN)_6$ complexes are associated with shape resonances within CN ligands. An excited photoelectron of low kinetic energy (10–30 eV) emitted by the central Fe atom can be "trapped" in virtual bound states built up of repeated scatterings from the C and N atoms of a CN group. This can produce a resonance and enhance the back-scattering amplitude of the ligand shell as a whole at these energies. This is reflected in the absorption cross section in a way which depends on the geometrical arrangement of the CN groups around the Fe atom. The same statement holds for our case. The confinement of the molecular multiple-scattering cage formed by rigid small molecules, can produce very intensive "shape resonances". In view of the molecular orbital theory, this enhanced electronic state in the MTPP can be associated with the π-π interactions exerted by p_z orbitals of the metal and the carbon atoms of the phenyl rings.

In conclusion a series of multiple-scattering calculations for XANES spectra from ZnTPP demonstrate that a peak at the rising edge of main absorption is greatly enhanced by the stacking of phenyl rings below and above the ZnTPP plane. This enhancement is associated with the shape resonant effect of the molecular cage. DOS calculations indicate that it arises likely from π-π interactions exerted by p_z orbitals of the metal and the carbon atoms of the phenyl rings. These XANES features of ZnTPP or CuTPP can be used to identify the solvation states in non-ligating solution.

Abstract

The Biophysics Collaborative Access Team (BioCAT) undulator beam line at the Advanced Photon Source, Argonne, IL is a user facility devoted to the study of partially ordered and disordered biological materials by X-ray scattering, diffraction and absorption spectroscopy. Two sagital focussing, double-crystal (Si(111) and Si(400)) monochromators and a 1 m mirror provide monochromatic, horizontally and vertically focussed X-ray beams in the range of 4–35 keV. The small focal spots produced by this optics are well matched to novel XAFS detectors developed by BioCAT: a multilayer analyzer array and Bent Laue crystal based analyzers. Fast on-the-fly scans (∼5 s/scan) have been implemented to take full advantage of the high X-ray flux at the Advanced Photon Source. Such fast scans not only allow high throughput but also reduces radiation damage to labile biological samples. A closed–cycle displex cryostat is routinely used for low temperature XAS measurements. For continuous flow and time resolved XAS experiments, a dual syringe stopped-flow system has been implemented.

1. Introduction

The Biophysics Collaborative Access Team (BioCAT) undulator beam line, 18ID, at the Advanced Photon Source, Argonne, IL, is a high performance instrument designed for and dedicated to the study of partially ordered and disordered biological materials. X-ray Absorption Spectroscopy experiments include studies of dilute metalloprotein solutions (with a special emphasis on small volumes and time resolved XAS studies), oriented films, and oriented single crystals. High flux delivered into a small spot size is required for many practical time-resolved XAFS experiments and high throughput modes that employ flow systems. To this end, the beam line was designed to deliver doubly focused undulator beam, scannable over a wide energy range while maintaining a fixed position on the sample. The beamline has been operating since 1997 as an open facility to all researchers on the basis of peer reviewed research proposals. Here we describe the beamline optics, EXAFS specific instrumentation and performance. Representative experimental results of low temperature, room temperature flow experiments and time-resolved experiments are presented.

2. Beamline Optics

APS undulator "A" [1] provides a source of very intense monochromatic radiation in the 3.2–14 keV range (first harmonic) and 9.6–42 keV (third harmonic). The undulator gap may be scanned at rates of ca. 1 mm/sec under beamline control, permitting very fast scans over a typical XAS range of ca. 1 keV in 10 seconds. The undulator gap can also be tapered to deliver a smooth energy range on the order of 1 keV but with a significant loss in peak intensity. A differential pump separates the beamline vacuum structure from the storage ring permitting windowless operation so that experiments near the calcium edge at 4 keV are practical. Two independent double-crystal monochromator assemblies [2] cover the energy range of BioCAT interest. The two monochromators have identical mechanisms, but monochromator #1 has Si (111) crystals to cover an energy range from 3.4 keV to 14.6 keV, while those in monochromator #2 have a (400) orientation for energies from 7.9 keV up to 33.8 keV. Both monochromators have a cryo-cooled first crystal [3] and sagittal focusing second crystal assemblies for horizontal focusing of the beam. Horizontal focal spot sizes with a FWHM of 120–150 μm are typical for the energy range of 4.0–10.0 keV. An ULE glass-ceramic mirror (Rocketdyne Corporation) is used for harmonic rejection and it can be either used flat or eliptically bent to allow vertical focusing independently of any horizontal focusing. The mirror surface is divided into three lanes: bare ULE, Pd coated, and Pt coated to cover the full energy range of the beamline. When focused at the center of the experimental table the beam profile has been observed to be as small as 40 μm (FWHM). Additional details of the beamline optics can be found elsewhere [4].

3. Control software

The beamline control software is based on the Experimental Physics and Industrial Control System (EPICS) which is a distributed system using VME-based electronics with crate controllers running the proprietary real-time UNIX-like operating system VxWorks (Wind River Systems). To take full advantage of the high X-ray flux at the Advanced Photon Source and to reduce radiation damage to labile biological samples, two types of fast on-the-fly scans have been implemented: a "generic" fast scan and "energy" fast scan. With the generic scan we can scan any servo or stepper motor at the beamline while recording the output into the Joerger VCS16 scaler, with 16 inputs. The scan may use one of three different algorithms but all of them have the same lower limit to the time resolution of ∼150 ms/point. As a result, the typical generic scan time is ∼15–60 seconds. These scanning protocols have been very useful in beamline diagnosis and alignment and have found use in various experimental protocols. The fast energy scan is implemented for both the beamline monochromators. This scan makes use of a Struck 7201 multichannel scaler, with 32 inputs and 4k memory arrays per each input, which simultaneously record the monochromator encoder outputs and

*e-mail: barrea@bio.aps.anl.gov

the X-ray intensities. The minimum time per point for this scan is ∼1 ms and the total scan time is typically 1–10 s. We have also included the synchronous motion of monochromator and the beamline undulator into the energy scans so that the energy of the two devices can be changed simultaneously. Finally, all the energy and generic scans provide for two or three dimensional scans with stepwise motion of the second and the third motors respectively retaining continuous scanning in the first dimension.

For positional feedback, we have implemented an in-vacuum beam position monitor (BPM) developed by SBC-CAT [5]. This BPM is linear over a range of a few millimeters with a resolution of less than 2 μm. Using this BPM and a feed-forward approach to adjust the beam angle, we have been able to maintain constant exit height to ±25 μm over an XAS scan. In addition, a variable offset in the equations of motion of the monochromator conditions has been used to minimize energy-dependent beam position changes.

To maintain peak X-ray beam intensity during energy scans we have installed an analog feedback system consisting of: 1) a piezo-electric actuator, mounted to adjust the tilt angle of the second crystal relative to the first crystal 2) a lock-in amplifier (Stanford Research Systems model SR830 DSP), and 3) a custom-designed analog electronic feedback control unit. A small amplitude sine wave of frequency, f, is fed to the piezo actuator to impose a periodic variation on the beam intensity. When the two crystals are misaligned, the lock-in amplifier detects this intensity signal with signal strength proportional to the slope of the rocking curve. With the proper choice of phase angle, the sign of this correction signal will indicate the direction to drive the piezo in order to recover peak intensity. The correction signal is fed into an integrator, the output of which is summed with the dither sine wave and a manually adjustable offset, and then transmitted to the piezo amplifier. Amplitude of about 20% of the FWHM of the rocking curve is sufficient to drive the second crystal to the peak. The feedback system is capable maintaining a lock on the peak intensity for energy changes at a rate of 200 eV/s, allowing monochromator scans of 1000 eV in 5 seconds without losing intensity.

4. Experimental Equipment

Transmission ionization chambers modified from the CHESS design (Advanced Design Consultants, Lansing NY) are available for incident flux and transmission measurement. There are 4 current amplifiers (Keithley model 428), which are interfaced through the RS232 ports on the beamline workstations. For fluorescence detection there are fluorescence ionization chambers and large area plastic scintillator/photomultiplier tubes that can operate in either pulse counting or integrating modes in conjunction with a two dimensionally focused Soller slit assembly designed for the point-focused beam. Highly dilute systems require the capabilities of the multilayer analyzer [6, 7] and a bent Laue crystal based analyzer [8] for experiments at the Cd K edge, Mo K edge and Zn K edge.

XAS measurements on biological samples are conventionally performed at low temperature to reduce the radiation damage caused by the production of free radicals, and also to reduce the damping effect of temperature in the EXAFS oscillations. A low vibration, closed–cycle displex cryostat permits such experiments at temperatures down to 10 K. A Lakeshore Model 330 controller allows regulation of the Displex temperature under EPICS control.

In some cases it is desirable to measure the samples in solution at room temperature to characterize the dynamic changes in structure that bridge the static endpoints provided by crystallography and to avoid the artifacts that can be introduced by freezing. Furthermore, flow systems can reduce the duty cycle for a given measurement providing faster throughput of samples that will permit more elaborate types of experiments to be designed and executed than is possible with conventional approaches. For continuous and stopped-flow XAS experiments, a dual syringe stopped-flow system [9] has been implemented at BioCAT. The stop flow chamber can be cooled to temperatures as low as 233 K to lengthen the lifetime of a reaction. A portable UV-Vis spectrometer (Ocean Optics model 2000) is integrated into the stopped flow device through optical fiber and lenses allowing optical spectra to be collected simultaneously with an XAS measurement.

5. Results and discussion

The combination of the doubly focused beam and the efficient detectors available at BioCAT allow the study of dilute samples (ca. 1 mM). A typical scan time is 20–60 seconds with ca. 50 scans typically required to obtain good statistics, thus, a total time of 20–60 minutes suffices to complete an XAFS spectrum for each sample with either frozen samples or using the continuous flow system. Low temperature XAS experiments use the Displex

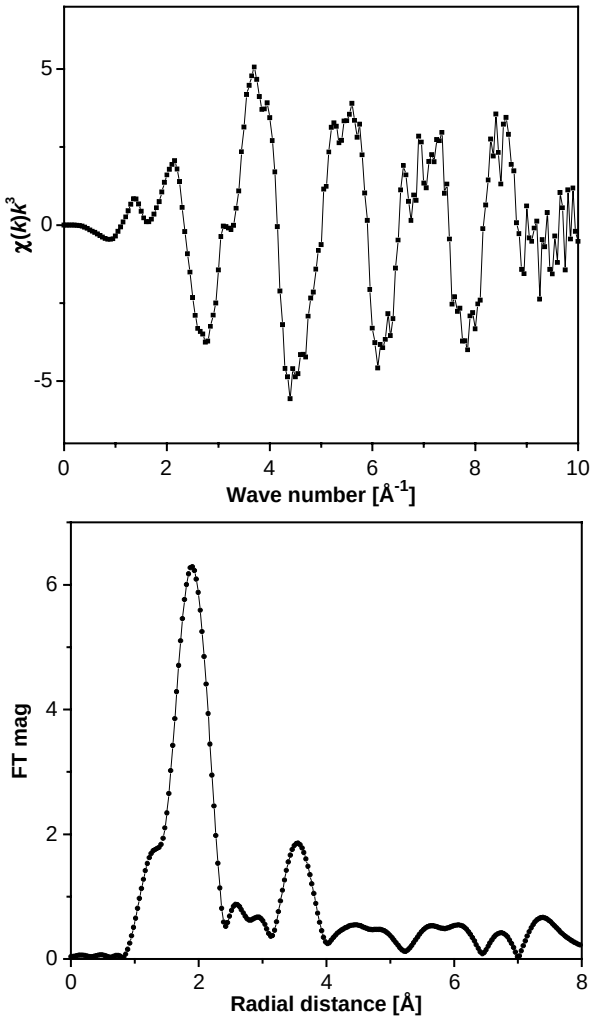

Fig. 1. EXAFS signal of a ∼1 mM Ca sample measured at 30 K with the multilayer analyzer (courtesy of Prof. C. Carmeli- Tel Aviv University).

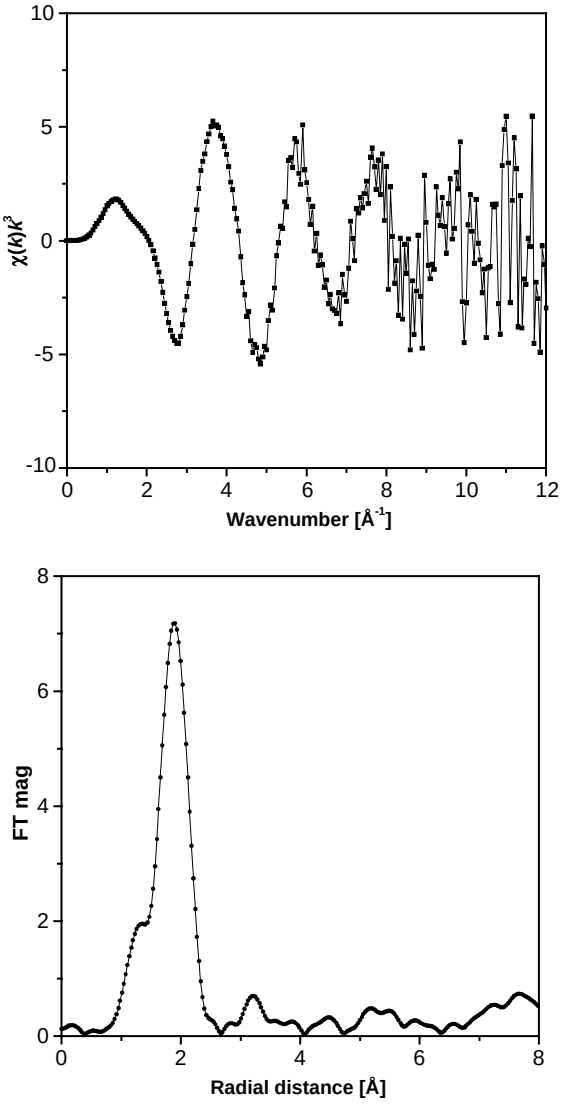

Fig. 2. EXAFS signal of a ∼1 mM Npl4 Zinc Finger protein measured at 40 K with the Zn Bent Laue analyzer (courtesy of Prof. T. Stemmler – Wayne State University).

cryostat and an aluminum sample holder, which can contain up to 5 sample cells. The multilayer analyzer or bent Laue analyzer, as appropriate, is mounted on one side of the cryostat exit windows, while the other window is used for sample exchange. The cryostat itself is mounted on an x-y stage that allows the user to raster scan the sample in two dimensions during the experiment. Depending on the particular case, each sample spot is exposed to the beam from 20 s to 120 s maximum and then a new spot is selected for subsequent scans. More than 200 spots may be measured in a single cell in our standard sample holders. This feature has been demonstrated to be very useful when working with samples that are sensitive to radiation damage. Figures 1 and 2 show EXAFS signal of a ∼1 mM Ca sample measured at 30 K measured with the multilayer analyzer (courtesy Prof. C. Carmeli-Tel Aviv University), and Zn protein samples at low temperature (35 K) measured with the Laue analyzer (courtesy Prof. T. Stemmler – Wayne State University).

The stop-flow system has also proved to be a versatile instrument for both time-resolved XANES studies [10] and continuous flow experiments. The Multilayer analyzer is currently being upgraded from 2 to 18 detection channels to increase maximum count rate. The Laue analyzer detector is also being upgraded to increase solid angle acceptance. Enhancements continue to improve overall beamline performance.

Abstract

Acute promyelocytic leukemias relapses are treated by solubilised arsenic trioxide. The elimination rate of arsenic during the treatment is crucial. One way of elimination is by incorporating arsenic metabolites in hair. Micro-XANES experiments were performed at the ESRF ID-22 beamline on transversal hair cuts from two patients. A special code (LASE) was developed in order to refine the analysis of such data and led us to conclude that arsenic oxidation degree was +III. Micro-XANES experiments were coupled with X-Ray fluorescence elemental maps of hair sections. Given the dilution of the samples, maps were collected on thick slices. Hence width effects became sensible and caused distortions of the final image. In order to refine the location of arsenic in hair, we developed models to handle these width effects. These models allowed us to conclude that arsenic was distributed at the periphery of hair. Statistical tests were developed to evaluate the relevance of the models.

Résumé

Les rechutes de leucémies promyélocytaires aiguës sont traitées avec du trioxyde d'arsenic solubilisé. Connaître la vitesse d'élimination de l'arsenic au cours du traitement est important. L'étude des cheveux, l'une des voies d'élimination des métabolites de l'arsenic, permet d'apporter des éléments de réponse à cette question.

Pour réaliser cette étude, nous avons effectué, sur la ligne ID22 de l'E. S. R. F., des expériences de micro-XANES sur des coupes transversales de cheveux provenant de deux patients. Nous avons développé dans notre logiciel d'analyse LASE des procédures automatiques qui permettent d'affiner nos analyses. Cela nous a permis de conclure à un degré d'oxydation +III pour l'arsenic inclus dans les cheveux. Ces études par micro-XANES ont été couplées à des cartographies élémentaires par fluorescence X des coupes de cheveux. Ces cartes ont dû être faites à partir de coupes épaisses, pour lesquelles les effets d'épaisseur introduisent des distortions dans l'image finale. Pour mieux interpréter ces cartes, nous avons développé des modèles qui prennent en compte ces effets. Ils sont inclus dans le logiciel LASE et permettent de conclure à une distribution homogène de l'arsenic en périphérie du cheveu. Enfin, nous avons développé des outils statistiques pour quantifier la qualité des modèles obtenus.

1. Introduction

En s'inspirant de remèdes traditionnels chinois, diverses équipes ont pu montrer que le trioxyde d'arsenic, As_2O_3, est efficace dans le traitement de la leucémie promyélocytaire [1–4]. La Pharmacie centrale des hôpitaux de Paris (PCH) a donc mis au point un traitement à partir de ce composé, solubilisé en milieu basique. Cependant, compte-tenu de la toxicité de l'arsenic, il est important de bien connaître le devenir de cet arsenic injecté dans l'organisme. Deux questions se posent alors : quelles transformations chimiques subit l'arsenic et par quelle voie peut-il être éliminé, d'une part ; d'autre part, à quelle vitesse cette élimination est-elle effectuée.

Parmi les diverses voies d'élimination des éléments exogènes qui peuvent être étudiées, les cheveux présentent l'avantage d'être facilement prélevables, sans gêne notable pour le patient (contrairement au sang, par exemple) et, du fait de leur pousse, permettent d'accéder en un seul prélèvement au suivi temporel des concentrations en ces éléments exogènes (contrairement aux urines, par exemple).

Le but de l'expérience est de suivre la concentration (relative) en arsenic et son évolution chimique L'intensité des raies de fluorescence X permet d'accéder à la composition élémentaire des éléments traces tandis que des informations sur l'environnement chimique d'un atome absorbeur donné peuvent être obtenues par une analyse des spectres XANES enregistrés en mesurant le rendement total de fluorescence X en fonction de l'énergie d'excitation. De plus, la brillance des sources de rayonnement synchrotron actuelles permet de travailler sur des échantillons très dilués, ce qui permet ainsi de travailler sur un seul cheveu, voire sur une coupe d'un seul cheveu. On peut donc ainsi remonter à l'information temporelle, en suivant l'évolution du spectre de fluorescence le long d'un cheveu, compte-tenu de la vitesse de pousse du cheveu.

2. Localisation de l'arsenic dans les cheveux

Des études préliminaires, effectuées sur la ligne D15 du L. U. R. E., ont permis de vérifier que l'on pouvait détecter, sur un seul point d'un seul cheveu, la présence d'arsenic provenant du traitement (les cheveux des témoins présentant un signal pour l'arsenic négligeable par rapport au signal mesuré pour les cheveux des patients ayant commencé le traitement [5, 6]). Nous avons pu procéder à une analyse plus fine des cheveux, en utilisant le faisceau intense de la ligne ID-22 de l'E. S. R. F. à Grenoble.

L'étude de la localisation longitudinale permet de suivre la quantité d'arsenic éliminé par le cheveux au cours du temps. Nous avons donc, pour les cheveux de deux patients, suivi cette concentration le long d'un cheveu avec un pas de 0,5 mm au L. U. R. E. et 35 µm à l'E. S. R. F. ; chaque point a été répété trois fois. Les spectres obtenus ont été traités avec le logiciel WAPI [7]. Lorsque l'on suit la concentration en arsenic le long de ces cheveux avec un pas aussi faible, on note une variation rapide de la concentration en arsenic. Cette variation est à relier au dossier clinique du patient : on retrouve, par exemple, le nombre de prises du patient (fig. 1).

Ces résultats suggèrent que l'arsenic est rapidement capté par le cheveu, puisque l'on retrouve dans le cheveu les variations dues à l'injection discontinue du médicament. Ils suggèrent aussi qu'il n'existe pas d'organe de stockage transitoire de l'arsenic, qui capterait l'arsenic circulant dans le sang pour ensuite le relarguer, pour la même raison ; en particulier, les transitions sont rapides y compris lorsque l'on quitte les plateaux, alors qu'un éventuel relargage s'accompagnerait d'une décroissance plus lente. Au vu de ces résultats, on peut se poser la question de la forme de l'arsenic captée par le cheveu : s'agit-il d'une forme métabolisée, de la forme médicamenteuse ou d'un mélange des deux ?

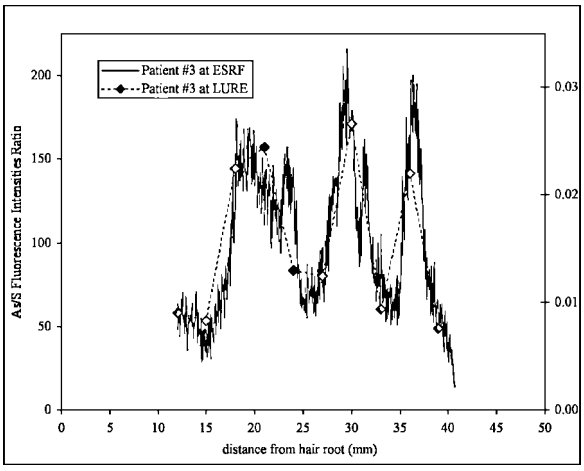

Fig. 1. «Évolution longitudinale du signal de fluorescence de l'arsenic le long d'un cheveu de malade, suivie au L. U. R. E. et à l'E. S. R. F.»

Pour savoir dans quelle partie du cheveu (de la périphérie vers le centre : cuticule, cortex, medulla – cette dernière parfois absente des cheveux humains) se trouvait l'arsenic, nous avons effectué des coupes fines de cheveu (épaisseur : 10 µm) à l'aide d'un cryomicrotome. Ces coupes ont été déposées sur un film en mylar, puis cartographiées sur la ligne ID-22 de l'E. S. R. F. Si les coupes des cheveux de patients avant le traitement, comme celles des témoins, ne présentent pas d'arsenic, comme l'on peut s'y attendre, les coupes effectuées au cours du traitement présentent, au contraire, une répartition très nette de l'arsenic dans le cheveu (fig. 2). Ces cartes suggèrent une répartition de l'arsenic plutôt en périphérie du cheveu ; cependant, elles présentent une nette asymétrie verticale. Compte-tenu de l'épaisseur, cette asymétrie peut très certainement provenir de la déformation de la carte, du fait de la géométrie de l'expérience, et n'est alors pas significative.

Pour valider cette hypothèse, nous avons construit dans notre logiciel d'analyse LASE (Logiciel d'analyse des spectres expérimentaux [8]) un modèle simple de l'expérience : nous avons dans un premier temps assimilé le cheveu à un cylindre, de symétrie radiale, l'arsenic étant disposé en périphérie. La concentration en arsenic en fonction de la localisation dans le cheveu est donc une fonction $f(x, y, z)$.

En pratique, le faisceau arrive avec un angle θ (45° idéalement) sur la coupe. Si l'on choisit le repère de sorte que la face d'entrée définisse les axes Ox et Oy, la normale à cette face (dans la direction de propagation du faisceau) l'axe Oz, alors les points de l'échantillon irradiés par le faisceau, supposé ponctuel et entrant en $(x_0, y_0, 0)$, sont sur la droite d'équation $(x, y, z) = (x_0, y_0, 0) +$

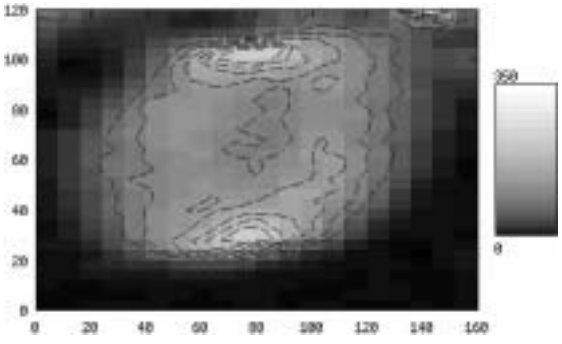

Fig. 2. «Répartition de l'arsenic dans une coupe transversale de cheveu, obtenue par micro-fluorescence X»

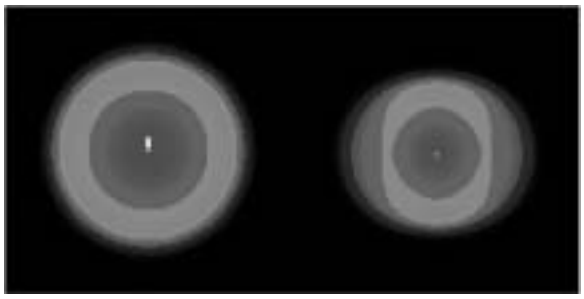

Fig. 3. «Modélisation des distorsions induites par l'épaisseur de la coupe de cheveu. À gauche, modèle de répartition idéale, symétrique, pour une coupe infiniment fine; à droite, distorsion de cette répartition lors de l'observation d'une coupe épaisse (10 µm).

$t\ (\cos\theta, 0, \sin\theta)$, avec t variant entre 0 (entrée du faisceau dans l'échantillon) et e, épaisseur de la coupe. Si l'on néglige la réabsorption par l'échantillon, le signal vu par le détecteur pour le point (x_0,y_0) de la carte finale est alors proportionnel à

$$F(x_0, y_0) = \int_0^e f(x_0 + t\cos\ \theta, y_0, t\sin\ \theta)\,\mathrm{d}t.$$

À partir de cette expression et du modèle de symétrie radiale avec localisation périphérique de l'arsenic, nous avons pu comparer la carte idéale (coupe infiniment fine, $F(x, y) = f(x, y, 0)$) et la carte attendue pour une coupe épaisse. Comme l'indique la fig. 3, on retrouve la déformation observée sur les coupes expérimentales. L'utilisation de ce modèle permet donc de valider l'hypothèse d'une localisation uniforme de l'arsenic en périphérie du cheveu[2]. Cette uniformité et la localisation spécifique sont en accord avec l'élimination de l'arsenic principalement sous une seule forme et mettant en jeu un seul mécanisme ; la localisation périphérique suggère que ce n'est pas directement dans le bulbe capillaire, mais plus loin, dans la zone de kératinisation ou de durcissement au niveau de la glande sébacée, qu'aurait lieu la capture de l'arsenic par le cheveu.

3. Nature chimique de l'arsenic inclus dans le cheveu

L'arsenic au degré d'oxydation +III peut être métabolisé dans l'organisme, ce qui s'accompagne d'une oxydation au degré +V. Les métabolites principaux du trioxyde d'arsenic sont l'acide arsénique et l'acide cacodylique (acide diméthylarsonique). Suivant l'étape à laquelle se fait la capture de l'arsenic par le cheveu, on peut s'attendre à trouver l'un ou l'autre de ces degrés d'oxydation dans le cheveu. Pour préciser ce degré d'oxydation, nous avons réalisé des expériences de micro-XANES au seuil K de l'arsenic, sur une coupe de cheveu contenant de l'arsenic, toujours sur la ligne ID-22 de l'E. S. R. F. Compte-tenu du résultat précédent, suggérant la présence d'une espèce majoritaire d'arsenic, nous avons travaillé sur l'ensemble de la coupe, de façon à avoir un signal suffisamment intense pour être utilisable.

Parallèllement, les spectres d'absorption au seuil K de l'arsenic ont été enregistrés, dans les mêmes conditions opératoires, pour plusieurs composés de référence : orpiment (As_2S_2 ; As^{III}), réalgar (As_2S_3 ; As^{III}), trioxyde d'arsenic (As_2O_3 ; As^{III}), arsénite de sodium ($NaAsO$; As^{III}), arséniate de sodium (NaH_2AsO_4 ; As^{V}),

[2] Quoiqu'il soit en théorie possible d'inverser l'expression pour retrouver la carte idéale à partir de la carte expérimentale, les essais que nous avons effectués montrent une très grande sensibilité au bruit qui rend difficilement exploitable la carte ainsi obtenue.

cacodylate de sodium ($NaAsO_2(CH_3)_2$; As^V), qui présentent les deux degrés d'oxydation attendus de l'arsenic dans l'organisme.

La comparaison des énergies de seuil mesurées sur ces références et sur le cheveu montre très nettement que l'arsenic dans le cheveu se trouve au degré d'oxydation +III. Rappelons par ailleurs que le spectre d'absorption au seuil K de l'arsenic de la solution injectable de médicament montre la présence d'arsenic III en solution [5].

L'analyse de ces spectres a nécessité le développement d'outils pour automatiser l'analyse. En effet, du fait de la dilution importante, il est nécessaire de répéter plusieurs fois la mesure. Cependant, pour réaliser la moyenne de ces spectres, il faut pouvoir contrôler leur superposition optimale. Nous avons donc développé d'une part un test permettant de savoir si la superposition était optimale, d'autre part des outils permettant de commencer le traitement de façon à obtenir cette optimalité. Une fois la moyenne réalisable, nous avons utilisé le modèle de propagation des erreurs que nous avons développé [9] au préalable pour réaliser le traitement. Le principe et les propriétés de ce test seront présentés dans un article dédié ; signalons juste que le critère de décision revient à une loi du khi-deux à $n - 1$ degrés de liberté. Si ce critère n'est pas satisfait, il n'est pas possible de faire les moyennes sans comprendre au préalable l'origine de la différence, pour y remédier ou pour inclure cette différence dans les incertitudes d'origine systématique.

Le plus souvent, le test précédent n'est pas satisfait à cause de décalages entre les spectres. En transmission, il suffit de corriger lors de l'élimination du fond continu pour obtenir des spectres superposables ; en fluorescence, la hauteur de seuil varie et une normalisation permet de s'affranchir de la difficulté. Il est cependant délicat de choisir manuellement les conditions de ces « corrections » pour obtenir un ensemble de spectres moyennables. C'est pourquoi nous avons intégré dans LASE les options permettant de réaliser cela : un spectre servant de référence, il est possible d'ôter le fond continu de, ou de normaliser, tous les autres spectres de la série de mesure en minimisant la distance (au sens des moindres carrés) entre la référence traitée et le résultat.

4. Conclusion & perspectives

Notre étude suggère que, lors de l'injection du traitement à base de trioxyde d'arsenic, l'arsenic est capté par le cheveu avant d'être métabolisé, puisqu'il reste au degré d'oxydation +III comme dans sa forme originelle. Cette captation se ferait rapidement, sans relargage puisque l'on retrouve le long du cheveu la structure temporelle des apports en arsenic. Elle se ferait sans doute après le bulbe folliculaire puisque l'on retrouve l'arsenic uniquement en périphérie du cheveu.

Pour mener à bien cette analyse, nous avons été amenés à développer divers outils d'analyse : modélisation des déformations induites par l'épaisseur sur la carte élémentaire obtenue par fluorescence des rayons X, test statistique pour contrôler l'homogénéité des spectres expérimentaux, automatisation des procédures de traitement des spectres pour palier au mieux l'inhomogénéité expérimentale révélée par les tests ci-dessus. Ces outils sont disponibles dans le logiciel d'analyse LASE qui peut être téléchargé librement [10].

Nous travaillons actuellement sur l'inclusion des effets d'épaisseur dans le modèle de cartographie, ainsi que sur la résolution du problème inverse (reconstruire l'image originale, en admettant une distribution homogène selon l'axe orthogonal à la coupe) malgré les problèmes de bruit. De plus, nous étudions l'amélioration du test de contrôle d'homogénéité, qui pour l'instant ne détecte pas certains types d'hétérogénéités.

Remerciements

Nous tenons à remercier Anne Héron, du Laboratoire de physiologie de la faculté de pharmacie de Paris V, qui a mis à notre disposition le cryomicrotome ; François Guyon, de la PCH, qui nous a fourni les échantillons de cheveux ; Virginie Lasserre, du laboratoire de biomathématiques, pour les discussions autour du test statistique développé.

Abstract

We measured natural circular dichroism (CD) for biomolecules in soft X-ray region for the first time. Natural linear dichroism (LD) for K(TiO)PO_4 (KTP) crystal was also measured at the K-edge energy of oxygen. Measurements of CD and LD spectra were performed at the soft X-ray undulator beamline BL23SU of SPring-8 in Japan. In this beamline, an APPLE-2 type variable undulator was installed as a light source. This undulator was operated under the phase modulation mode in which left and right circularly polarized light (LCPL and RCPL) was switched with about 0.1 Hz.

As a sample for CD measurement, we used sublimated film of L-, D- and DL-phenylalanine (Phe) and L- and D-serine (Ser) (thickness ∼300 nm) and measured CD (A_L−A_R) spectra in the nitrogen and the oxygen K-edge region, respectively. Here, A_L and A_R mean the abbreviation of absorption for LCPL and RCPL, respectively. For the Phe film, we observed a negative peak at about 407 eV for the L-Phe spectra. On the contrary, a positive peak for the D-Phe spectra and no spectral feature for the DL-Phe were observed. For the Ser film, we observed positive CD peaks at around 540 eV and 548 eV at the L-Ser spectra, on the contrary, negative peaks for the D-Ser. These results are the first CD spectra for biomolecules in the soft X-ray region.

We also used KTP crystal cut parallel to the plane (1,2,0) or (1,−2,0) as a sample of LD measurement and measured (A_L−A_R) spectra in the oxygen K-edge region and observed some peaks at about 530 eV. Since sign of these peaks were dependent on sample rotation angle in a plane perpendicular to the incident light, we concluded that these peaks are derived from linear anisotropy of crystal. Because of a weak linear polarization component of incident light, we could measure such LD spectra.

1. Introduction

Chirality is one of the characteristics of biomolecules such as amino acids and sugar; hence, they show natural circular dichroism (CD) which is a difference in the magnitude of absorption coefficient for left and right circularly polarized light (LCPL and RCPL). For a long time, CD in visible to ultraviolet region has been utilized to study structures of chiral molecules.

With the rapid advance of synchrotron radiation techniques such as undulators for circularly polarized radiation and a well-designed polarimeter and a retarder, natural circular dichroism measurements become possible in vacuum ultraviolet (VUV) to X-ray region. In the hard X-ray region, X-ray natural circular dichroism (XNCD) spectra of gyrotropic crystals have been measured by the group of J. Goulon [1–4] by a helical undulator, and by Y. Ueji [5] by a polarimeter and retarder made of diamond. Theoretical study of XNCD of gyrotropic crystal based on electric dipole (E1) – electric quadrupole (E2) interference have reported by Natoli [6]. In the 140 to 300 nm wavelength region, CD of gas phase [7] and aqueous solution [8] of organic molecules have been examined using a combination of synchrotron radiation and a photoelastic modulator. In the 180 ∼ 250 nm wavelength region, CD of amino acid film [9, 10] have been examined with modulation technique. In the VUV region higher than 9 eV, no result of CD measurement was reported to the best knowledge of the authors. In the soft X-ray region, pioneer work of CD measurement for metal complexes at Ti $L_{2,3}$ edges (around 460 eV) was reported by J. Goulon *et al*. [11]. However, no CD study has been reported for biomolecules in soft X-ray region as far as the authors know.

At the soft X-ray undulator beamline BL23SU [12–14] of SPring-8 in Japan, one can switch the LCPL and RCPL quickly (∼0.1 Hz) [15]. At this beamline, we have already measured X-ray absorption near edge structure (XANES) of amino acid sublimated films [16], as fundamental data of XNCD. In addition, a result of theoretical calculation of XNCD in the K-edge region of carbon, nitrogen and oxygen in amino acids were reported [17, 18], in which the electric dipole (E1) – magnetic dipole (M1) interference was suggested as a basic mechanism.

In this work, being encouraged by the theoretical calculation, we tried to measure CD spectra and natural linear dichroism (LD) spectra of amino acid films and KTP crystal in soft X-ray region. The reason of choosing amino acid for the present experiment is as follows: a) D-, L- and racemic samples are easily available. b) One can expect that the CD spectrum of D- and L-enantiomer sample should be the same magnitudes with the opposite sign each other. c) A racemic sample will be expected to show no CD. We selected phenylalanine (Phe) and serine (Ser) as samples for XNCD detection at the nitrogen and the oxygen K-edge region, respectively, because these amino acids show the strongest XNCD intensity in theoretical calculation [18]. We measured LD of a single crystal of KTP (potassium titanyl phosphate: $KTiOPO_4$), which was reported to show strong LD intensity and weak CD intensity in the hard X-ray region [3, 4].

2. Material and Experimental Method

2.1. *Sample Preparation*

Powder of D-, L-, DL-phenylalanine (D-Phe, L-Phe and DL-Phe), D- and L-Serine (D-Ser and L-Ser) were purchased from Wako Chemical Co. and KTP crystal (5 mm × 5 mm × 1 mm) cut parallel to the planes (1,2,0) and (1,–2,0) was purchased from Castech Co. The molecular structures of Phe and Ser were shown in Figure 1. These samples were used without further purification. Thin films of these amino acids were carefully prepared with vacuum sublimation technique [9, 10]. Powder of amino acid was put on a Kapton sheet, heated by a nichrome heater and evaporated at 370 ∼ 400 K onto an Au-coated BeCu substrate in vacuum

*corresponding author: Kazumichi Nakagawa, e-mail: nakagawa@kobe- u.ac.jp

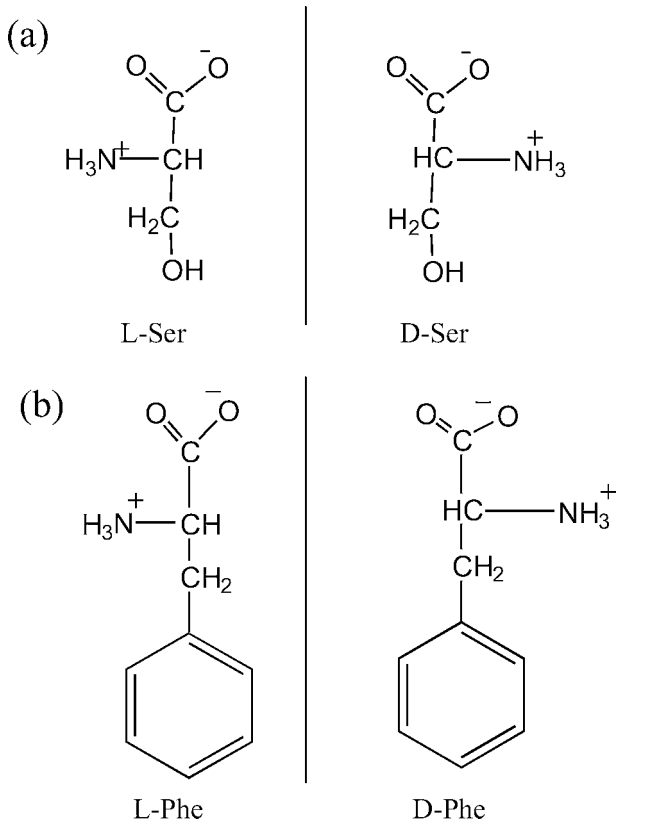

Fig. 1. Molecular structures of amino acids. (a): L- and D-Serine, (b): L- and D-phenylalanine.

($\sim 10^{-3}$ Pa). The thickness of each film was estimated to be about 300 nm by a quartz oscillator. Evaporated films were analysed by high performance liquid chromatography to confirm that thermal decomposition of samples during the vacuum sublimation did not occur. In the case of a KTP crystal, we sublimated thin carbon film ($\sim$5 nm) in order to eliminate charge up effects.

2.2. *XNCD measurement*

Measurements of XANES and XNCD spectra were carried out at Spring-8 BL23SU [12–15]. A double-array variable undulator of advanced planar polarized light emitter type (APPLE-2 type) was installed as a light source. This undulator was operated under the phase modulation mode in which LCPL and RCPL was switched with about 0.1 Hz [15]. In this work, LCPL is defined as the electric vector of circularly polarized light rotating counter-clockwise in a fixed plane by an observer looking at the light source.

Soft X-rays were monochromatized by a varied line-spacing monochromator [14]. The spectral width was set to less than 1 eV. The pressure of the sample chamber was lower than 10^{-6} Pa. All experiments were carried out at 300 K.

We measured the drain current from a sample (I) and that from the post focus mirror (I_0) by a picoammeter (Model TR8652, Advantest Co.) and obtained the quantity $A \equiv I/I_0$ which is proportional to the absorption coefficient. I_0 was measured to compensate the change in the electron beam current of the SPring-8 storage ring. We measured values of A as a function of photon energies and obtained XANES spectra. Denoting the value of A for LCPL as A_L and that for RCPL as A_R, we defined CD $\equiv A_L - A_R$, which is proportional to the real magnitude of the circular dichroism.

An orginal procedure of XNCD measurement was as follows; (1) determine the photon energy by grating rotation under the LCPL mode of the undulator, (2) measure the value of A_L, (3) switch the polarization to RCPL, (4) measure the value of A_R, (5) move to the next photon energy and measure the value of A_R, (6) switch the polarization to LCPL, (7) measure the value of A_L, and back to (1) to continue. In order to minimize the experimental time, we did not switch the polarization in step (5). In addition, in an attempt to obtain better statistics, we started step (1) under the LCPL mode, while in the next run we started from RCPL mode, and averaged those spectra. We measured four to eight XNCD spectra for each sample and averaged all spectra.

We moved the position of the soft X-ray spot on the amino acid sample at every XNCD measurement in order to avoid radiation damage. Since our evaporated films were uniform, we had a great advantage in normalizing the photocurrent intensity from different positions of a sample.

3. Result and Discussion

Figure 2-(a) shows a XANES spectrum of KTP crystal in the oxygen K-edge region and Figure 2-(b) shows $A_L - A_R$ spectra of KTP crystal with rotation angle $\theta = 0^\circ$, 45° and 90° in a plane perpendicular to the incident light. XANES of KTP crystal shows

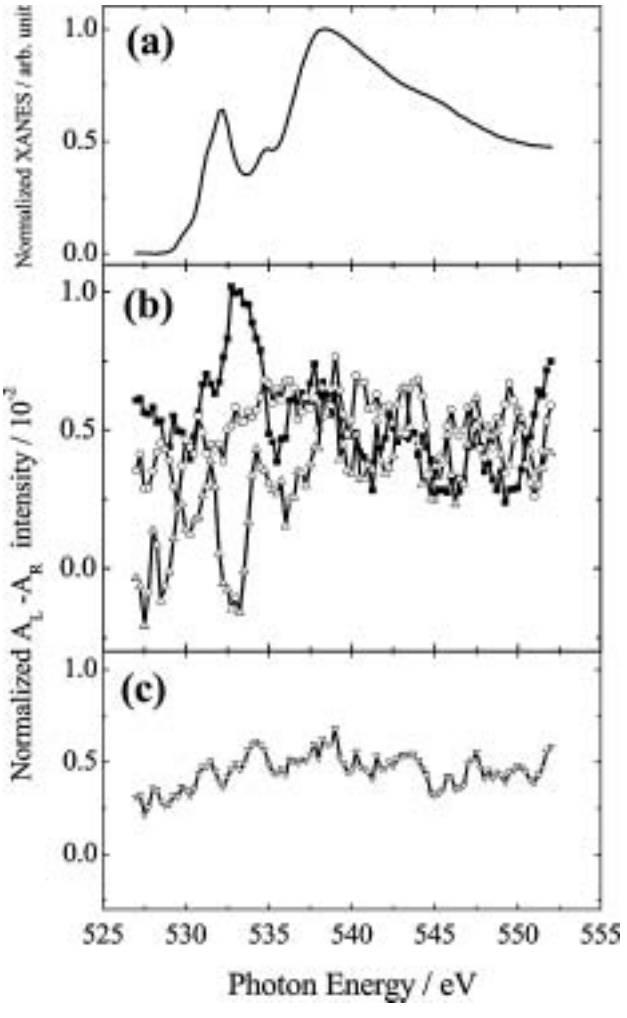

Fig. 2. (a) Normalized XANES spectrum of KTP crystal ($\theta = 0^\circ$) near the oxygen K-edge. (b) Normalized $A_L - A_R$ spectra of KTP crystal; closed square: $\theta = 0^\circ$, opened circle: $\theta = 45^\circ$ and opened triangle: $\theta = 90^\circ$. (c) Average of three $A_L - A_R$ spectra in Fig. 2-(b).

a strong peak at around 532 eV which is ascribed to the oxygen $1s \rightarrow \pi^*$ resonance. The $A_L - A_R$ spectrum at $\theta = 0^\circ$ shows a positive peak (∼0.5%) at around 533 eV. In the spectra at $\theta = 90^\circ$, this peak clearly reversed the sign to negative. At $\theta = 45^\circ$, this peak disappeared. In the higher energy region, we could not find any clear feature due to noisy signal. A similar angle dependence of the CD signals was reported by Goulon *et al*. [3, 4] in the hard X-ray region, near the Ti, K and P K-edge energy (∼4.98 keV, ∼3.61 keV and ∼2.15 keV). They ascribed the angle dependence to be due to LD. It is natural to conclude that our observation of the angle dependence can be ascribed to LD component of the soft X-ray absorption near the oxygen K-edge energy of the KTP crystal. Because of a weak linear polarization component of incident light, we could measure such LD spectra. Figure 2-(c) shows the average of three $A_L - A_R$ spectra. As seen from the figure, this average curve shows no features. This means that no CD component is found under the present signal to noise ratio. Detailed experiment of the angle dependence is now being planned.

Figure 3-(a) and -(b) show the XANES spectrum and the $A_L - A_R$ spectra of a Phe film near the nitrogen K-edge, respectively. The large peak at around 407 eV in XANES spectra was ascribed to the nitrogen $1s \rightarrow \sigma^*$ resonance. XANES of the Phe was similar to that of Gly [19], which is reasonable because Gly and Phe have the nitrogen atom at the same position (only in the amino group). Although the $A_L - A_R$ spectra of DL-Phe shows no feature, that of the L-Phe shows a negative peak at around 406 eV ($A_L - A_R$ intensity was about -0.2%), and that of the D-Phe shows positive peak and similar absolute intensity ($+0.2\%$). The molecular structures of the L-Phe and D-Phe are typically chiral. Because we observed the opposite sign and similar magnitude of $A_L - A_R$ intensity for L- and D-Phe, it is natural to conclude that we succeeded to observe the natural circular dichroism for biomolecules in the soft X-ray region for the first time. Reproducibility of these signals was sufficient to make this conclusion. The XNCD calculation for Phe by Li Yang [18] predicted some peaks within this energy region. Among them, the peak near the energy of 405 eV is in good agreement with our experimental results.

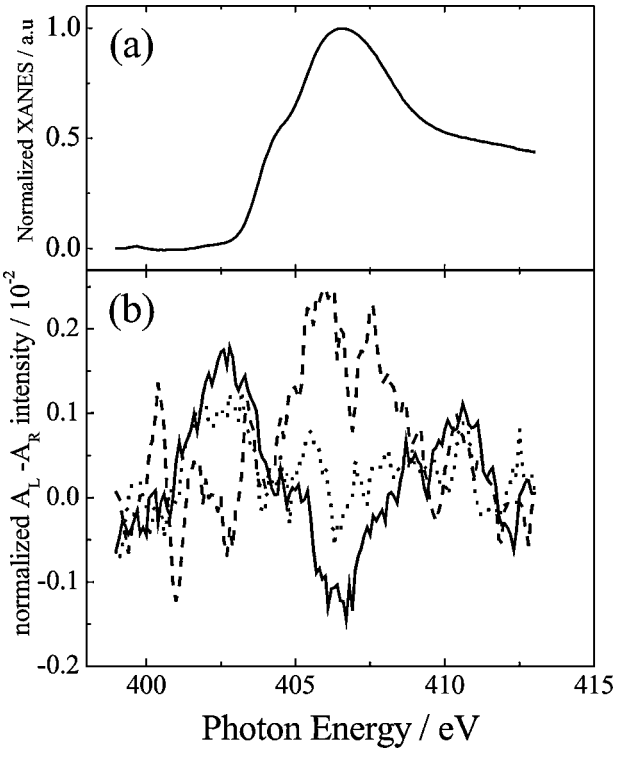

Fig. 3. (a) Normalized XANES spectrum of L-Phe film near the nitrogen K-edge. (b) Normalized $A_L - A_R$ spectra of Phe film; solid line: L-Phe, dashed line: D-Phe and dotted line: DL-Phe.

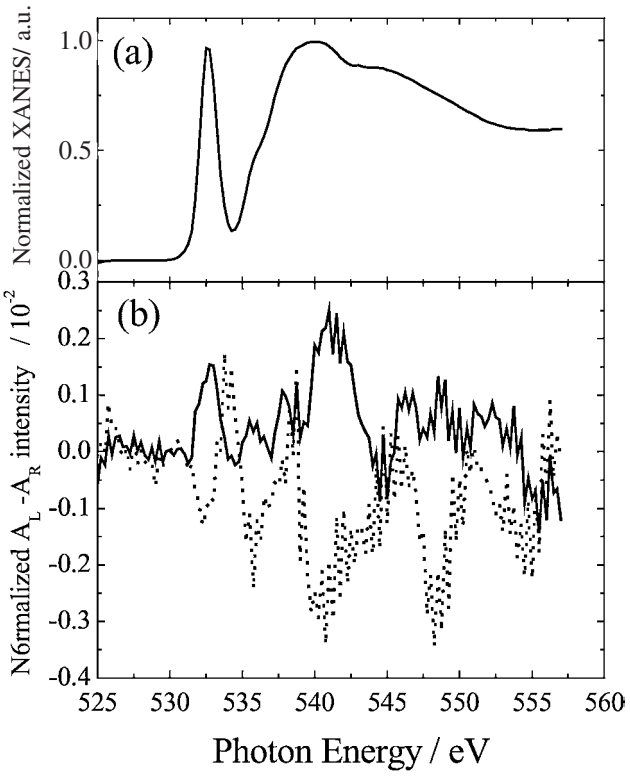

Fig. 4. (a) Normalized XANES spectrum of L-Ser film near the oxygen K-edge. (b) Normalized $A_L - A_R$ spectra of Ser film; solid line: L-Ser and dotted line: D-Ser.

Figure 4-(a) and -(b) show a XANES spectrum and $A_L - A_R$ spectra of Ser film near the oxygen K-edge, respectively. Details of Ser XANES were described in our recent paper [16]. As seen from Fig. 4-(b), at around 540 eV, positive and a negative peak was observed for L-Ser and D-Ser films of which $A_L - A_R$ intensities are about $\pm 0.2 \sim \pm 0.3\%$, respectively. This means that these peaks can also be ascribed to soft X-ray XNCD. In XANES spectrum (Fig. 4-(a)), the structure at around 540 eV was ascribed to the oxygen $1s \rightarrow \sigma^*$ resonance of the -OH group [16]. Thus, we concluded that this XNCD also originated from the -OH group. This result is good agreement with XNCD calculation [17]. In addition, we found small XNCD peaks at around 548 eV. According to the XANES peak assignment [16], this XNCD peak was considered to correspond to the $1s \rightarrow \sigma^*$ resonance of the $-COO^-$ group. However, in the theoretical calculation [17], such a XNCD peak was not predicted. The theoretical calculation [17] also predicted XNCD peaks within the region from 533 to 535 eV. In our experimental results, such XNCD peaks were sometimes found at around 532 eV. However, these peaks did not reproduce so well. Detailed experiment is necessary.

We succeeded to detect the XNCD of biomolecules besides of crystals in the soft X-ray region at the first time. More accurate and detailed experiment, for example, rotation angle dependence of XNCD spectra of KTP crystals, as well as improvement of the signal to noise ratio are now being planned.

Acknowledgement

This work was carried out at SPring-8 under the approval of the Japan Synchrotron Radiation Research Institute (JASRI) (2002A0123-NS1-np, 2002B0487-NS1-np and 2003A0380-NS1-np). Authors would like to thank deeply the machine group of JASRI and JAERI for their technical help and operating the beamline, especially Dr. Tomohiro Matsushita of JASRI for his adequate modification of the control programs for phase modulation and data acquisition.

Polarization Dependent Grazing Incidence (GI) XAFS Measurements of Uranyl Cation Sorption onto Mineral Surfaces

Melissa A. Denecke[1], Dirk Bosbach, Kathy Dardenne, Patric Lindqvist-Reis, Jörg Rothe and Ri Zhu Yin

Forschungszentrum Karlsruhe, Institut für Nukleare Entsorgung, P.O. Box 3640, D-76021 Karlsruhe

Received June 26, 2003; accepted in revised form January 8, 2004

Abstract

Measurement of the polarization dependence of surface sensitive grazing incidence (GI) X-Ray absorption fine structure (XAFS) spectra at the U L3 edge is applied to identify reactive U(VI) sorption sites on various mineral surfaces. We use the known polarization dependence of the dioxouranium(VI) or 'uranyl' cation, $[O{=}U{=}O]^{2+}$, to experimentally determine its orientation when sorbed onto single crystal mineral surfaces (α-Al_2O_3, $CaCO_3$). The GIXAFS signal measured at different orientations of a U(VI) sorbed α-Al_2O_3 (11-20) wafer relative to the polarization vector of the incident synchrotron radiation, ε, indicates that the uranyl surface species exhibit a preferred surface orientation. Analysis of the EXAFS substantiates our previous findings, identifying the reactive sorption sites as AlO_6 octahedral edges on the surface. Initial results of uranyl sorbed onto freshly cleaved (10-14) surface of natural calcite indicate that uranyl cations sorb onto terrace step edges and not onto the surface plane or with an orientation of the $[O{=}U{=}O]^{2+}$ unit parallel to the (10-14) surface.

1. Introduction

In order to differentiate between specific sorption sites and to identify reactive sorption sites at specific crystallographic planes of minerals, we have begun polarized dependent GIXAFS investigations of uranyl loaded single crystal surfaces [1]. GIXAFS has been employed for many years to study single crystal surfaces in various fields of science [2]. We have introduced using the uranyl cation as a probe for polarized GIXAFS studies of cation mineral surface sorption. The uranyl cation, or other actinyl cations such as neptunyl and plutonyl cations, are excellent probes for such studies due to their linear structure. The linear $[O{=}U{=}O]^{2+}$ cation is structurally a long rod generally near 3.6 Å in length. When these units are oriented in a common direction, they exhibit remarkable differences in both their U L3 and L1 edge XAFS spectra, depending on their orientation relative to the polarization vector (ε) of the incident synchrotron beam [3]. By observing the polarization dependence of the GIXAFS U L3 edge signal of uranyl sorbed onto single crystal surfaces, their orientation can be deduced. From this, specific sorption sites can be identified.

Here we report polarization dependent U L3 edge GIXAFS results for uranyl sorbed onto the (11-20) surface of α-Al_2O_3 and onto the (10-14) surface of a natural calcite sample. Our previous investigation of uranyl sorbed onto the α-Al_2O_3 (11-20) surface showed that the octahedral edges (O_d-O_d-sites), with a O-O distance 2.61 Å , are the uranyl binding sites on the α-Al_2O_3 (11-20) surface. In that study, spectra recorded at only two relative angles between ε and the crystallographic c axis (ϕ) were available. To support the interpretation of those results, measurements of uranyl loaded α-Al_2O_3 (11-20) at defined ϕ angles are performed. The angles chosen are where ε is parallel and perpendicular to O_d-O_d-sites. In addition, measurements are made at angles where ε is parallel and perpendicular to the crystallographic c-axis. This is to probe two additional candidates for bidentate binding sites on the (11-20) surface; both are located at right angles to the c-axis. We consider bidentate sites because the polarization dependence previously observed [1] indicates uranyl to be bound in a bidentate fashion; a monodentate surface species would not be expected to exhibit any polarization dependence.

Uranyl sorption onto the cleavage plane of natural calcite is investigated to ascertain if preferential sorption occurs at either acute or obtuse angled terrace step edges, associated with the $[-441]_-$ and $[48\text{-}1]_-$ and with the $[-441]_+$ and $[48\text{-}1]_+$ steps, respectively. Investigations by other groups report a differential incorporation of uranyl cations between the two symmetrically non-equivalent vicinal surfaces associated with growth at these + and − steps during calcite single crystal growth [4]. The question remains if the step selective incorporation may result from a site-selective sorption.

2. Experimental

2.1. *Sample preparation*

Sorption sample preparation is carried out in Teflon® containers. A polished α-Al_2O_3 (11-20) wafer (three inches in diameter and 0.5 mm thick; TBL Kelpin, Neuhausen, Germany) is pre-cleaned with ethanol and in an ultrasound aqueous bath. The surface roughness is measured with AFM to be less than 1 nm. XPS studies of a smaller wafer surface of the same crystal cut before and after the cleaning process show that 6–7 at-% carbon remains on the cleaned wafer surface. The cleaning procedure quantitatively removed metals found on the uncleaned surface (Cu, Ni, Ca, Na, Mg, Zn). Laser fluorescence spectroscopy studies of the surface show that trace amounts of chromium are dispersed in the wafer bulk. Following equilibration in Milli-Q water overnight, the cleaned wafer is set to float atop 50 mL aqueous sorption solution for 26 h. The wafer is held on the sorption solution meniscus by the solution surface tension. The solution volumes and the pH and U content of the U perchlorate stock solution used to prepare the sorption solution are selected to yield $5.4 * 10^{-6}$ mol/L nat-U(VI), pH 5.4. The amount of U(VI) sorbed is quantified from analysis of samples prepared similarly using XFA and from autoradiographic measurement of an α-Al_2O_3 (11-20) wafer loaded with 233-U instead of nat-U. The wafer shows a homogeneous distribution of cations over the surface with ∼1 U atom/nm^2 loading. The sample is measured 4 weeks after preparation.

The calcite sample is prepared from a freshly cleaved crystal of natural origin (Creel, Chihuahua, Mexico). The cleaved (10-14) $CaCO_3$ surface is $2.5 \times 3.5\,cm^2$ with a calculated number of surface binding sites $= 4.4 * 10^9$ [5]. Sorption with U(VI) is performed by suspending the crystal from wooden toothpicks

[1] denecke@ine.fzk.de

attached to the backside of the crystal such that the freshly cleaved (10-14) surface is in contact with 20 mL aqueous $1.3 * 10^{-4}$ M U solution overnight. The $-\log H_c$ at the end of the contact time is measured to be 8.3. The calculated aqueous U speciation of the sorption solution is dominated by $UO_2(CO_3)_3^{4-}$ (87%) and $UO_2(CO_3)_2^{2-}$ (8%) [6].

The $UO_2(CO_3)_3^{4-}$ solution is prepared by diluting and mixing aliquots of aqueous $NaHCO_3$, Na_2CO_3 and UO_2^{2+} solutions to yield $[HCO_3^-]$, $[CO_3^{2-}]$ and $[UO_2^{2+}]$ concentrations of 45.5 mM, 45.5 mM and 9.09 mM, respectively. The measured $-\log H_c$ is 9.6.

2.2. *GIXAFS measurements*

The GIXAFS apparatus used is described in [1]. Uranium L3 edge GIXAFS measurements are performed at the X1 experimental station at the Hamburger Synchrotronstrahlungslabor (HASYLAB) using synchrotron light from the DORIS storage ring operating at 4.436 GeV with ring currents between 90 and 130 mA. Si(111) crystals are used in the double-crystal monochromator (DCM) in pseudo-channel cut mode. The energy of the beam is calibrated against the first derivative in the XANES spectrum of a Pt foil, defined as 11564.0 eV. The rocking curve is measured to give a FWHM of 1.5 mdeg. Samples are mounted in a circular, domed cell with two sets of double Kapton windows (for incident and reflected beam) located at right angles to one another and a window on top of the cell, perpendicular above the sample plane. The top window is for registering the fluorescent signal using a Canberra LEGe 5-element solid state detector, mounted above it. The incoming intensity is measured using 50 : 50 Ar : N_2 in the ionization chamber. A number of drops of Milli-Q water is placed in a circular trough inside of the domed sample cell in order to keep the samples moist during measurement. The calcite samples are held in place with carbon paste (Leit-C, Plano, Münster, Germany), the α-Al_2O_3 wafer by adhesive force exerted by a water drop placed between sample mount surface and the underside of the wafer.

The GIXAFS spectra of the U(VI) sorbed α-Al_2O_3 are measured with the sample surface oriented with respect to the impinging beam at an incident angle (θ_i) $\sim$ 90 mdeg below the observed angle of total external reflection. θ_i is determined from the measured vertical displacement of the reflected beam relative to the transmitted intensity. Spectra are recorded at four different orientations (see fig. 1). Because ε is at right angles to the incident beam, these angles are equivalent to ε being parallel and perpendicular to connecting O_d-O_d sites (32° and 122°), as well as parallel and perpendicular to the c-axis (0° and 90°). The calcite crystal is measured with θ_i set to a nominal angle of 100 mdeg. Two spectra are recorded with the sample oriented with the impinging beam at approximately 45° and 90° relative to the c-glide plane. This corresponds to ε being approximately parallel to the [-441] and [48-1] directions. The spectra are designated SO_0 and SO_270, respectively.

EXAFS, $\chi(k)$, are isolated from the raw, averaged data via standard procedures (background subtraction; normalization of the absorption to unity; conversion to wave vector, k, space; fitting k^2-weighted data with cubic spline functions to obtain the atomic background function, $\mu_0(E)$, for subsequent extraction of $\chi(k)$ [7]) using the WinXAS software [8]. Four or five scans for the α-Al_2O_3 samples and seven scans for the calcite samples are averaged in order to improve the signal to noise ratio of the measurements. The maximum of the most intense absorption feature in the individual spectra, the white line (WL) is used as the ionization energy (E_0), the origin for calculation of the $\chi(k)$-function and defining k. Spectra are analyzed using the feffit software [9] and phase/amplitude functions calculated with feff7 [10]. Theoretical fits are performed in R-space.

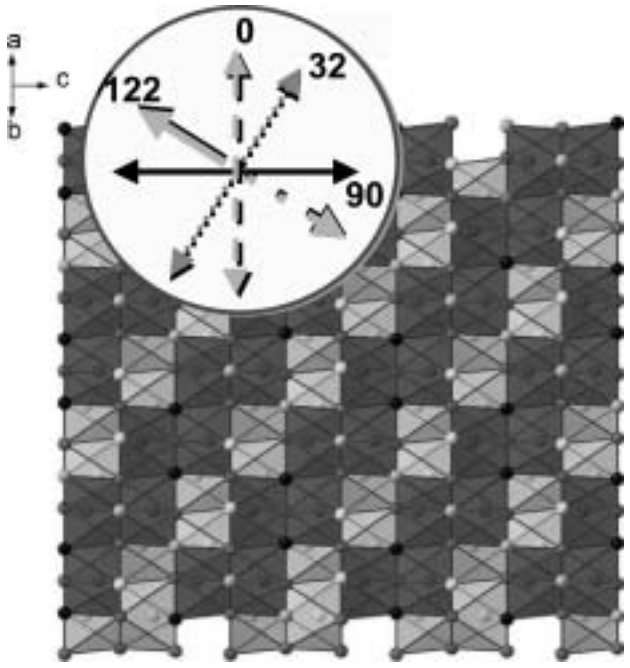

Fig. 1. View of the α-Al_2O_3 (11-20) surface normal to the crystallographic c-axis, intersecting the a,b-plane. Also shown is a cartoon of the wafer with lines depicting orientation for the spectra shown in fig. 2. Lines show orientation of the incident beam for the four measurements, numbers give angles between ε and the c-axis.

3. Results and discussion

3.1. *Uranyl sorbed α-Al_2O_3 (11-20)*

The k^2-weighted U L3 edge EXAFS and their corresponding Fourier transforms (FT) for uranyl sorbed α-Al_2O_3 (11–20) at the four different angles studied are shown in fig. 2. Because of the low loading of uranyl on the surface (1 cation/nm^2), the data quality is not good. There are subtle differences between spectra in the amplitude of the first two maxima and in the interference pattern between k 6.5 and 9 Å^{-1}. The data is fit to the EXAFS equation considering the polarization dependence of the EXAFS amplitude. This is done by introducing an effective coordination number (N_{eff}), which is related to the actual coordination number (N) by $N_{eff} = 1/2N(1 + 3\cos^2 \Theta)$ [3], where Θ is the angle between the bond axis and ε and N is, in this case, 2 and 5 for the axial (Oax) and equatorial (Oeq) oxygen coordination shells. The independent variables Θ(U=Oax) and Θ(U-Oeq) are included in the fit to describe the angle between ε and the $[O{=}U{=}O]^{2+}$ unit and between ε and the equatorial plane. The fit is performed on pairs of data sets simultaneously, i.e., the 122 and 32 spectra as one set and the 0 and 90 spectra as the other. The 90° relationship between the spectra in these pairs is defined in the fit. In this way, Θ(U-Oax) and Θ(U-Oeq) in the first spectrum are 90° from the corresponding values in the second spectrum of each pair. This procedure has the advantage that the number of parameters allowed to vary in the fit remains below the permitted degrees of freedom and the correlation between parameters is in all cases less than 60%. In contrast, for fits to individual data, the correlation between amplitude related variables N and Debye-Waller factors (σ^2) is estimated to be greater than 95%. Bond distances,

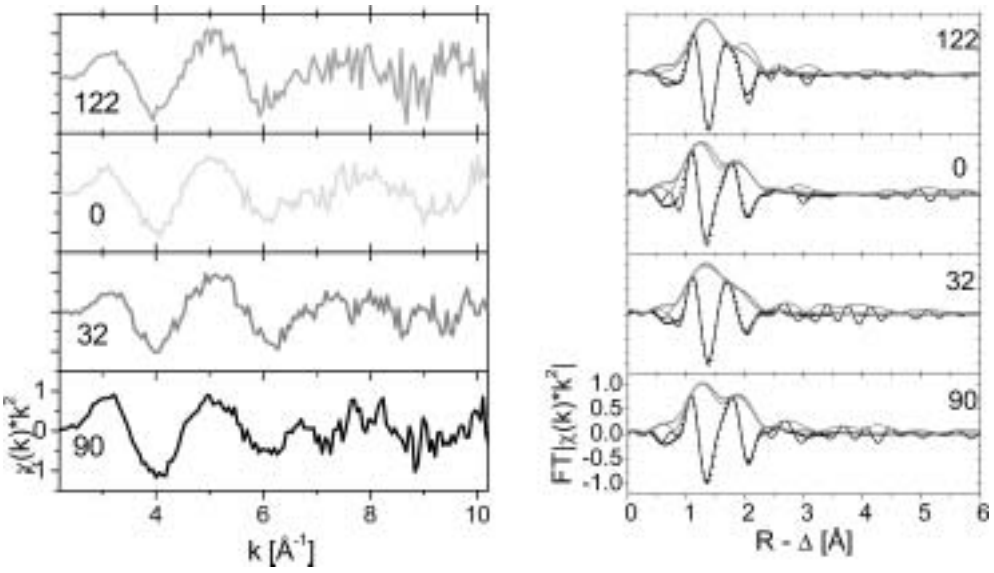

Fig. 2. U L3 EXAFS (left) and corresponding Fourier transforms (right) for the uranyl sorbed α-Al_2O_3 (11-20) sample measured at angles of the incident beam relative to the c-axis indicated (compare fig. 1). Fit results to the FT spectra are shown as triangle symbols.

Table I. *Metric parameters from fits to the U L3 EXAFS of the uranyl loaded α-Al_2O_3 (11–20) surface measured at angles indicated in fig. 1. The model for fits is described in the text.*

Spectrum	N_{eff} (Oax)	N_{eff} (Oeq)	R(Oax) [Å]	R(Oeq) [Å]	σ^2 (Oax) [Å^2]	σ^2 (Oeq) [Å^2]	Θ(U = Oax) [deg]	Θ(U = Oeq) [deg]
				First pair of data				
122	3.90	2.92	1.77	2.38	0.004	0.016	170	256
32	1.10	9.58					80	166
				Second pair of data				
0	2.64	5.47	1.74	2.42	0.005	0.013	42	129
90	2.36	7.03					132	219

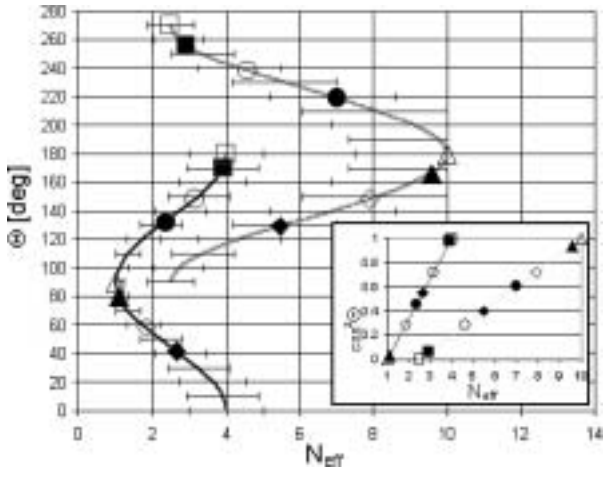

Fig. 3. Θ(U-Oax) (left) and Θ(U-Oeq) (right curve) as a function of N_{eff} for uranyl sorbed α-Al_2O_3 (11-20). Solid symbols are the values obtained from fits listed in Table 1 and open symbols theoretical values expected for binding to O_d-O_d surface site. Squares = 122; Triangles = 32; Diamonds = 0; Circles = 90. 25% error bars for N_{eff} are shown (values for N_{eff} for Oax below 1 and for Oeq above 10 are not defined). Corresponding values for N_{eff} versus $\cos^2\Theta$ are displayed in the insert.

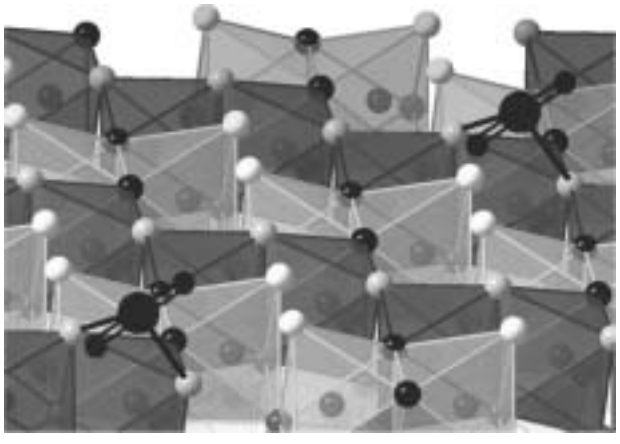

Fig. 4. Three dimensional cartoon of a single uranyl cation bound to an AlO_6 octrahedra edge on the α-Al_2O_3 (11-20) surface. The remaining equatorial ligands (three water molecules) have been omitted for clarity.

(R(U-Oax) and R(U-Oeq), and σ^2 are treated as global parameters for both spectra. The relative shift in ionization potential (ΔE_0) is held constant at −2.5 eV. The fit results are listed in Table I and depicted as triangular symbols in the FT spectra in Fig. 2. Fig. 3 compares the values for N_{eff} and the corresponding Θ(U-Oax) and Θ(U-Oeq) obtained from the fits with expected theoretical values for uranyl binding at the O_d-O_d sites.

EXAFS analysis corroborates our previous results [1] that uranyl cations sorbed onto the α-Al_2O_3 (11-20) surface are bound in a bidentate fashion through attachment of two Oeq in its equatorial plane to AlO_6 octrahedra edges (fig. 4). The Θ(U-Oax) and Θ(U-Oeq) obtained in the fits are all within 10–19° of values expected for binding at the O_d-O_d sites. ε is perpendicular

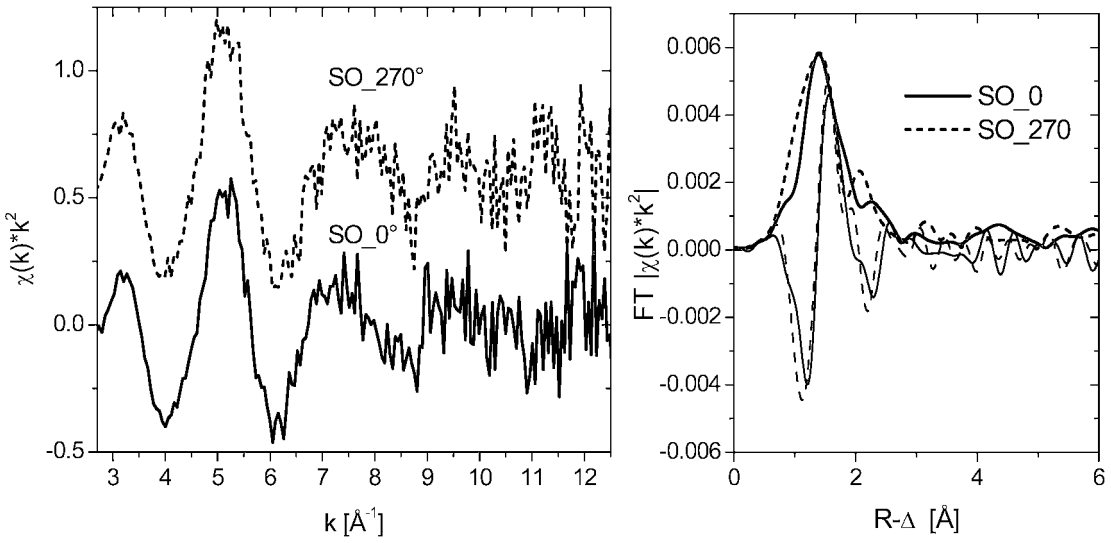

Fig. 5. U L3 EXAFS (left) and corresponding Fourier transforms (right) for the uranyl sorbed natural calcite (10-14) sample measured at angles with ε being approximately parallel to the $[-441]_-$ and $[48\text{-}1]_+$ directions (designated SO_0 and SO_270, respectively).

and parallel to O_d-O_d sites in the 122 and 32 spectra and we expect Θ(U-O*ax*) to be 180° (or 0) and 90°, respectively. The fit yields values 10° away. For the 0 and 90 spectra, ε is parallel and perpendicular to the c-axis. This translates to ε being 58° and 148° from expected values for $[O{=}U{=}O]^{2+}$ bound to O_d-O_d sites. The fit yields 42° and 132°, values only 16° smaller than expected for binding to AlO_6 octrahedra edges. If the other candidate binding sites situated at right angles to the c-axis were binding uranyl cations, Θ(U-O*ax*) values near 0° and 90° should be obtained; they are not. Although varied independently, the fit parameters obtained for Θ(U-O*eq*) are exactly 3° from the expected value of Θ(U-O*ax*) + 90° (the O*eq* plane is generally at a right angle to O*ax* atoms). This indicates that the linear uranyl units are parallel to the sample surface, otherwise a larger deviation of the fit values for Θ(U-O*eq*) from Θ(U-O*ax*) + 90° would be observed, i.e., the values obtained would be systematically shifted up or down from the curve Θ(U-O*eq*) as a function of N_{eff} in fig. 3. Also evident in fig. 3 is the relatively large deviation of the fit results for Θ(U-O*eq*) from the theoretical values for the 0 and 90 spectra. These are the spectra with largest Θ(U-O*eq*) deviation (19°) from that expected for binding to AlO_6 octrahedra edge. Possible explanations may have to do with poor quality of the data or relaxation/deviation of the surface atoms from their bulk crystalline terminated positions. More experiments are needed to determine the accuracy and precision of this particular technique.

3.2. *Uranyl sorbed calcite (10-14)*

The k^2-weighted U L3 edge EXAFS and their corresponding Fourier transforms (FT) for uranyl sorbed onto the natural calcite sample are depicted in fig. 5. Because the calculated aqueous U speciation of the alkaline uranyl solution used to prepare the sorption sample is dominated by $UO_2(CO_3)_3^{4-}$, we compare the EXAFS for the uranyl sorbed calcite with that for a $UO_2(CO_3)_3^{4-}$ reference solution shown in fig. 6. In order to correctly model the $UO_2(CO_3)_3^{4-}$ spectrum, multiple-scattering (MS) to the distal oxygen (*Odis*) along the U-C-*Odis* path must be included. Path analysis reveals this MS path to be responsible for the 'triplet' structure for k between 6.5 and 8.5 $Å^{-1}$. This oscillatory fingerprint of the $UO_2(CO_3)_3^{4-}$ EXAFS is missing in the EXAFS of the uranyl sorbed calcite in fig. 5. We conclude that the surface sorbed species does not reflect the majority solution species during sorption and is not simply a tricarbonato species. Studies of uranyl incorporated into calcite report loss or partial loss of three carbonato ligands [11], [4]. This seems also to be the case for the calcite sorbed species here.

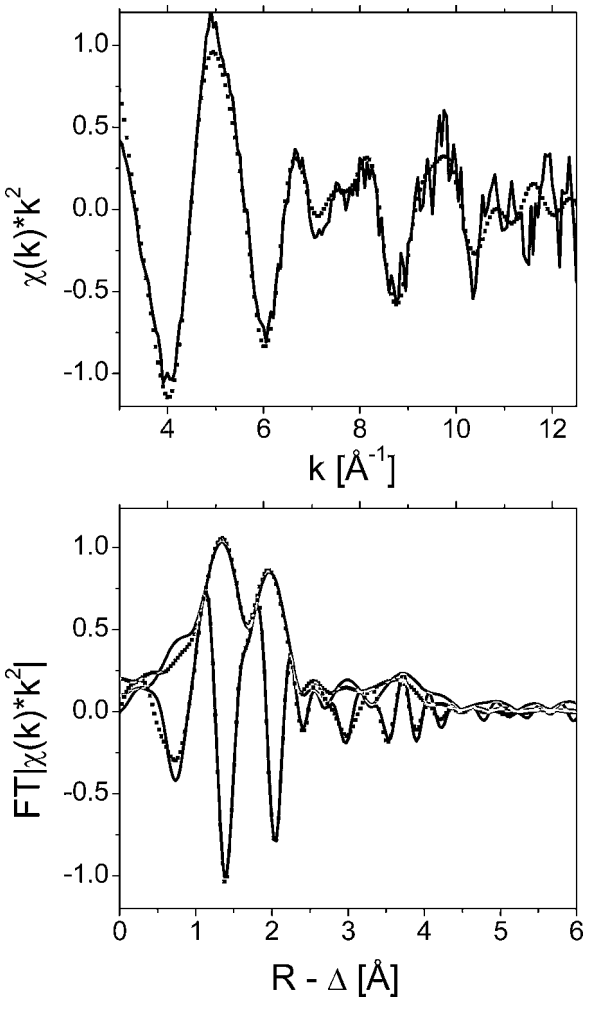

Fig. 6. U L3 EXAFS (top) and corresponding Fourier transforms (bottom) for an aqueous $UO_2(CO_3)_3^{4-}$ solution. Continuous lines are the experimental data; symbols represent a theoretical model of the data including multiple-scattering (U-O*ax*-U-O*ax* and U-C-O*dis*) paths.

Qualitative examination of the two spectra in fig. 5 provides the following information. The U-O*ax* shell in both spectra exhibits similar amplitudes. However, the U-O*eq* signal in the SO_0 spectrum is significantly different than in the SO_270 spectrum. There are two possible explanations for this apparent non-variance in Θ(U-O*ax*) with ε. Either the linear $[O{=}U{=}O]^{2+}$ units are perpendicular to ε or they are oriented at a small constant 'tilt' relative to ε in both the SO_0 and SO_270 spectra. That Θ(U-O*eq*) is observed to change with relative orientation of ε may infer that the coordination of U(VI) in its equatorial plane is significantly asymmetric. That uranyl appears to be oriented perpendicular (or at a constant tilt) to the (10-14) surface and that the equatorial coordination shows asymmetry in these measurements with the beam incident to [-441] and [48-1] directions may result from preferential sorption of uranyl cations onto one of the steps. These are preliminary, qualitative results. A more detailed analysis of these measurements and securing data recorded at additional angles is necessary before we are able to identify which step.

4. Conclusions

This method taking advantage of the GIXAFS polarization dependence for characterization of surface sorbed species offers great potential. Such molecular surface sorbed speciation at the mineral-water junction enables identification of reactive surface sites, differentiation between sorption reactions occurring at specific surface sites at different mineral crystallographic planes and verification of the presence of sorbed surfaces species proposed from bulk investigations. This information can, e.g., aid in predictive modeling of sorption reactions onto natural sorbents. This tool will be extended in the near future to polarization dependent Pu L3 edge GIXAFS studies of plutonyl cations sorbed onto mineral surfaces. It is also applicable to investigations of neptunyl sorption. Generally, the actinyl cations may become excellent probes for such molecular surface speciation studies due to their linear structure, which effects the large anisotropy of their XAFS signal utilized in this method.

Abstract

Current X-ray absorption spectroscopy (XAS) data-analysis of ordered and disordered systems is based on a peak decomposition of the n-body distribution functions. The limitation of this approach can be particularly severe for the purpose of modeling the local geometry in liquid and amorphous systems. We have developed a successful method for quantitative analysis of highly disordered structures using the Reverse Monte Carlo (RMC) refinement that can be applied simultaneously to diffraction and XAS data, allowing the construction of realistic tridimensional models. Here we present the results of the application of the method to gaseous Br_2 and to liquid Cu. The method incorporates all of the advances related to the application of advanced multiple-scattering (MS) codes and the n-body expansion for XAS data-analysis (GNXAS).

1. Introduction

Modern XAS (X-ray absorption spectroscopy) data-analysis is based on the structural refinement of the raw XAS data through accurate multiple-scattering (MS) calculations of the X-ray absorption cross-section. In particular, the GNXAS *ab-initio* data-analysis method for XAS data-analysis allows us to obtain fast and accurate simulations of the $\gamma^{(n)}$ MS XAS n-body signals, associated with the n-body distribution functions g_n describing the local structure around selected photoabsorbing atoms [1, 2]. The current strategy for the structural refinement requires modelling of the distribution functions as a superposition of distinct peaks associated with the neighboring atomic shells (first and further neighbors) for the pair distribution function g_2, with typical triangular atomic configurations (g_3), and so on [2, 3]. This approach is clearly appropriate for molecules or for ordered condensed matter, where the assumption about the existence of distinct g_2 and g_3 peaks at short distances is obviously fulfilled. In these systems, this "peak-fitting" method is a very fast and efficient tool, usually able to ensure a reliable reconstruction of the shape of the short-range distributions through a limited number of structural parameters defining suitable model functions.

In highly disordered substances, such as amorphous or liquid systems, short-range peaks of the n-body distribution functions are usually merged into a long-range tail and suitable constraints must be used in order to obtain meaningful structural results through XAS data [4]. The application of physical constraints into a still model-dependent peak-fitting approach has been shown to be very successful in describing the short-range pair distribution function of "simple" elemental melts ionic binary liquids and aqueous solutions (see ref. [4–9] and the review paper [10]). However, the extension of the peak-fitting approach to disordered multi-component systems is not a trivial task [11] and a reliable reconstruction of the shape of the higher-order distribution functions is practically impossible even in simple monatomic systems.

In view of the potential of the XAS technique in measuring the local structure in highly disordered systems through higher-order correlations, advances in XAS data interpretation are particularly important. In fact, knowledge of the pair distribution $g_2(r)$ does not allow us to obtain a unique tridimensional model of the local structure. The reconstruction of the local geometry in liquid systems needs additional improvements to current XAS data analysis schemes. A successful method for quantitative analysis of highly disordered structures is the Reverse Monte Carlo (RMC) refinement [11–13] that can be applied simultaneously to diffraction and XAS data, allowing the construction of a tridimensional model of the disordered system compatible with the observables under consideration. In particular, XAS data probe the local structure around photoabsorbing centers, while diffraction data provide the necessary medium and long-range constraints.

Application of the RMC method for XAS data-analysis was already suggested by Gurman and McGreevy [12] and preliminary applications to silver bromide and crystalline and amorphous silicon presented. The method was also applied for data-analysis of liquid GaSb and InSb [14]. We have now developed such a RMC method using state-of-the-art simulation techniques for calculating the XAS signal starting from ensembles of either molecular replicas or atoms in a box with cyclic boundary conditions. In the latter case, the RMC refinement is applied both to XAS experimental data and the $g(r)$ curve obtained by diffraction techniques.

2. Method

The RMC method [11, 13] is a variation of the standard Metropolis Monte Carlo procedure [15] whose aim is to produce a statistical ensemble of particles following the canonical distribution. In the original MMC technique the probability of finding a particular configuration of the ensemble of particles is proportional to $e^{\frac{-U}{KT}}$ where U is the total potential energy and T is the temperature. A weighted sampling procedure (Markov chain) allows to decrease the total energy U by moving the coordinates of the particles until it reaches and oscillates around an equilibrium value. In the RMC method, the role of the potential energy is played by the sum of the weighted squares of the difference between measured (A^E) and calculated (A^C) physical observables:

$$\chi^2 = \sum_{i=1}^{N} [A_i^E - A_i^C]^2 / \sigma_i^2. \quad (1)$$

As shown in the original papers [11, 16], the probability distribution is proportional to $e^{-\chi^2/2}$ and therefore $\chi^2/2$ in RMC equivalent to $\frac{U}{KT}$ of the original Monte Carlo.

In the present work, we have applied the method for the simultaneous RMC refinement of XAS and $g_2(r)$ data obtained by X-ray or neutron diffraction using the "state-of-the-art" multiple-scattering simulation techniques provided by GNXAS programs [1, 3].

For a single component system the structural XAS signal is related to the n-body distribution functions by:

$$\langle\chi(k)\rangle = \int_0^\infty \mathrm{d}r\ 4\pi r^2\rho\ g_2(r)\gamma^{(2)}(r,k) + \int \mathrm{d}r_1\ \mathrm{d}r_2\ \mathrm{d}\theta\ 8\pi^2 r_1^2 r_2^2 \times \sin(\theta)\rho^2 g_3(r_1,r_2,\theta)\gamma^{(3)}(r_1,r_2,\theta,k) + \cdots \quad \cdots \qquad (2)$$

where the short range nature of the n-body XAS $\gamma^{(n)}$ signals limits the integral in a region of linear dimensions of the order of few Å. The g_n functions are easily calculated using the atomic coordinates of the ensemble of atoms in the RMC box, and appropriate calculation strategies have been actually implemented to evaluate the XAS signal associated to the g_2 in a box of thousands of atoms. The main difference with the application described in ref. [12] is the use of sophisticated MS calculations within the n-body expansion and of the relationship given by Eq. (2) (a term $(g_2 - 1)$ instead of g_2 appears in the integral in ref. [12]).

These advances have been incorporated in a program (RMCXAS) interfaced with GNXAS [2, 3] and currently able to perform structural refinements of both molecular and condensed structures by using either an ensemble of replicas of the molecule or applying cyclic boundary conditions on a cubic box. The χ^2 function at each RMC step is simply given by:

$$\chi^2 = \sum_{i=1}^{N_{XAS}} [\chi^E(k_i) - \chi^C(k_i)]^2/\sigma_i^2 + \sum_{j=1}^{N_g} [g_2^E(r_j) - g_2^C(r_j)]^2/\sigma_j^2 \qquad (3)$$

where in the first term of the r.h.s. χ^C is calculated by the program starting from the actual atomic coordinates using Eq. (2) and the $\gamma^{(2)}$ signals given by GNXAS, χ^E is the raw XAS signal and σ_i^2 the noise function obtained from the experiment and evaluated by FITHEO (GNXAS program). In the second term, not used in molecular cases, g_2^C is the pair distribution associated with the atomic coordinates of the RMC box, g_2^E is a model pair distribution obtained by neutron/X-ray diffraction or molecular dynamics, and σ_j^2 is the variance associated with the pair distribution.

3. Results and Discussion

A first application to molecular bromine shows the main features of the RMC approach for the simpler diatomic structure and the validity of the structural results. The bond distribution of the Br_2 molecule has been investigated by XAS by several authors (see for example [17, 18] and ref. therein). Here we have used the Br K-edge experimental data measured at LURE, beamline D42, and published in ref. [17]. In previous works the data-analysis was performed using the standard Gaussian peak-fitting approach (average distance $R = 2.288$ Å and bond variance $\sigma^2 = 0.0019$ Å^2 for the XAS data under consideration, see [18] and ref. therein).

The RMC model used in this work is based on the calculated XAS signal associated with an ensemble of 500 Br_2 molecular replica. The starting configuration was chosen to mimic a Gaussian distribution with displaced values with respect to those found with the peak-fitting approach.

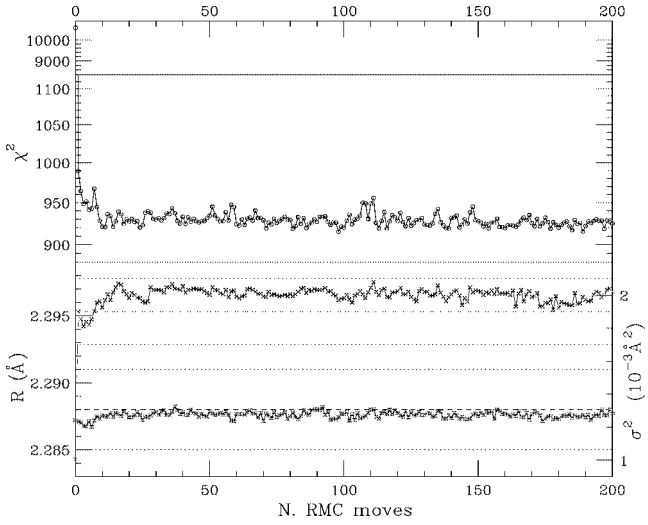

Fig. 1. Upper panel: trend of the χ^2 residual function for successive RMC moves. The χ^2 rapidly converges near to the expected value. Lower panel: average molecular distance R and distance variance σ^2 (upper curve) calculated for the set of RMC coordinates at each simulation step. Average distance and variance evaluated using the GNXAS peak-fitting procedure are shown as dashed lines (error bars indicated as dotted lines).

In Fig. 1, upper panel, we show the trend of the χ^2 residual function for successive moves of the 500 molecular replica of the Br_2 molecule, up to a total of 200 RMC moves. Each RMC move corresponds to 500 molecular distance moves (speed is about 1 s per RMC move on 500 MHz alpha CPU). The χ^2 is found to converge very rapidly near to the expected value (in the χ^2 distribution this is simply $E[\chi^2] = N$, where N is the number of data points). The average molecular distance R and distance variance σ^2, reached their equilibrium values after 10–20 RMC moves, as shown in the lower panel of Fig. 1. RMC average distance and variance are found to be in excellent agreement with those evaluated by using the GNXAS peak-fitting procedure in the Gaussian approximation on the same data set (dashed lines) and on more accurate experimental data [18]. In Fig. 2, upper panels we compare the raw $k\chi(k)$ XAS data with $k\chi(k)$ RMC simulations. In the corresponding lower panels we report the histograms of the radial distribution function $n(r)$, calculated starting from the RMC molecular configurations, Calculated $k\chi(k)$ signals and $n(r)$ before reaching equilibrium are shown in the left panels (initial configuration and those after 10, 20, 30, 40 steps). The results of the last 150 moves are reported in the right panels. In this case, $k\chi(k)$ simulations and residual (below) associated with successive RMC steps can not be distinguished. The different $n(r)$ corresponding to equilibrium configurations are shown with the average distribution (thick histogram) and compared with Gaussian distributions measured in previous works [18]. The results of the peak-fitting procedure and of the RMC refinement are clearly compatible confirming the validity of the approach.

In Fig. 3 we briefly report about the results of an RMC XAS data-analysis of liquid Cu measured at 1398 K (1-Cu) at the ESRF (BM29). The RMC simulation has been performed in a 864-atom cubic box of fixed density and considering both the XAS experimental data and the published $g_2(r)$ curve obtained by neutron diffraction (ND) [19] which acts as a constraint for the long-range behaviour (see Eq. (3)). The initial atomic configuration has been chosen to be compatible with the ND g_2. The RMC run needs more steps and longer times for equilibration,

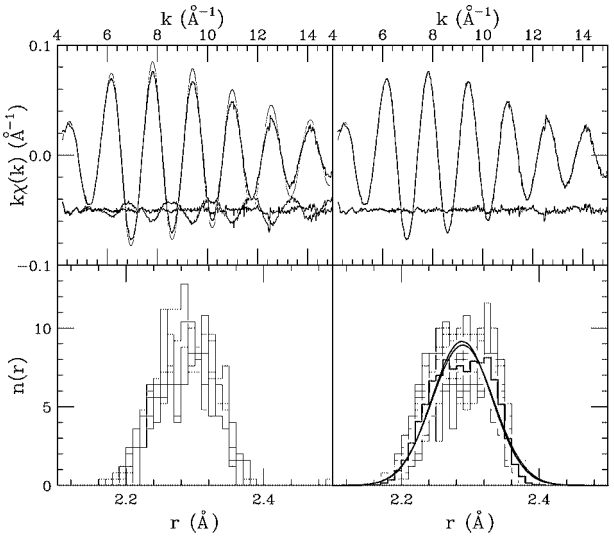

Fig. 2. Upper panels: on the left raw $k\chi(k)$ XAS data are compared with the first RMC simulations calculated before reaching equilibrium. Those corresponding to equilibrium configurations are shown on the right (16 simulations every 10 steps up to 200). Lower panels: on the left the histograms of the RMC radial distribution function $n(r)$ are shown for non-equilibrium configurations. On the right the different $n(r)$ corresponding to equilibrium configurations are compared with the average distribution (thick histogram) and with Gaussian distributions measured in previous works.

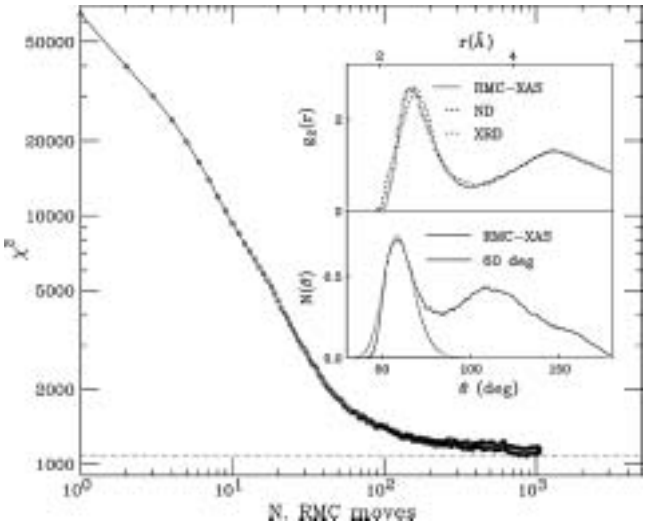

Fig. 3. Trend of the χ^2 residual function in liquid Cu at 1398 K. The inset (upper panel) shows the $g_2(r)$ associated with the RMC simulation and previous determinations using neutron (ND) and X-ray (XRD) diffraction. In the lower panel of the inset the full bond-angle $N(\theta)$ distribution resulting from the RMC simulation is compared with that of equilateral triangles.

that is reached after about 100–500 steps. The $g_2(r)$ obtained by the last 400 RMC steps reproduces almost exactly those given by ND [19] and XRD [20] above about 4 Å while the first-neighbour peak is narrower and shifted to shorter distances (see inset of Fig. 3, upper panel). The short-range shape of the RMC $g_2(r)$ is accurately reconstructed due to the unique sensitivity of the XAS signal. The RMC bond-angle distribution shown in the inset is calculated counting the number of triangular configurations per atom up to a selected limiting distance ($R_{cut} = 2.98$ Å).

The typical shape of the distribution contains a distinct peak around 60° associated with equilateral configurations and a second broad hump at about 110°. The 3-body contribution of the equilateral configuration is found to be very important to reproduce the XAS signal and the consequences on our understanding of the local structure of liquid Cu are discussed in detail elsewhere [22].

4. Conclusions

We have developed a new XAS data-analysis program based on the RMC approach that fully incorporates the advances contained in the GNXAS method. In particular, simultaneous refinement of raw XAS data and $g_2(r)$ curves is possible giving realistic reconstructions of the local structure compatible with both XAS and diffraction data. This is particularly important in disordered systems where the RMC model provides a tridimensional model compatible with the observables without the intrinsic limitations of the peak-fitting approach. The validity of the method has been put to a test on a simple molecular case (Br_2) where the results of a standard data-analysis have been reproduced. The application of this method to the study of the structure of liquid copper shows that realistic pair and triplet distribution functions can be measured and analysed by XAS.

Abstract

High-resolution manganese and iron K-edges XANES spectra were collected on several samples of archeological interest: prehistorical paintings and medieval glasses. XANES spectra were collected at the ID21 facility (ESRF, Grenoble, France) using a micro-beam device and at the 11-2 beamline (SSRL, Stanford, USA) using a submillimetric beam.

The medieval glasses studied are from gothic glass windows from Normandy (XIVth century). The aim of this study is to help understand the chemical durability of these materials, exposed to weathering since the XIVth century. They are used as analogues of weathered glasses used to dump metallic wastes. These glasses show surficial enrichment in manganese, due to its oxidation from II (glass) to III/IV (surface), which precipitates as amorphous oxy-hydroxides. Similarly, iron is oxidized on the surface and forms ferrihydrite-type aggregates.

The prehistorical paintings are from Lascaux and Ekain (Basque country). We choose in that study the black ones, rich in manganese to search for potential evidences of some "savoir-faire" that the Paleolithic men could have used to realize their paint in rock art, as shown earlier for Fe-bearing pigments. A large number of highly valuable samples, micrometric scaled, were extracted from these frescoes and show large variation in the mineralogical nature of the black pigments used, from an amorphous psilomelane-type to a well-crystallized pyrolusite. Correlation with the crystals morphology helps understanding the know-how of these early artists.

1. Introduction

Recently, a number of XAFS methods have been applied to archeology to help characterize highly valuable artifacts of historical importance such as Medieval gems [1] and Roman glasses [2]. Other applications currently underway include the study of the corrosion of inks used by J. S. Bach (cf. Dahn and co-workers in Berlin, Germany), the corrosion of Celtic weapons (Janssens's group in Antwerp, Belgium), the determination of growth rate of desert varnish to help dating petroglyphs (Lytle's group at SSRL) or the sulfur speciation in old and modern woods (see Jalilehvand, this volume).

Archeological studies require some extensive, multi-disciplinary studies, as the number of samples can be high and highly valuable (so undestructive). Also μ-techniques are useful to scan the sample heterogeneities, which can help highly to provide more clues on origins, uses and goals of the artifacts probed. For instance, extensive corrosion studies of Celtic weapons require a thorough study of the pre-edge feature of Fe at its K edge. From the pre-edge feature, accurate mapping of the iron redox can be achieved, which evidence, in the case of these weapons, some very localized areas (microns) of less corroded metal. Such characteristics can be used as tracers for some past technologies, commercial exchanges, creative actions (composers) or even legends. Surprisingly, we observed that reference studies are missing to help archeologists to perform their characterization in a robust manner. For instance, few studies exist to accurately determine the redox state of Mn from the analysis of its pre-edge feature at the K-edge.

Similarly, manganese shows large variation in redox and speciation, due to the large number of possible redox states that Mn can adopt under ambient conditions (metal, II, III, IV, V, VI and VII). As a result, studies of artifacts in which manganese plays a key role (such as pigments) are essential to trace past technologies. However, extensive studies of the redox of manganese are lacking. They might be useful also for other domains such as geochemistry and material sciences. In this study, we present a XANES study of a large number of Mn-bearing mineral samples in which the pre-edge feature is understood under the light of *ab initio* calculations. The obtained results are applied to the study of black prehistorical paintings (in which manganese dominates) and in medieval glasses (in which manganese is diluted at the 1–2 wt.% level).

2. Experimental

Mn K-edge XANES spectra for model compounds and archeological artifacts (pigments and glasses) were collected under high resolution conditions (∼0.6 eV) at SSRL (Stanford, USA) using beamline 11-2, Si(220) double-crystal monochromator, 0.3 vertical height for the slits before and after the monochromator. The energy reproducibility of the monochromator is ∼0.05 eV. Pre-edge features were collected using 0.1 eV steps whereas the main edge crest were collected with 0.3 eV steps to 300 eV above the absorption edge. Self-absorption effects were taken into account as the archeological samples could not be optimally prepared. Then, the XANES spectra were collected in the fluorescence mode. Several model compounds were used to check the accuracy of these corrections (using the code FLUO [3] and transmission data). In parallel, micro-XANES spectra were collected in order to map at the micron scale the manganese speciation. A Si(111) monochromator and a Fresnel focusing device were used at the ID21 beamline at ESRF (Grenoble, France). Spectra were collected in the fluorescence mode using a pin-diode and, when necessary corrected for self-absorption.

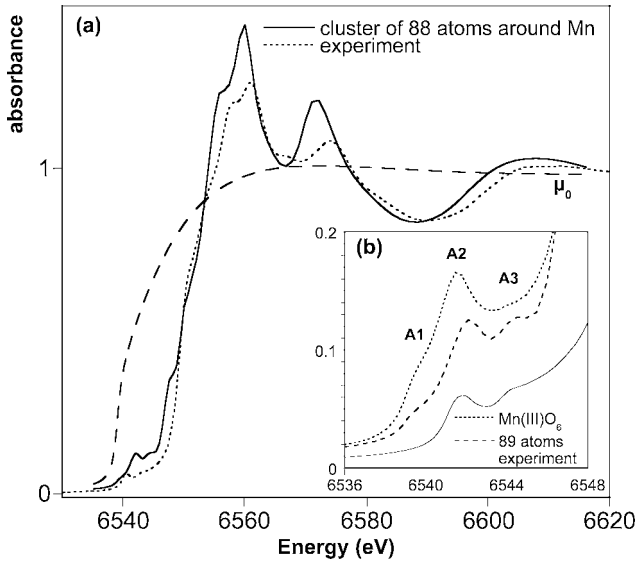

Fig. 1. (a) XANES and (b) pre-edge feature in manganite, (Mn(III)OOH): experimental (solid lines) versus *ab initio* calculations (FEFF, dotted lines), showing the importance of next-nearest manganese neighbors in the pre-edge feature (feature A3).

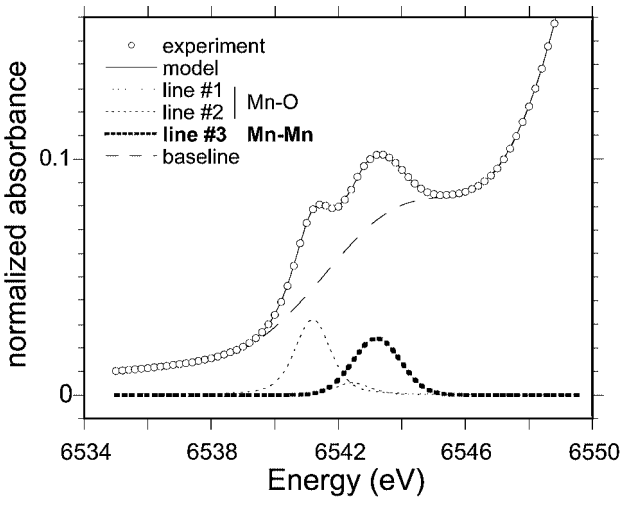

Fig. 2. Example of pre-edge model for Mn(IV), considering lines related to the Mz-O moiety and lines related to more distant Mn neighbors.

Mn-bearing model compounds include numerous oxides and silicates, natural or synthetic, well characterized and containing Mn(II,III,IV,V,VI,VII) in octahedral, square planar, cubic or tetrahedral geometry. The archeological artifacts include black pigments from the Lascaux cave (Dordogne, France – 18,000 years old) and medieval glasses (more or less weathered) from various gothic buildings (XIVth century BC) from Normandy (France) such as Ste Opportune du Bosc.

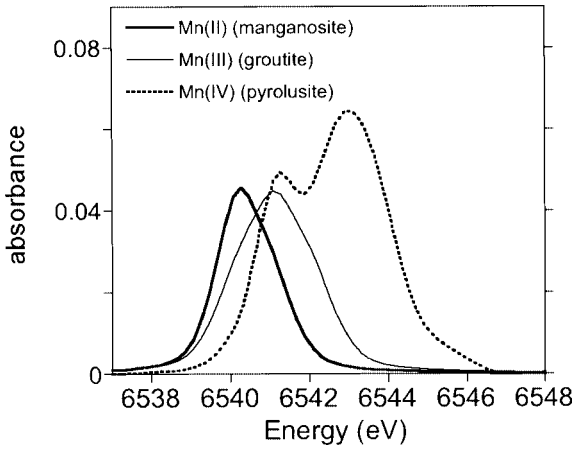

Fig. 3. Shift of the normalized pre-edge feature with Mn-redox, when transitions related to distant Mn are excluded.

3. Results

3.1. *Model compounds*

Figure 1a shows normalized, self-absorption corrected XANES spectra collected at the manganese K-edge in a typical model compound, namely Mn(III)OOH. Figure 1b shows its normalized pre-edge, obtained using a method described elsewhere [4]. The obtained pre-edge features for a given redox and geometry shows large variation among themselves, suggesting that the Mn-speciation is not the only contributor to the spectra. This is confirmed by *ab initio* calculations of the XANES (including the pre-edge feature assuming dipolar and quadrupolar transitions) performed using the FEFF8.28 package [5]. When the medium-range environment around manganese is included in the model, the pre-edge feature area increases, sometimes up to a factor 2. Multiplet calculations performed by F. de Groot on Mn(II,III,IV)O_6 clusters (*pers. comm.*) also confirm this observation: the calculated pre-edge with multiplets is, especially for Mn(IV), much smaller in area than that measured. A similar phenomenon was already observed for Fe-bearing oxides, for which the pre-edge features show transitions related to next-nearest Fe neighbors [6]. Based on these observations, we could find a strategy to consider only the transitions in the pre-edge feature related to the Mn-speciation (redox and geometry). In order to achieve this, we modelled the pre-edge with pseudo-Voigt lines with a fixed width and Gaussian percentage (1.3 and 45%, respectively). Only the first lines (2 for Mn(II) and Mn(III) and 3 for Mn(IV)) were taken into account (see Fig. 2) to derive robust redox and geometric information. As for Fe [4], the pre-edge information must be calculated based on the pre-edge centroid (weighted by the respective area of each line) versus its integrated area. When taken into account, the Mn pre-edge centroid shifts nearly linearly with redox (Fig. 3) and follows *ab initio* predictions.

3.2. *Prehistorical paintings*

Mn K-edge XANES spectra were normalized following the same protocol as the one for the model compounds. The samples were previously characterized using a wide combination of other methods, such as imaging (TEM and SEM, transmission and scanning electron microscopies, respectively), diffraction (electronic) and chemistry (EDXS and PIXE, energy dispersive and particule induced X-ray spectroscopy/emission, respectively). PIXE information was used to provide chemical information required for self-absorption corrections. For instance, two pigments from the "Great Black Bull" (GLAS65) and the "bichrome horse" (GLAS66) from the Painted Gallery (Fig. 4) show large differences in manganese speciation related to the

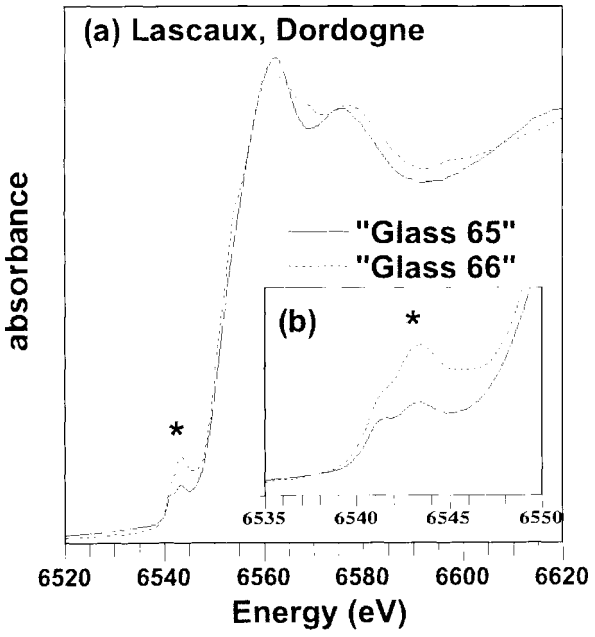

Fig. 4. Mn K-edge XANES spectra for 2 Lascaux pigments from the "Great Black Bull" (GLAS65) and the "bichrome horse" (GLAS66) from the Painted Gallery, showing changes in the XANES (a) and in the pre-edge feature (b) related to the presence of romanechite and pyrolusite.

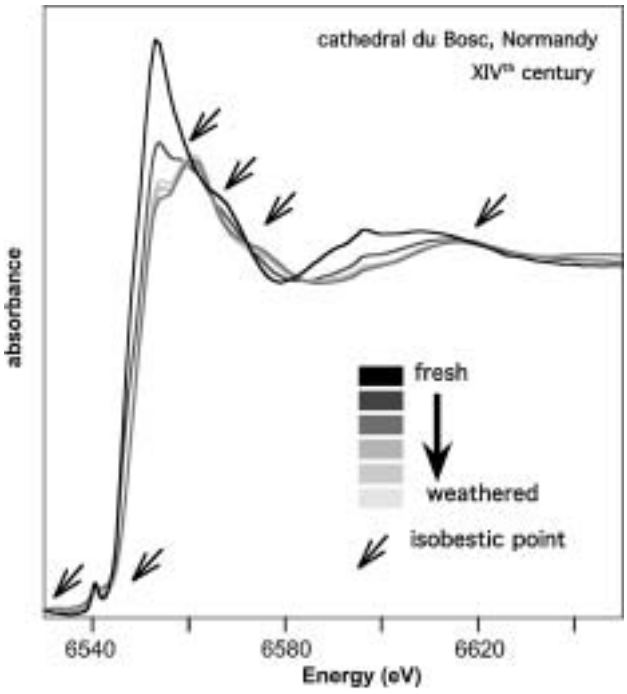

Fig. 5. XANES Profile at the Mn K-edge as a function of the glass thickness for a medieval glass window exposed to progressive weathering (from dark – "fresh" glass to light "weathered"). The data shows an oxidation of manganese from II to IV, which resulted in precipitation of manganese oxi-hydroxides at the origin of the darkening of the building. Isobestic points shows the number of knots in that data set of 6 spectra, suggesting that 2 end members can be extracted by inversion as suggested by PCA analysis.

presence of romanechite and pyrolusite. However, neither the XANES nor the morphological studies performed for these samples evidence the presence of any heating that would have modified the texture of these pigments prior to the painting [7]. 2D mapping experiments of the manganese K-edge XANES were carried out and are still under reduction to determine if some other paintings were manufactured from primary Mn-ore or from heat-treated ores.

3.3. *Medieval glasses*

Several medieval glasses were examined to study the weathering of the glass windows. Since the XIVth century, these glasses suffered from corrosion, especially the ones exposed to the outside (corrosion from water, pollution, seasonal changes etc.). Some samples were recovered from the building and show a progressive corrosion, as a function of their exposition to weather. Manganese K-edge spectra (Fig. 5) show a progressive shift of the Mn K-edge from the "fresh", unweathered glass (protected) to the highly corroded areas of the glass. In the fresh glass, manganese is divalent (as in most glasses) and in a "silicate"-type environment. When weathered, manganese oxidizes to +IV and forms environments close to these for manganese oxi-hydroxides (this promotes a surficial enrichment in manganese). A Principal Component Analysis of these spectra reveals that 2 end members can be extracted by inversion. These pure end-members (fully fresh and fully weathered) confirm these trends. This explains why the inside luminosity of medieval building is affected by the precipitation of these complex manganese hydroxides. Similar observations were made at the iron K-edge, where ferrihydrite-type materials precipitated in the corroded zones.

4. Conclusions

The availability of optimized sources, providing high-resolution, low noise and focusing techniques makes it an unique tool to study highly valuable samples from archaeologists. However, more methods (to diagnose reliably redox and speciation) are needed to help the archaeologists to accurately interpret their data. The main information that synchrotrons can provide is less matter/beam interaction (as compared to proton or electronic sources), drastic improvements in beam source, optics and detection. If "standard" laboratory methods are still required to first investigate these samples, X-ray absorption methods provide important information on redox and environments that can be used to source an origin or a technology. In some other cases (such as for medieval glasses presented here), archeological artefacts provide an interesting outlook on how materials can be preserved or react to ageing. This information is also important for curators to conserve their artefacts or for physicists and chemists to better understand material durability (for nuclear wastes for instance).

Abstract

Natural manganese oxide nanoparticles and grain coatings are ubiquitous in the environment and profoundly impact the quality of sediments via their ability to degrade and sequester contaminants. These oxides are believed to form dominantly via oxidation of Mn(II) by marine and freshwater bacteria and have extremely high sorptive capacities for heavy metals. We have used XANES, EXAFS, and synchrotron (SR)-XRD techniques to study biogenic manganese oxides produced by spores of the marine *Bacillus* sp., strain SG-1 in sea water as a function of reaction time under fully *in-situ* conditions. The primary biogenic product is a nanocrystalline solid with an oxidation state and layered phyllomanganate local structure similar to that in δ-MnO_2. XRD data show the biooxides to have a phyllomanganate 10 Å basal plane spacing, suggesting the interlayer is hydrated and contains calcium. Fits to EXAFS spectra suggest the octahedral layers of the biooxides to be relatively flat (out-of-plane bend $<10^{\circ}$) and to have relatively low octahedral layer Mn site vacancies (12 to 14%). These results suggest that aqueous Ca^{2+} is inserted into the biogenic oxide structure after completion of the enzymatic oxidation process. The biooxides observed in this study may be the most abundant manganese oxide phase suspended in the oxic and sub-oxic zones of the oceanic water column.

1. Introduction

Bacterially generated Mn oxides are ubiquitous in natural waters as reactive nanoparticles and grain coatings and have profound impacts on contaminant degradation, nutrient cycling, and carbon cycling in the environment. They have high sorptive capacities for metal ions, can degrade toxic organic contaminants, including aromatic hydrocarbons, and oxidize a variety of inorganics, e.g., Cr(III), Co(II), and hydrogen sulfide. Sequestration of dissolved heavy metals during Mn oxide biogenesis is believed to be a key mechanism for attenuation of contaminants in polluted waters. The most important pathway for environmental Mn oxidation is believed to be catalytic oxidation of Mn(II) by freshwater and marine bacteria [1–3]. Understanding the chemical mechanism(s) by which this process occurs is therefore crucial to understanding the cycling of essential and toxic trace constituents in the environment. In spite of their importance, relatively little is known about the mechanisms and products of bacterial Mn oxide biogenesis.

Our overarching goals are to define the mechanisms of bacterial Mn(II) oxidation and the structures, compositions, and reactivity of the resulting biooxides. In addition, manganese oxides are important reactive components of the oceanic water column, and we seek their identities and properties. We have previously investigated the products of bacterial Mn(II) oxidation in 50 mM NaCl solutions [4–6]. This work indicated that the primary biogenic oxidation product is a poorly crystalline phyllomanganate oxide with local structure and oxidation state similar to δ-MnO_2. We extend this work here to investigate how these reactions proceed in sea water (SW), which contains relatively high concentrations of dissolved magnesium (60 mM) and calcium (10 mM). Both solutes can react with manganese to form tunnel-structured manganese oxides such as todorokite. We seek to investigate whether such phases are created during bacterial Mn(II) oxidation, and to discern the implications for bacterial Mn(II) oxidation mechanisms.

2. Methods

SG-1 spores were incubated in 10 µM Mn(II) (added as $MnCl_2{\cdot}4H_2O$) in filtered (0.2 µm pore diameter) sea water (SW) obtained from the Scripps Pier. Experiments were started by adding approximately 1.3×10^{10} spores to each incubation vessel resulting in 2.2×10^6 spores $\cdot$ mL^{-1}. The sampling times for the experiment ranged from 6 to 80 hours. For each time point the entire sample was harvested by settling and centrifugation (4 °C). Samples were stored at −20 °C in about 10 mL of their original medium until analysis.

Mn K-edge XAS spectra were collected at room temperature from wet homogeneous spore-biooxide samples in rigid thermoplastic sample holders at SSRL beamline 4-3, which was equipped with a Si(220) monochromator and harmonic rejection mirror set at a 9 keV cut-off energy. Data were collected in transmission geometry to eliminate spectral distortion from self absorption, which is unavoidable and substantial in fluorescence data. Spectra were background subtracted and splined using the SIXPack software [7]. Linear combination fitting and EXAFS fitting were also performed with SIXPack. Energy was allowed to float by up to 0.15 eV during fits. In comparison, the energy difference between birnessite and δ-MnO_2 is about 0.4 eV. Model compound spectra were fit as unknowns, the results of which were fit with a linear regression to obtain the following:1-sigma error estimates: +/−1.7% for Mn(II), +/−2.6% for Mn(III) oxides, and +/− 2.9% for Mn(IV) oxides. These estimates are substantially larger than the ESDs obtained from individual fits (which typically had values of ∼0.5%). Phase and amplitude files for the EXAFS fitting were created with FEFF7 [8]. Mn EXAFS were fit using a model based on a layered phyllomanganate structure [6], which follows the concept used previously by Ressler *et al.* [9] and explicitly accounts for splitting of the Mn-O and Mn-Mn distances in the structure due to Jahn-Teller distortions, angular deviations from planar sheets (particularly important with Mn-Mn multiple scattering), aqueous and spore-bound Mn(II), Mn bound to the surfaces of Mn oxides, and vacancies present in the manganese octahedral layer. This model has been tested on relevant model spectra (birnessite, δ-MnO_2, and

*e-mail: bargar@ssrl.slac.stanford.edu

todorokite) and found to fit the EXAFS up to $R + \mathrm{SR} \sim 5.5$ Å for samples with good data up to k of 15 Å^{-1}.

X-ray diffraction intensity data were collected on wet solids in transmission geometry using the two-circle diffractometer on SSRL beamline 2-1 using a Bicron NaI detector equipped with Soller slits. The incident X-ray beam was tuned to 10 keV ($\lambda = 1.24$ Å) to improve beam penetration in to the wet samples and to provide Q-space access up to about 15 Å^{-1}. Wet sample slurries were placed in an aluminum sample cell with lexan windows. The diffractometer was calibrated with LaB_6 and has a 0.04° 2θ fwhm resolution. Data were collected in Q-space 0.004 Å^{-1}intervals in dose mode of 10,000 counts per point. Several scans were added together to improve signal to noise ratios for interesting regions.

3. Results and Discussion

Results from linear combination fits to Mn K-edge XANES spectra are summarized in Figure 1. Only Mn(II) (intracellular Mn(II) in clean spores) and δ-MnO_2 spectra were required to fit all sample spectra. Mn(III)-bearing phyllomanganates (birnessite, todorokite) were attempted as components in fits, but the amplitude of these components floated to zero during fitting. In addition, the edge intensity maximum (*i.e.*, the "white line") occurs at the same energy as obtained in δ-MnO_2. These observations suggest that the manganese local structure is similar to that in δ-MnO_2 (*i.e.*, a defected phyllomangante structure [10]) with an oxidation state close to Mn(IV). The proportion of δ-MnO_2 in the samples reaches 100% within 80 hours of reaction. This apparent oxidation rate is faster than obtained in 50 mM NaCl solution [4, 6]. The faster rate can be attributed to the presence of Ca^{2+}, which enhances the activity of the manganese-oxidizing enzyme [4].

The XRD intensity data for the 12 and 80 hour samples is shown in Figure 2. Prominent in the pattern are a 10.0 Å basal plane (001) reflection and a 5 Å (002) reflection. The presence of these reflections suggests the oxide to be a phyllomanganate, while the broad peaks indicate a very small particle size in the c stacking direction [11]. A basal plane spacing of 10.0 Å has previously been reported for a calcium-substituted phyllomanganate (*i.e.*, "Ca buserite") [12], for which Ca^{2+} was bound at interlayer sites.

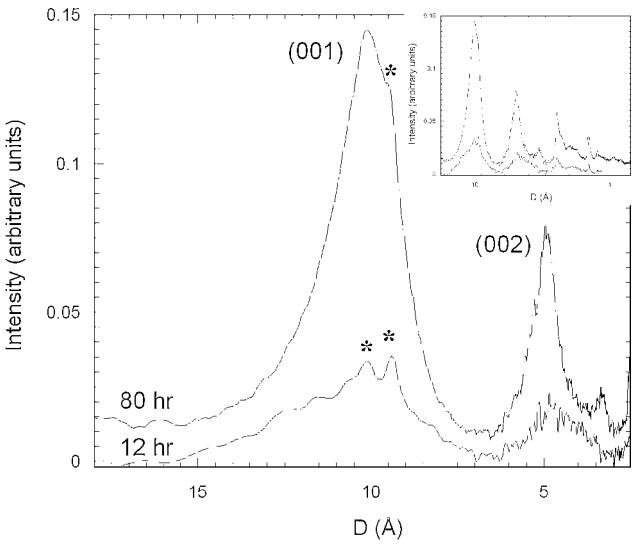

Fig. 2. X-ray diffraction intensity data for the 12 hr (bottom) and 80 hr (top) spore-biooxide samples. Inset gives the entire data range. *This peak/shoulder is from an unidentified trace compound in the spores.

Table I. *Summary of model parameters from the Mn K-edge EXAFS fitting results for the 6 and 80 hr spore-Mn(II) incubation samples. * Describes the fraction of the total Mn sites in the manganese octahedral layer that are unoccupied. † Describes the out-of-plane bend of the manganese octahedral layer in the direction parallel to the a axis. ‡ Describes the out-of-plane bend of the manganese octahedral layer in the direction parallel to the b axis.*

Sample	Vacancies (%)*	Out-of-plane bend angle (a-axis)†	Out-of-plane bend angle (b-axis)‡
6 hr	14	5°	0°
80 hr	12	10°	0°
todorokite	40	6°	19°
δ-MnO_2	23	0°	0°
birnessite	23	15°	0°

Biogenic mangese oxides prepared in the absence of dissolved Ca(II) (*i.e.*, in 50 mM NaCl solutions [4, 6]) did not exhibit any 10 Å basal plane reflections. The correlation between the 10 Å basal plane reflection in the sample XRD patterns and the presence of calcium suggests that the 10 Å stacking structure of the biooxide prepared in SW is controlled by incorporation of Ca^{2+} at interlayer sites.

Major details of the EXAFS fits to the 6 and 80 hour samples are summarized in Table I and fits are shown in Figure 3. We focus our discussion here on parameters specific to the linear multiple scattering Mn-Mn-Mn path in the manganese octahedral sheet, which has an effective scattering distance of about 5.5 Å. The amplitude of the linear multiple scattering feature is sensitive to bending of the manganese octahedral layer (*i.e.*, non-linear Mn-Mn-Mn angles) and to manganese site vacancies, both of which reduce multiple scattering intensity [9]. Fit-derived parameters for out-of-plane bend and manganese layer site vacancies are therefore a sensitive metric for comparing structures to one another and to triclinic birnessite, a phyllomanganate, and todorokite, a 3 × 3 tunnel-structure tektomanganate [11]. Todorokite has apparently high out-of-plane bend and relatively large vacancies due to the fact that it does not have continuous

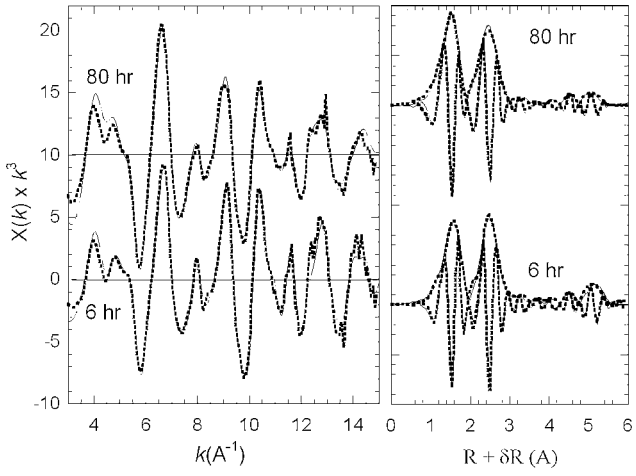

Fig. 3. EXAFS spectra and Fourier transforms (magnitude and imaginary component) (dotted lines) and fits (solid lines) to the 6 and 80 hour samples.

manganese octahedral layers. We refer the reader to Ressler *et al.* [9] for a detailed discussion of this model concept.

A summary of these fitted EXAFS parameters for the samples is provided in Table I. The octahedral layers in the biooxides (out-of-plane angles of 0° to 10°) less rumpled than in birnessite (0° to 15°) or todorokite (6° to 19°). The biooxides have a lower concentration of layer vacancies (12–14%) than δ-MnO_2, birnessite, or todorokite (23–40%). Vacancy values have a strong inverse correlation to particle size (*i.e.*, edge vacancies) for very small particle sizes. Thus a lower apparent vacancy concentration suggests larger particle sizes in addition to highly occupied layer structures.

4. Conclusions

Manganese biooxides are rapidly produced in sea water by reaction of Mn(II) with spores of the marine *Bacillus* sp., strain SG-1. XANES and EXAFS spectra and XRD intensity data indicate that the primary biogenic oxides are finely particulate phyllomanganates having a 10 Å basal plane spacing. Comparison of the present results to previously reported lattice constants for calcium-substituted phyllomanganates and to XRD data reported for biooxides produced in the absence of dissolved Ca^{2+} suggests that Ca^{2+} binds in the interlayers of the 10 Å biooxides. No other solid phase is identified in the samples over the time scale examined. EXAFS fits indicate that the biooxides have relatively high manganese octahedral layer site occupancies in comparison to other phyllomangantes (birnessite and δ-MnO_2) and only moderate out-of-plane bending of the octahedral layer.

Bacterial oxidation of Mn(II) by SG-1 spores generally does not require net consumption of calcium relative to Mn(II) and calcium is therefore not required to be present in the biooxides. SG-1 spores readily oxidize Mn(II) in calcium-free solutions to produce poorly crystalline δ-MnO_2-like biooxides with no basal plane reflections [4, 13]. Therefore, it is interesting that the primary biogenic product identified in the present study appears to contain calcium. This observation implies that calcium is acquired by the biooxide structure after completion of the enzymatic oxidation process.

Bacillus sp., strain SG-1 is a marine bacterium and a good general model for microbial manganese oxidizers. It is therefore likely that the 10 Å biooxide observed in this study could be one of the most abundant manganese oxides in the oceanic water column.

Abstract

Although Absorption Edge Spectroscopy has been widely applied to the speciation of actinide elements, specifically at the L_{III} edge, understanding and interpretation of actinide edge spectra are not complete. In that sense, semi-quantitative analysis is scarce. In this paper, different aspects of edge simulation are presented, including semi-quantitative approaches. Comparison is made between various actinyl (U, Np) aquo or hydroxy compounds. An excursion into transition metal osmium chemistry allows us to compare the structurally related osmyl and uranyl hydroxides. The edge shape and characteristic features are discussed within the multiple scattering picture and the role of the first coordination sphere as well as contributions from the water solvent are described.

1. Introduction

X-ray Absorption Near Edge Spectroscopy has long been used in a phenomenological approach as a fingerprint of the absorbing atom polyhedron geometry and electronic state. This approach is particularly useful to gather structural information when EXAFS data are not possible to collect. In some cases, the edge spectrum can also be informative about the spin density or central atom formal or effective charge. Many works have aimed at simulating and better understanding the edge features, especially in the case where the absorbing atom is a transition metal. Both phenomenological and *ab initio* approaches have been used in order to identify the edge features.

It is well beyond the scope of this paper to detail all the work that has been achieved in this area and in the present paper the authors intend to focus on the analysis of the absorption edge of actinide cations within actinyl molecular adducts. Because most of the early actinide cations (except Th) with oxidation states higher than IV form the actinyl AnO_2^{n+} ($n = 1, 2$) transdioxo entity, they are of technological and environmental importance [1]. Furthermore, the ubiquity of the uranyl cation in the geosphere, because of its remarkable stability, makes it one of the most extensively investigated cations within the actinide family. The major characteristic of actinyl cations is the occurrence of quasi linear O-An-O units with a short An-O multiple bond ranging from 1.7 to 1.9 Å in length, depending on the cation. This characteristic is also specific to the actinide family as only one analogue (the osmyl cation OsO_2^{2+}) is stable in the d block [2]. This is a good evidence of this specific type of bonding which involves significant participation of the 5f and 6d orbitals in the valence orbitals of the AnO_2^{n+} unit [3–6].

According to the selection rules associated with the dipolar transition of the absorption process, several final states can be probed in the case of actinides. Going from high to low energy (or from low to high primary quantum number of the initial state), L_I ($2s^27p^0 - 2s^27p^1$ transition at c.a. 21760 eV for U) or L_{III} edges ($2p^66d^0 - 2p^56d^1$ transition at c.a. 16730 eV for U) are particularly informative about the geometrical arrangement of the coordination sphere because of strong multiple scattering features [7, 8]; the M_{III} edge ($3p^66d^0 - 3p^56d^1$ transition at c.a. 4300 eV for U) shows the same features as the L_{III} edge with a reduced core hole life time broadening; $M_{IV,V}$ or $O_{IV,V}$ edges ($3,5d^{10}5f^n - 3,5d^95f^{n+1}$ transition at c.a. 3700 eV and 100 eV for U) allow one to probe directly the 5f states of the cation [9, 10]. In the search for a better understanding of the bonding properties of the actinyl cation with its ligands, a complementary analysis of the various absorption edges is needed, assuming that the technical experimental conditions related to actinide studies are met.

2. Experimental

Part of the experimental conditions related to either sample preparation or data acquisition have already been reported in the literature and will be referenced in the course of the article. For the osmium samples OsO_4(aq) (0.16 M) was prepared from solid OsO_4 (Acros Inc.) in KOH (1.6 M) solution. $OsO_2(OH)_4K_2$ was prepared from the above solution with addition of 0.5 ml of ethanol. A pink-red precipitate appeared readily. RAMAN spectra (not shown) were recorded for sample characterization. Os XANES spectra were recorded at the LURE facility (DCI ring) on the D44 experimental station using a double crystal Si(111) monochromator (calibration at the L_{III} edge of W). Spectra were recorded in transmission mode with air filled ion chambers.

XANES simulations were performed with versions .1 and .2 of the Feff8 code [11, 12]. All the simulations were performed with similar parameters using self consistentcy, full multiple scattering or path expansion (XANES 6 0.07 0.5; SCF x 0 30 0.05 10; FMS y 0; FOLP 0 1.15; UNFREEZEF; EXCHANGE 0 0 1) where x is the cluster size taken into account in the SCF loop and y is the cluster size taken into account in the FMS procedure. Clusters used for simulation were $UO_2(O)_4$ for solid state uranyl hydroxide; $OsO_2(O)_4$ for solid state osmyl hydroxide; $[OsO_4]_5$ for osmium tetra oxide in aqueous solution from crystallographic data [13]; $NpO_2(O)_4$ and $NpO_2(OH)_4$ for neptunyl hydroxide in aqueous solution in a 20 Å water box from molecular dynamics simulation.

Molecular dynamics simulations of neptunyl hydroxide in aqueous solution (AMBER6) have been carried out from the starting NpO_2O_4 cluster (fixed geometry). Optimization of the

*e-mail: christophe.denauwer@cea.fr

hydrogen atoms to complete the Np coordination sphere as well as the water molecules in a 20 Å box has been carried out. Note that for the Feff simulations, only one snapshot of the molecular dynamics simulation has been considered.

3. The edge spectrum as a fingerprint of the actinyl polyhedron

At the starting point of this investigation we have noticed the structural similarities between the uranyl cation and the osmyl cation (both at formal oxidation state VI) in their solid state hydroxide form. Both compounds exhibit two short axial M-O bonds in agreement with the "yl" structure and larger equatorial M-L bonds. In the case of $UO_2(OH)_2$ (Schoepite) and $OsO_2(OH)_4K_2$, 4 oxygen atoms are present in the equatorial plane (distorted in the case of Schoepite [14]). The EXAFS data fitting has given the following structural parameters : uranyl 2 O @ 1.76 Å, 2 O @ 2.31 Å, 2 O @ 2.47 Å in agreement with the literature [15]; osmyl 2 O @ 1.75 Å, 4 O @ 2.02 Å. It is now well known that all the actinyl adducts exhibit a characteristic high energy shoulder at the L_{III} edge (at c.a. 15 eV above the white line, depending on the distances [16]). This shoulder as been identified using multiple scattering theory as the sum of multiple scattering paths within the linear transdioxo unit O-An-O. Figure 1 compares the experimental absorption edges of solid state $UO_2(OH)_2$ [17] and $OsO_2(OH)_4K_2$ with the corresponding simulated spectra. The difference in intensity and sharpness between the two white lines A and A′ can be attributed to two factors : the core hole life time difference between uranium (7.4 eV [18]) and osmium (5.2 eV [18]) plus the localization effect of the 6d (uranium) or 5d (osmium) states. From a path expansion analysis, feature B (and B′) has been attributed to the transdioxo unit O-Os-O, and feature C to the triangular Os-O_{ax}-O_{eq} paths (which is 8 time degenerated within the square planar geometry around Os). The agreement between the experiment and the simulation is better in the case of uranyl than of osmyl. This is not yet fully understood. The difficulty might arise from the high symmetry of the osmyl coordination that leads to numerous scattering paths with only slight differences in scattering length (4-leg paths O-Os-O = 3.5 Å; 3-leg paths Os-O_{ax}-O_{eq} = 3.2 Å).

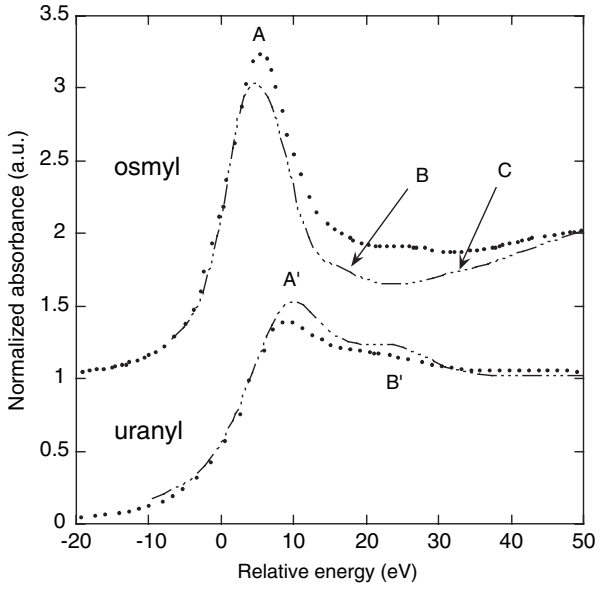

Fig. 1. Experimental (● ● ●) and simulated (—● ● ●—) (feff8.2, $x = y = 2.6$ Å) L_{III} edges of solid state $UO_2(OH)_2$ (uranyl) and $OsO_2(OH)_4K_2$ (osmyl). The experimental and simulated spectra have been shifted in energy with respect to their inflexion point value.

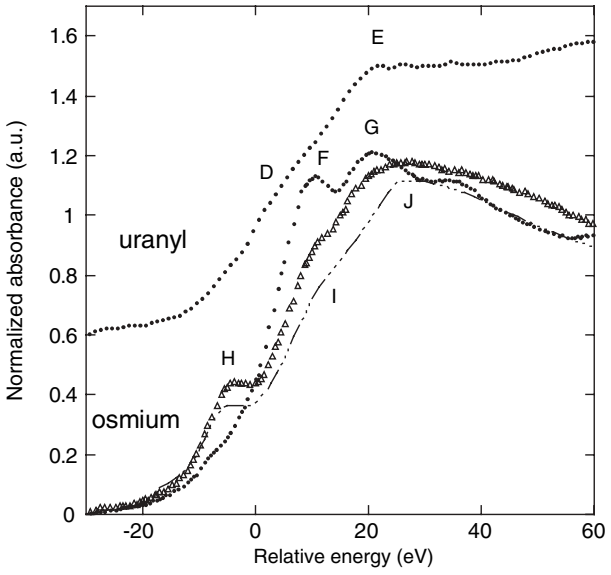

Fig. 2. Experimental L_I edges of OsO_4 in aqeous solution (ΔΔΔ), solid state $OsO_2(OH)_4K_2$ (● ● ●) and $UO_2(NO_3)_2.6H_2$ (● ● ●). Comparison is made with the simulation of OsO_4 (—● ● ●—) (feff8.2, $x = y = 3.5$ Å). The experimental and simulated spectra have been shifted in energy with respect to their inflexion point value.

At the L_I edge (see Fig. 2) the white line intensity is dramatically reduced. In the case of solid state uranyl nitrate, features D and E have been attributed respectively to the scattering contributions from the axial oxygens and from the equatorial oxygens [8]. For osmyl hydroxide, the absorption edge exhibits much sharper features F and G. To date, the simulation of this edge within a path expansion formalism has failed and features F and G have not been described. At the oxidation state VIII, osmium tetra oxide in aqueous solution is a slightly distorted tetrahedron by comparison with the solid state structure [13] (Raman spectra and EXAFS fitting have confirmed the structural similarity) with Os-O distances around 1.71 Å. The L_I edge of OsO_4 in aqueous solution exhibits the well known pre-edge feature attributed within the molecular orbital picture to a transition to the allowed hybridized 5d-6p manifold [19]. Within the multiple scattering picture, feature H (Fig. 2) can be built from constructive 3-leg (triangular Os-O-O′) and 4-leg (Os-O-Os-O) scattering paths (10 paths) within the tetrahedron, and feature I can be identified as arising from 3-leg paths (9 paths) including the oxygen atoms of vicinal tetrahedrons. With this procedure, a total of 27 paths is needed to reproduce the full multiple scattering calculation.

In aqueous solution, simulation of the actinyl absorption edge using a simple model cluster often lacks the influence of the solvent molecules. Similar to the osmyl coordination sphere in the solid state, the neptunyl(VI) polyhedron in basic aqueous medium [20] is composed of 2 axial oxygens at 1.82 Å and 4 O at 2.21 Å [21]. Comparison between Figures 1 and 3 shows that the position of the high energy shoulder B depends on the cluster geometry [16]. The intensity of white line A is poorly reproduced in the simulation when only 7 atoms are considered in the cluster ($x = y = 2.5$ Å) : $NpO_2(O)_4$. In order to position the hydrogen atoms around each oxygen of the 4 OH ligands as well as water molecules to mimic the solvent medium, a molecular dynamics calculation has been carried out, starting

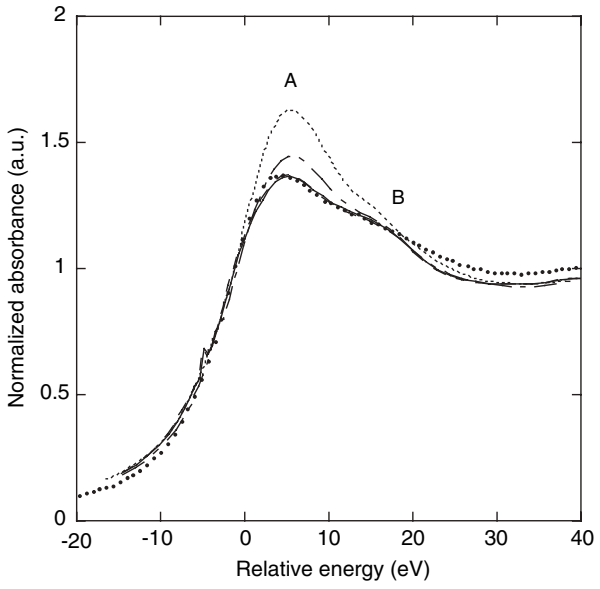

Fig. 3. Experimental (• • •) L_{III} edge of neptunyl hydroxide in aqueous solution compared to the simulation (feff8.1) of *i*) the $NpO_2(O)4$ cluster (· · · · · · · ·) ($x = y = 2.5$ Å); *ii*) the $NpO_2(O)_4$ cluster within a water box of 20 Å (— – —) ($x = y = 3.4$ Å); *iii*) the $NpO_2(OH)_4$ cluster within a water box of 20 Å (— —) ($x = 3.4$, $y = 2.5$ Å) and *iv*) the $NpO_2(OH)_4$ cluster within a water box of 20 Å (———) ($x = y = 3.4$ Å).

from $NpO_2(O)_4$. In a first step a better simulation of the edge was obtained when only the water solvent molecules were added around the 7 atom $NpO_2(O)_4$ moiety, up to 20 Å ($x = y = 3.4$ Å). This suggests an improvement in the potential calculation due to continuity around the atoms included in the SCF loop. In a second step the 4 hydrogen atoms of the 4 hydroxy ligands were also included as a second coordination sphere. Definite satisfactory agreement between the experiment and the edge simulation was then achieved ($x = y = 3.4$ Å). The same result was obtained with the above cluster and only the $NpO_2(O)_4$ moiety included in the FMS routine ($x = 3.4$, $y = 2.5$ Å). This confirms the influence of the cluster size in the calculation of the potentials. Furthermore it suggests that the hydrogen atoms of the 4 OH ligands play no or a negligible role in the scattering process.

4. Conclusion

Within the multiple scattering picture, L_{III} edges of the actinyl adducts have been satisfactorily simulated. Consideration of the 5d transition metal series shows that the structurally related osmyl hydroxide compound exhibits a significantly different L_{III} edge. This is attributed to slight structural differences between osmyl and uranyl hydroxide, and differences in core hole life time and localization of the 5d *versus* 6d states. From the bipyramidal osmyl hydroxide to the tetrahedral osmium tetra oxide, the L_I pre-edge feature can be used as a fingerprint of the polyhedron geometry. In addition to the well known molecular interpretation of the pre-edge transition, it has been simulated within the multiple scattering picture.

As suggested by the simulation of neptunyl hydroxide in aqueous solution, inclusion of second coordination sphere atoms as well as solvent molecules is essential in order to obtain reliable potentials. Thus, inclusion of a tridimensional network around the $OsO_2(O)_4$ moiety should improve the simulation of the osmyl hydroxide compound. Finally, quantum chemical calculations are being carried out on both uranyl and osmyl hydroxide in order to compare the valence orbital properties and in particular the 5d and 6d states.

Acknowledgments

This research was mainly carried out at the Laboratoire d'Utilisation du Rayonnement Electromagnétique (Orsay, France) a national user facility operated by CEA/CNRS/MR and the Stanford Synchrotron Radiation Laboratory (Stanford, USA), a national user facility operated by Stanford University on behalf of the U.S. Department of Energy, Office of Basic Energy Sciences. This work has been financially supported by CEA/DEN, PRACTIS (France) and by DOE OBES Division of Chemical Sciences under Contract W-7405 (USA).

Abstract

We combined X-ray absorption near edge spectroscopy (XANES) and extended X-ray absorption fine structure (EXAFS) spectroscopy to determine the coordination chemistry of methyl mercury (CH_3Hg) in natural organic matter from an organic soil (OS), potentially soluble organic matter extracted from the soil (PSOS) and in a humic stream draining the soil (SOS). The sum of concentrations of highly reduced organic S groups (Org-S_{RED}), such as thiol (RSH), sulfide (RSR) and disulphide (RSSR) was 39, 42 and 47% of total S in SOS, PSOS and OS, respectively. No traces of inorganic sulfides were detected. Hg L_{III}-edge EXAFS analysis were determined on samples added CH_3Hg to yield CH_3Hg/Org-S_{RED} ratios in the range 0.01–1.62. At low ratios Hg was associated to one C atom (the methyl-group) at an average distance of 2.03 ± 0.02 Å and to one S atom at an average distance of 2.34 ± 0.03 Å, in the first coordination shell. At higher CH_3Hg/Org-S_{RED} ratios RSH groups were saturated and O and/or N atoms gradually took part in the bonding. Based on the assumption that RSH is the only S group accounting for the very strong complexation of CH_3Hg, approximately 17% of total organic S consisted of RSH groups in the organic soil, 14% in potentially soluble organic matter extracted from soil and 9% in aquatic organic matter.

1. Introduction

Mercury released into the atmosphere by combustion of fossil fuels may be long-range transported as $Hg^0(g)$. After oxidation to Hg^{2+}, mercury is deposited and partly transformed to methyl mercury (CH_3Hg) in wetlands and soils [1]. Subsequent accumulation of the highly bioavailable methyl mercury in organisms (e.g. fish) is a severe environmental problem in regions dominated by forest and wetlands [2, 3]. In order to understand mechanisms behind the formation and decomposition of methyl mercury, as well as how it is transported and made available for organisms in soils and waters, detailed information about the coordination chemistry of mercury and methyl mercury in natural organic matter (NOM) is crucial. We combined sulfur K-edge X-ray Absorption Near Edge Spectroscopy (K-XANES) and mercury L_{III}-edge Extended X-ray Absorption Fine Structure (L_{III}-EXAFS) spectroscopy in order to determine the coordination chemistry of methyl mercury in stream and soil NOM. Sulfur XANES was used to quantify the concentration of reduced sulfur groups (Org-S_{RED}). The same samples were added CH_3Hg to collect Hg EXAFS at varying Org-S_{RED}/CH_3Hg ratios.

2. Material and methods

2.1. *Organic soil and stream samples*

Organic samples were collected along a 2 m long "hydrological transect" situated in a 50 ha forested catchment at Svartberget Research Station, Vindeln, N Sweden. An organic peat soil (OS), potentially soluble organic substances from the organic soil (PSOS) and organic substances collected in a stream (SOS, stream organic substances) located 2 m away from the sampling point of the organic soil were sampled. pH in soil solution was 3.7 and in the stream 4.5. A soil sample was also collected from a fen peat (FP) of a sub-alpine environment, but within 5 km from the Atlantic Ocean, at Ifjord in northern Norway. This soil had a pH of 5.7 and a relatively high concentration of total sulfur (2.0%), as compared to samples from the hydrological transect. Soil samples were freeze-dried and homogenized by a tungsten carbide ball mill. Potentially soluble organic substances were gently extracted from OS and FP samples at pH 6 using a metal-chelating resin, and were thereafter flocculated by a minimal concentration of $Al(NO_3)_3$ [4]. Stream organics (19 mg organic C per liter) were collected from the Kallkällebäcken stream at Svartberget during spring flood (mid-May) when water moved through the organic soil close to the stream. A total of 48% of the organic carbon in the stream water was collected after flocculation by $Al(NO_3)_3$. Excess $Al(NO_3)_3$, and other salts, was removed by equilibrating the flocculate for 30 min in three portions of 100 ml distilled water. The SOS sample was freeze-dried and homogenized. XANES was determined on freeze-dried samples. Prior to the EXAFS study methyl mercury hydroxide, dissolved in a minimum of double-distilled water, was added to yield molar CH_3Hg/Org-S_{RED} ratios of 0.01–1.62 in the OS sample, 0.01–1.41 in PSOS, 0.01–1.19 in SOS and 0.30 in the FPOS sample. High-viscosity suspensions were mixed continuously for 7 days to reach equilibrium. OS, PSOS and SOS samples were freeze-dried and pellets were prepared 1–2 hours before each EXAFS experiment. For FPOS a newly prepared moist sample was used for EXAFS determination. Thiol (Amberlite GT73, Rohm and Haas) and carboxyl (Bio-Rex 70) resins added CH_3HgOH corresponding to 0.3 and 0.1% saturation of functional groups, were together with cinnabar (HgS-red, Merck) used as model compounds for EXAFS studies.

2.2. *XANES data collection and analysis*

Sulfur K-edge XANES data were collected on beamline X-19A at the National Synchrotron Light Source (NSLS) at Brookhaven National Laboratory (Upton, NY). Preparation and mounting of freeze-dried soil and stream organic samples is described in [4]. The energy was calibrated at 2482.5 eV with sodium sulfate. The energy drift between samples was corrected for by setting the energy of the sulfate peak to 10.0 eV above that of elemental S (2472.5 eV) [5]. All spectra were recorded in fluorescence mode using a Stern-Heald ionization detector filled with He gas [6]. The monochromator was detuned 70% at the S K-edge in order to reduce fluorescence induced by high-order harmonics.

Each XANES spectrum, representing an average of 3 to 12 scans, was deconvoluted into pseudo-components using a least-square fitting procedure. A series of Gaussian peaks was used to represent the s → p transitions and two arctangent step functions

*e-mail: ulf.skyllberg@sek.slu.se

were used to represent the transition of ejected photoelectrons to the continuum. The energy position of the s → p peaks and their peak areas are used to identify the oxidation states of S and their percentage of total S, after correcting for the change in absorption cross section area with increasing oxidation state. For further details on the fitting procedure see [7]. Electronic oxidations states were calculated for quantified XANES peaks using the linear relationship between the white line energy maximum and electronic oxidation state, derived from S compounds with identical formal and electronic oxidations states [5, 7].

2.3. *EXAFS data collection and analysis*

EXAFS data for the FPOS were collected at the bending-magnet beam line (X11A) at the National Synchrotron Light Source, Brookhaven National Laboratory (NSLS, Upton, NY, USA). EXAFS data for all other samples were collected at the undulator beam line ID26 at the European Synchrotron Radiation Facility (ESRF, Grenoble, France). At NSLS we mounted a moist sample in a 1.5 mm-thick polycarbonate holder with Kapton-tape (CHR-Furon) windows. The Si(111) double-crystal monochromator was detuned by 10%. The detector was a Stern-Heald fluorescence ion chamber filled with Kr gas. The monochromator energy was calibrated by selenium (K-edge, 12658 eV). At ESRF freeze-dried samples were mounted without any tape windows. A Cr-coated Si mirror allowed removing the high-energy harmonics from the incident X-ray beam. A cryogenically cooled fixed-exit double-crystal monochromator with Si(111) was used. The fluorescence signal was detected with a silicon photodiode and a Ga filter was installed between the sample and the detector to reduce the scattering radiation. The monochromator energy was calibrated at the Hg L_{III}-edge (12284 eV) using HgO (s).

An EXAFS spectrum represents the merged results of 4 to 10 scans. Details about data reduction and procedures used for fitting of the EXAFS spectra are found in [8]. Theoretical EXAFS scattering curves and parameters for first shell Hg−S, Hg−O and Hg−C bonding were generated by the FEFF-7 computer program [9]. Theoretical structural parameters for Hg−S, Hg−O and Hg−C bonds in organo-mercury compounds [10] were used as input for FEFF calculations. The accuracy of these was confirmed by fits of cinnabar (red HgS) compared with its theoretical structure and by model compounds with C−Hg−S coordination in thiol resin and with C−Hg−O coordination in carboxyl resin.

3. Results

Figure 1 shows the S XANES spectrum for the fen peat soil. In the raw data spectrum, two large peaks appear: the left one is represented by reduced sulfur and the right peak represents oxidized sulfur. The two peaks with highest oxidation states (electronic oxidation state 5.0 and 6.0) represent sulfonates and sulfate-esters, respectively. The peak designated Org-S_{RED} has an electronic oxidation state of 0.2 and represents sulfur functionalities of importance for trace metal binding. This peak represents the sum of organic poly- and disulfides (RSSR), organic sulfides (RSR) and thiols (RSH). In the OS, PSOS and SOS samples 47, 42 and 39% of total S was represented by Org-S_{RED}. The FP and FPOS samples contained 64 and 27% Org-S_{RED} of total S. No traces of inorganic S species (e.g. FeS, FeS_2) were detected in any of the samples. This means that total S (S_{TOT}) in these samples is a measure of total organic S.

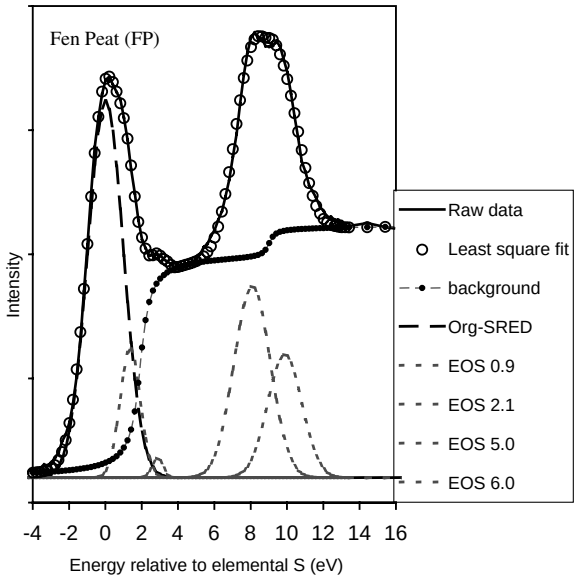

Fig. 1. Sulfur K-edge XANES spectrum for the FP sample. The *x*-axis is normalized to the K edge of elemental S (2 472 eV). Six Gaussian distribution peaks were found to be significant in the fit of the raw data. Electronic oxidation states (EOS) are given for each peak. The peak representing reduced organic S (Org-S_{RED}) has an EOS of 0.2 and made up 64% of total S in this sample.

In Fig. 2 Fourier-transformed Hg-EXAFS spectra for the FPOS sample and the OS (soil), PSOS and SOS (stream) samples are illustrated together with EXAFS spectra for two model compounds. The two peaks of the thiol (RSH) resin reflect a C−Hg bond (within the methyl mercury molecule) at 1.6 Å (corresponding to a bond length of 2.03 ± 0.02 Å) and an Hg−S bond at 2.0 Å (corresponding to a bond length of 2.34 ± 0.03 Å). A similar RSF for the FPOS suggests that CH_3Hg forms a

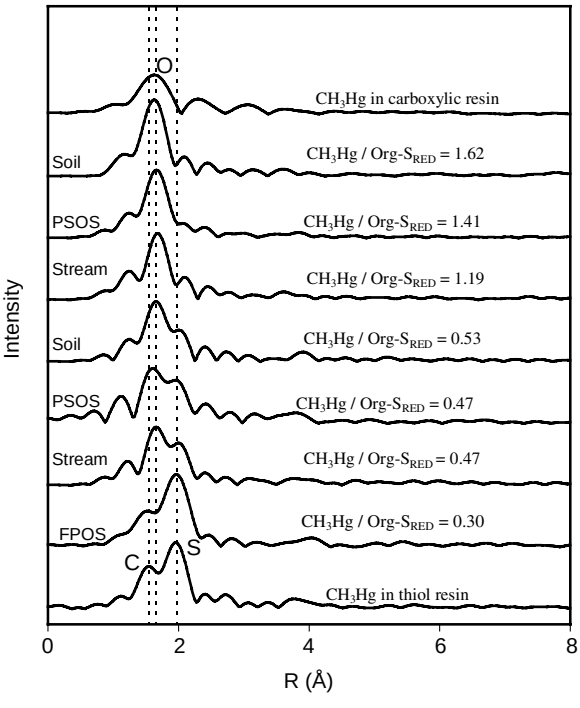

Fig. 2. Stacked, Fourier transformed EXAFS spectra for OS, PSOS, SOS and FPOS samples added methyl mercury to give different CH_3Hg/Org-S_{RED} molar ratios. As references spectra for a carboxyl resin (top) and a thiol resin (bottom), both added methyl mercury, are given. Spectra were not corrected for phase shift.

monovalent bond with RS^- groups in this sample. Above a certain CH_3Hg/Org-S_{RED} ratio, also oxygen (and possibly nitrogen, which cannot be separated from oxygen by EXAFS) functional groups take part in the bonding, due to a saturation of RSH groups. This is illustrated by a decrease of the shoulder at 2.0 Å, while the peak at 1.6 Å is broadened and slightly shifted to 1.7 Å for the OS, PSOS and SOS samples with CH_3Hg/Org-S_{RED} ratios of 0.47 to 0.53. For these samples the RSF represents a mixture of Hg−S and Hg−O/N bonds. In the samples with a CH_3Hg/Org-S_{RED} molar ratio of 1.19–1.62 the binding to O/N completely overrules the contribution from Hg−S and the RSF of these samples is quite similar to the RSF of methyl mercury bound to the carboxyl resin. The peak at 1.7 Å represents a mixture of C−Hg and Hg−O bonds, the latter having a bond length of 2.09 ± 0.01 Å. Exact coordination numbers and bond lengths were determined by fitting of EXAFS data in *k*-space (not shown here). All fits are reported in [8], and some CN's are given in table I.

Based on the assumption that methyl mercury forms monodentate bonds to RSH groups, thus not involving other S functionalities, and that all RSH groups will be saturated before any O/N sites become involved in the binding, EXAFS data could be used to calculate the concentration of RSH functional groups in OS, PSOS and SOC samples. For this purpose we used equation (1):

$$[RSH] = CN_S/(CN_S + CN_{O/N}) \times [CH_3Hg]. \quad (1)$$

CN_S and $CN_{O/N}$ are coordination numbers of sulfur and oxygen/nitrogen atoms in the first coordination shell and [ ] denote concentrations in mol kg^{-1}. Only samples added CH_3Hg exceeding the capacity of RSH were be used in the calculation of [RSH].

In table I calculated concentrations of RSH are related to concentrations of S_{TOT} and org-S_{RED} determined by XANES. It can be concluded that RSH contributed to less than 22% of total (in this case also organic) S and less than 38% of reduced organic S. An interesting observation is that the concentration of RSH seems to be highest in the soil, intermediate in potentially soluble organic matter from the soil and lowest in the stream. It should be noted that even if the pH at which EXAFS data were collected (3.8–4.0) was 6 orders of magnitude below the pKa of RSH, the concentration of protonated RSH groups still would be very small at the point O/N sites will be involved in the complexation of CH_3Hg. This is explained by the fact that the log k_1 for the binding of CH_3Hg to O/N sites is at least 8–9 orders of magnitude less than for RSH [4].

4. Conclusions

1) Only thiol groups (RSH) seems to be involved in the bonding of methyl mercury in oxidized soils and humic streams. Oxygen and nitrogen functionalities are involved only after saturation of RSH sites.
2) Between 24 and 37% of reduced organic S (likely representing the sum of RSH, RSSH, RSR and RSSR), as determined by S XANES, was represented by thiol groups (RSH) an organic soil, extracted organic substances from the soil and organic substances in the humic stream draining the soil.

Abstract

We measured XAFS spectra of trace amount of ytterbium (Yb) incorporated in calcite, a stable phase of calcium carbonate. Calcium carbonate was precipitated from a mixed solution of $CaCl_2$ aq and $NaHCO_3$ aq with a given amount of $YbCl_3$. Concentrations of Yb were 5 μmol kg^{-1} in the starting solutions and Yb/Ca molar ratio in the precipitated calcium carbonate was 1.2×10^{-3}. Ytterbium L_{III}-edge XAFS spectra were collected in the fluorescence mode at the beamline BL-12C of the KEK-PF. Analysis of the XAFS results indicated, (1) Approximately 15% Yb ion existed as divalent ions in the calcite. (2) Yb^{3+}, major Yb species in the calcite, is located at the Ca^{2+} site in the calcite. The local structure around Yb^{3+} is significantly different from that of Ca^{2+}. The coordination number of Ca^{2+} in the crystal structure of calcite is 6 and Ca-O distance is 2.36 Å. In contrast, the nearest Yb-O coordination for Yb-doped calcite is split into two shells, the nearest 4 oxygen atoms and the second nearest 2 oxygen atoms, and their Yb-O distances are 2.24 Å and 2.77 Å, respectively. It was shown that localized structural relaxation occurred around Yb^{3+} which has smaller ionic radius than Ca^{2+}.

1. Introduction

Exploring the detailed chemical mechanism of dissolution and crystallization of calcium carbonate ($CaCO_3$) is one of the crucial issues in understanding the global cycling of CO_2 on the earth surface. Trace amount of rare earth elements (REEs) induces significant effects on the crystal growth and dissolution of calcium carbonate [1–4]. The substantial increase in the solubility of $CaCO_3$ [1, 2], the stabilization of the vaterite (labile phase of $CaCO_3$) [2, 4] and the inhibition of calcite growth [3] were caused by the addition of trace amount of lanthanum into the aqueous system. Furthermore, enrichment of REEs in calcium carbonate was shown by several studies [5, 6]. Very little is known about the uptake mechanism of REEs in calcium carbonate and their chemical state. X-ray absorption fine structure (XAFS) is practically the only method for the structural characterization of trace elements in solid materials [7]. XAFS in a fluorescence mode offers the advantage of element-discrimination and potentially high sensitivity to trace elements. In the present work, we investigated the chemical species of ytterbium incorporated in calcite and the local structure around it using X-ray absorption near-edge structure (XANES) and Extended X-ray absorption fine structure (EXAFS) techniques.

2. Experimental procedure

2.1. *Precipitation procedure*

Yb-doped calcium carbonate was prepared from a mixture of calcium chloride and sodium hydrogen carbonate solutions (30 mmol kg^{-1}, respectively) containing a given amount (5 μmol kg^{-1}) of ytterbium chloride. The experiments were conducted in a closed system in a surface-silanized glass vessel at 30°C. The starting solution was transferred into the vessel and immediately sealed with a silicone rubber stopper in which a pH electrode was embedded [2]. The amount of precipitate and ion activity products (IAP $= \gamma\ Ca^{2+}\ [Ca^{2+}] \times \gamma CO_3{}^{2-}\ [CO_3{}^{2-}]$) were calculated from the initial concentrations of all the chemical species in the system and pH at each sampling time after a previously reported method [1, 2]. The pH of solution changed from 7.8 at the beginning of reaction to 6.4 at the end of reaction. After standing for 1 day, the precipitate was filtered with a membrane filter with a pore size of 0.45 μm (Millipore® HAWP 024 00), rinsed with milli-Q water and dried at 110°C. Powder X-ray diffraction pattern indicated that the sample obtained was composed of calcite exclusively. The concentrations of Yb in the precipitates were determined by an inductively coupled plasma atomic emission spectrometer (ICPS-7000, Shimadzu Inc.). The concentrations of Yb in the synthesized calcite samples were about 1.1×10^{-3} in Yb/Ca molar ratio. $Yb(OH)_3$, $NaYb(CO_3)_2 \cdot n(H_2O)$, Yb_2O_3, $Yb_2(CO_3)_3 \cdot n(H_2O)$ powders and 5 mmol kg^{-1} $YbCl_3$ solution were used as standard materials of XANES measurements.

2.2. *XAFS spectroscopy*

XAFS spectra were collected in the fluorescence mode at the beamline BL-12C of the Photon Factory, High Energy Accelerator Research Organization (KEK-PF) in Tsukuba, Japan [8]. The KEK-PF storage ring was operated at 2.5 GeV with a maximum current of 450 mA. An Si(111) double-crystal monochromator was used to produce a monochromatic X-ray beam, with one crystal detuned for reduction of harmonics and the beam was focused into an area smaller than 1 square mm by a bent cylindrical mirror [8]. The Yb L_{III} (8947 eV) absorptions of samples were measured by the fluorescence yield (Yb Lα: 7.4 keV) using a 19 elements pure Ge solid-state detector with energy resolution sufficient to separate Yb signals from elastic scattering and fluorescence of other elements [9, 10]. The energy region around Yb-Lα fluorescence was selected by single-channel analyzers

*e-mail: h.tsuno@aist.go.jp

(SCA). The monochromator was calibrated at 8947 eV (Yb L_{III} absorption edge) using ytterbium oxide powder. XAFS spectra of solid samples were measured at approximately 20 K. The incident X-ray intensity (I_0) was monitored by an ion chamber which was filled with nitrogen gas. The X-ray absorption (μ) is expressed as $\mu = I_f/I_0$, where I_f is the intensity of fluorescence X-ray and μ is plotted against incident X-ray energy. Multiple scans (typically 3–5 times) were carried out for each sample and then averaged. The averaged XAFS spectra were converted to k space. The atomic contribution to the absorption coefficient (μ_0) was regarded as the smooth background in the EXAFS region of the each averaged XAFS spectra by a cubic spline method. $\chi(k)$ was extracted as usual and Fourier transformed into r-space. Determination of average interatomic distance, coordination number, and Debye-Waller factor for the isolated shell about an absorber in an unknown material were made by least-square fitting of the Fourier-filtered $\chi(k)$ function. Analyses of the EXAFS spectra were performed with the PC program, REX2000 (Rigaku Co.), which uses theoretical phase functions and amplitudes from McKale's table [11]. The interatomic distances and coordination numbers were given by fitting with errors of respectively ±0.02 Å and ±15–20%, assuming that systematic errors have been minimized in the experiment and data analysis. XANES spectra were also deconvoluted by REX2000 (Rigaku Co.).

3. Results and discussion

3.1. *XANES: Spontaneously induced reduction of trivalent ytterbium in calcite*

XANES spectra of the calcite and Yb-bearing standard materials had a significant white line around 8948 eV, which was assigned to electron transition 2p→5d6s of Yb^{3+} [12, 13]. The XANES spectrum of Yb in calcite is shown in Fig. 1. A discernible shoulder (A) is observed in the lower energy side of the main white line (B). This shoulder was not observed on XANES spectra of Yb-bearing materials. We attempted to fit the main peak at 8948 eV and the shoulder by a couple of a Gaussian function for white line and an arctangent function for continuum absorption, respectively. The deconvoluted components of XANES spectrum of Yb in calcite are shown in Fig. 1. A small peak (A) was resolved from the spectrum of calcite. Resultant peak position, peak height and FWHM of Gaussian curve for Peak A are 8940.2 eV, 0.14 a.u. (arbitrary unit) and 6.1 eV, and those for Peak B are 8948.6 eV, 0.88 a.u. and 6.1 eV, respectively. The position of Peak A was at lower energy by 8 eV than that of Peak B and is close to that of the absorption of Yb^{2+} [12–15]. Thus, we attributed peak A to Yb^{2+}. These results indicate that significant proportion of ytterbium existed as divalent ions in the calcite structure. Tanaka *et al.* suggested that the ratio of areas of peak A and B indicates directly the relative amounts of Yb^{2+} and Yb^{3+} [13]. Based on the report, we calculated that the 14–17% of Yb exists as Yb^{2+} in calcite. Thermodynamic calculation indicates that the $[Yb^{2+}]/[Yb^{3+}]$ ratio in the starting solution is smaller than 10^{-31}. In the starting solutions, trivalent ytterbium was predominant and divalent ion was negligible. This suggests that a part of Yb was reduced at some stage of calcium carbonate formation.

Yb^{3+} substitutes in the six-fold coordination for the Ca^{2+} site in calcite as mentioned in the following section. The ionic radii of Ca^{2+}, Yb^{3+} and Yb^{2+} in the six-fold coordination are 1.00, 0.868 and 1.02 Å, respectively [16]. The ionic radius of Yb^{2+} is quite close to that of Ca^{2+}. It is expected that Yb^{2+} can substitute at the calcium site of calcite with higher stability (affinity) than Yb^{3+} without significant mismatches in ionic radius as well as the ionic valence. For the stabilization of Yb^{2+} in the calcite structure, it is possible that some defects such as oxygen vacancy in the crystal structure of calcite can compensate the formation of Yb^{2+} in the oxidative condition. Further information of this result is described in Tsuno *et al.* 2003 [17].

3.2. *EXAFS: The local structure of Yb^{3+} incorporated in calcite*

The extended X-ray absorption fine structure (EXAFS) spectra of Yb in calcite can be attributed to Yb^{3+}, the major species in calcite, although we showed the presence of Yb^{2+} in calcite on the previous section. We regarded the structural information of Yb for EXAFS analysis as Yb^{3+}. The k^3-weighted $\chi(k)$ EXAFS of Yb incorporated in calcite is shown in Fig. 2. The spectrum collected at 20 K showed better S/N ratio than that taken at Room temperature, thus, it was used for detailed analysis. We adopted the spectrum at 20 K for the EXAFS analysis. Fig. 3

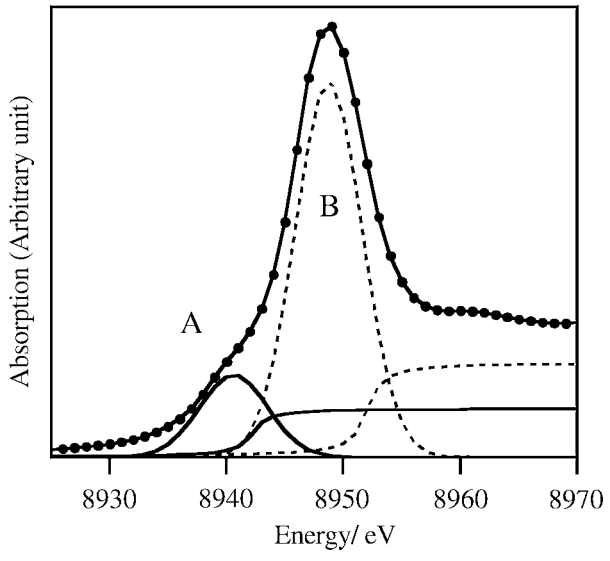

Fig. 1. Yb L_{III} edge normalized XANES and the deconvoluted spectra of Yb incorporated in calcite. A: Yb^{2+}, B: Yb^{3+}.

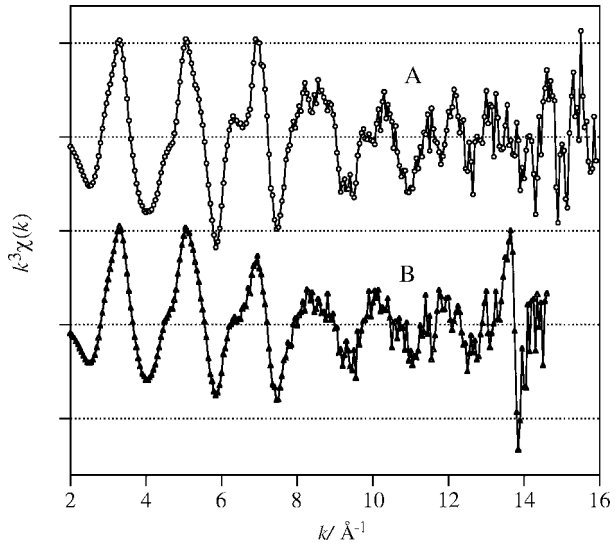

Fig. 2. The k^3-weighted $\chi(k)$ spectra for Yb incorporated in calcite. A: collected at 20 K, B: at room temperature.

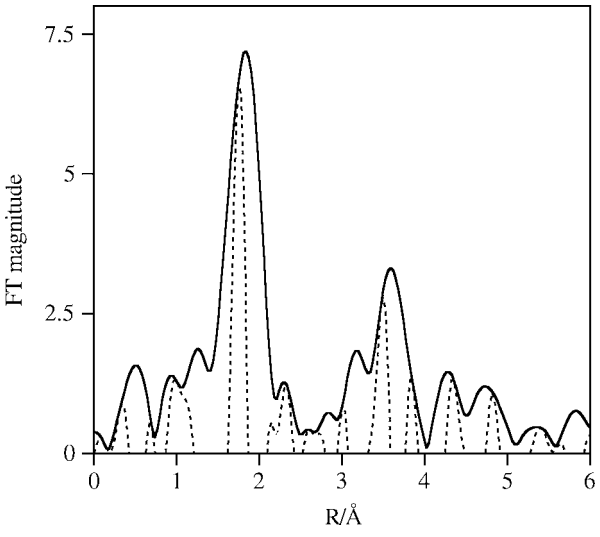

Fig. 3. Fourier transform of k^3-weighted Yb L_{III} EXAFS of Yb in $CaCO_3$ (no phase shift correction). Solid line: Radial structure function; Dashed line: imaginary part of FT.

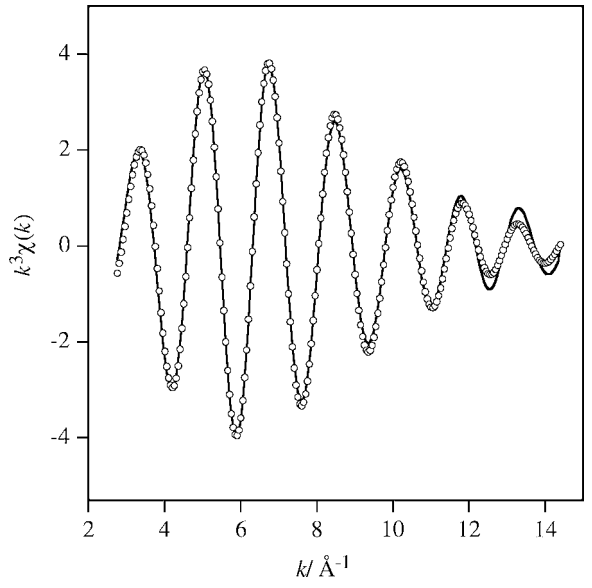

Fig. 4. Fit to the back Fourier transform of the first peak of k^3-weighted Yb L_{III} FT-EXAFS data shown in Fig. 3 performed in the range 1.5–2.1 Å. Open circle: experimental; Solid line: fitting.

shows Fourier transform of k^3-weighted $\chi(k)$ EXAFS of Yb-doped calcite (without phase-shift correction). A peak of radial structure function at about 1.8 Å is attributed to the nearest Yb-O interaction by assuming that Yb^{3+} occupies the Ca^{2+} site in calcite. The rough fitting for the back Fourier transform of the first peak in Fig. 3 brought the coordination number (N) as 4 and the larger residue of the fitting. It is an unreasonable value for Yb^{3+} coordination in calcite structure. Thus, we assumed that the first O-shell for Yb in calcite was splitting to near two shells. Fig. 4 shows the back Fourier transform of the first peak of k^3-weighted Yb L_{III} FT data between 1.5–2.1 Å shown in Fig. 3. The best fitting result indicates that there are 4 O atoms at 2.24 Å and 2 O atoms at 2.77 Å. The nearest Yb-O distance (2.24 Å) is comparative to the calculated Yb-O distance from the sixfold ionic radii of Yb^{3+} from Shanonn 1976 [16]. The nearest Yb-O distance (2.24 Å) in calcite is smaller than Ca-O distance (2.360 Å) of pure calcite [18]. Although the coordination number of Ca^{2+} for calcite is 6, all the

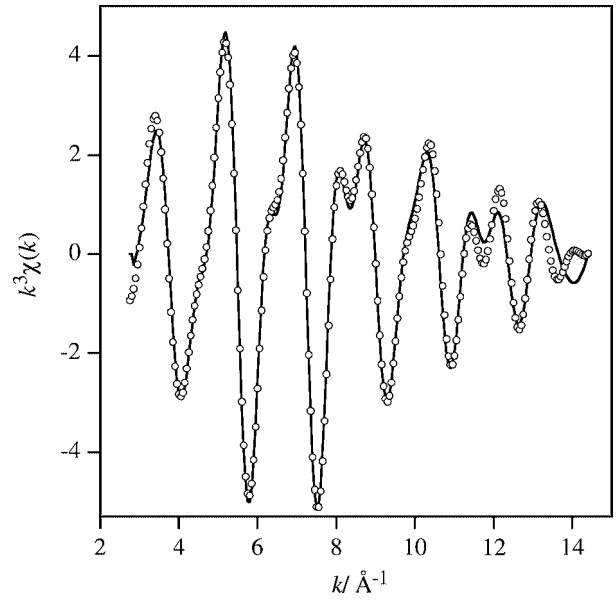

Fig. 5. The k^3-weighted Yb L_{III} edge EXAFS data, $\chi(k)$, for the calcite sample and the best-fit multishell model as a function of wave vector k. The data were fit with parameters described Table I. Open circle: experimental; Solid line: fitting.

six oxygen atoms could not be located in the same nearest shell to occupy Yb^{3+} at Ca^{2+} site in calcite. Thus, 4 oxygen atoms are located at the nearest shell with an Yb-O distance of 2.24 Å, while 2 oxygen atoms are pushed away from the nearest shell to a little far position. It was shown that the localized structural relaxation occurred around Yb^{3+} which has smaller ionic radius than Ca^{2+}.

Elzinga *et al*. showed that the nearest Yb-O shell in their Yb-doped calcite samples has coordination number of 7.5 and Yb-O distance 2.24 Å by EXAFS analysis [19]. Their fitting results had reasonable Yb-O distance but considerably large coordination number at Ca site in calcite structure. Thus, they fixed coordination number of 6 as chemical reasonable number from a comparison of the observed Yb-O distance with values predicted from sixfold and sevenfold ionic radii from Shanonn [16]. In contrast, our results are derived directly from EXAFS analysis and the distortion of YbO_6 octahedron was detected from the analysis.

For the Ca site of the calcite structure, the shells have the six nearest oxygen atoms at 2.360 Å, the nearest carbon atoms at 3.213 Å, the second nearest oxygen atoms at 3.459 Å, and calcium atoms at 4.048 Å and they have ideal coordination numbers (N) of 6 [18]. The mean Yb-O distance in calcite was 2.42 Å from the present experimental results. This mean value of Yb-O distance agrees with the size of the Ca^{2+} site in calcite. According to calcite structure, the coordination numbers of shells beyond the first oxygen group were fixed as 6 during refinement to reduce the

Table I. *Multishell best-fit parameters for Yb L_{III} EXAFS incorporated in calcite. N: coordination number; R: radial distance; σ: Debye-Waller factor.*

Shell	N	R(Å)	σ(Å)

Yb-O	6*	3.34	0.110
Yb-Ca	6*	4.04	0.088

*Parameter fixed during refinement to reduce the number of fit parameters.

number of fit parameter. The k^3-weighted Yb L_{III} edge EXAFS data, $\chi(k)$, for the calcite sample and the best-fit multishell model were shown in Fig. 5. The results were well fit with the observation values. Best-fit parameters for Yb^{3+} incorporated in calcite are shown in Table I. The EXAFS fitting results support that Yb occupied the Ca sites in calcite as was expected.

Abstract

It is well known that organotin compounds such as tributyltin (TBT) and triphenyltin (TPT) leached from ship's antifouling paints cause disrupting endocrine called "imposex" in some species of marine snails. In this paper, XANES and EXAFS spectra for some Sn species including TBT and TPT were measured. Tin L_I-edge (4.464 keV) and L_{III}-edge (3.928 keV) XAFS were recorded in fluorescence mode using a Lytle detector at BL-9A, KEK-PF, Japan. In the beam line, all paths including I_0 ion chamber and a sample cell were purged with He, which enabled us to measure XAFS at soft X-ray region even for liquid samples like TBT. The XANES and EXAFS spectra of Sn metal, $SnCl_2$, SnO_2, TBT, and TPT showed that we can distinguish these species by this technique. This shows that XAFS can be a powerful tool for the speciation of Sn. Since XAFS is a non-destructive method, it can exclude the alteration of Sn compounds during pretreatment of conventional chromatographic analyses. It was also suggested that the difference in the features of XANES is more distinct at the L_I-edge than at the L_{III}-edge, whereas the detection limit is lower for the L_{III}-edge. The XANES spectrum at the L_{III}-edge was obtained even for the sample containing only 50 ppm of Sn as TBT in ethanol. Although the sensitivity may be insufficient for the Sn in seawater, the method can be applied to the speciation of Sn enriched in some biological samples or used in antifouling paints.

1. Introduction

It is well known that organotin compounds such as tributyltin (TBT) and triphenyltin (TPT) used in ship's antifouling paints and fishing nets have been used since 1960's in the world [1]. TBT and TPT leached from the antifouling paints have caused disrupting endocrine called 'imposex' in some species of marine snails [2]. Imposex is the imposition of male sexual characteristics on female snails and has caused a decrease in the population of neogastropod species. Their use in antifouling paints and fishing nets has produced toxic effects on non-target aquatic species (especially mollusks), and they are among the most toxic contaminants released into the aquatic environment by human activities [3–5].

Speciation of their organotin compounds has been of great interest due to their species-dependent toxicity and their widespread application as biocides [6]. In recent years, chromatography techniques such as gas chromatography (GC) or liquid chromatography (LC) have been widely used for analysis of organotin compounds [7–8]. These analytical methods essentially need many pretreatment procedures, such as extraction, purification, and derivatization.

In this work, we investigated whether XAFS would be effective for the speciation of inorganic and organic tin compounds using XAFS as a non-destructive method. The XAFS spectra of Sn in organotin compounds, such as TBT and TPT, were measured for the first time in this work. By XAFS because we do not need any pretreatments, any alteration of Sn compounds during the analysis can be excluded. In order to measure Sn-L edge XAFS, we used BL-9A at Photon Factory, KEK, specially designed to measure XAFS in the soft X-ray region (>2.2 keV) using fluorescence mode. The beamline is equipped with a double mirror to remove the harmonics, which is essential in the soft X-ray region. It is also possible to purge all paths with He including an I_0 ion chamber and a sample cell.

2. Samples and experimental procedures

Three inorganic Sn compounds, (Sn metal, $SnCl_2 \cdot 2H_2O$, and SnO_2,) and two organic Sn materials, (TBT (tributyltin chloride, $[CH_3(CH_2)_3]_3SnCl$) and TPT (triphenyltin chloride, $[C_6H_5]_3SnCl$)), were employed as reference materials for XAFS for Sn speciation. The Sn metal was about 100 μm in thickness. $SnCl_2 \cdot 2H_2O$ and SnO_2 were diluted to 5 wt% by BN and pressed into a pellet. These pellets were sealed by 4 μm polypropylene (Prolene®) bags. TBT and TPT were diluted by 5 wt% by ethanol and sealed by a polyethylene bag. A sample containing TBT and TPT at a known ratio was also measured. An antifouling paint was also employed for an example of the application of the XAFS technique to actual environmental materials.

XANES and EXAFS spectra for all samples were measured at beamline BL-9A at the Photon Factory, KEK, in Tsukuba, Japan [9]. The storage ring operating conditions were 2.5 GeV electron energy and 450–300 mA electron current. The beam size used in this study was smaller than $1 \times 0.5\,mm^2$ at the sample position. Tin L_I-edge (4.464 keV) and L_{III}-edge (3.928 keV) XANES and EXAFS spectra were recorded at room temperature in a fluorescence mode. A Si(111) monochromator was used and the beam was focused by a pair of bent conical mirrors coated with Rh. The samples were placed at a 45 degrees angle to the incident focused X-ray beam and the Lytle detector. To suppress the absorption of X-rays by air, all the paths including an I_0 ion chamber and a sample cell were purged with He. A pair of flat double mirrors was inserted in order to reduce the higher order reflections. The energy resolution ($\Delta E/E$) is 2×10^{-4} at 9 keV. A detailed layout of the beamline has already been reported [10–11]. For all experiments, SnO_2 was used as an energy reference material, where we set the energy of the white line peak of SnO_2 at 4.464 keV and 3.928 keV for L_I-edge and L_{III}-edge, respectively. The X-ray absorption (μ) defined as $\mu = I_F/I_0$ (I_F: fluorescence X-ray intensity; I_0: incident X-ray intensity) was plotted against incident X-ray energy.

XANES spectra for L_I-edge and L_{III}-edge were recorded with a 0.25 eV step (1 second for 1 point). The scanned energy range for L_I-edge XANES was from 4.42 to 4.54 keV, and from 3.91 to 3.97 keV for the L_{III}-edge. More than two scans were measured

and averaged. After removal of a linear preedge, the spectra were normalized by defining the average absorption between 4.526 and 4.564 keV equal to one for the L_I-edge and absorption between 4.038 and 4.135 keV for the L_{III}-edge.

Tin L_I-edge and L_{III}-edge EXAFS spectra were recorded in the energy range between 4.20 and 5.00 keV. Background corrections to extract the EXAFS functions $\chi(k)$ were made using a program, WinXAS version 2.1 [12]. The k^3-weighted $\chi(k)$ functions were Fourier transformed from k space ($2.90\,\text{Å}^{-1} < k < 6.70\,\text{Å}^{-1}$ and $3.190\,\text{Å}^{-1} < k < 7.461\,\text{Å}^{-1}$ for L_I-edge and L_{III}-edge, respectively) into R space to obtain a radial structural function (RSF).

3. Results and Discussion

The Sn L_I-edge XANES spectra of the reference materials and antifouling paint are shown in Fig. 1. The absorption peak occurs at 4.465 keV for Sn-metal and occurs at 4.470 keV for $SnCl_2$ and SnO_2 (Fig. 1). The XANES spectrum of TBT exhibits a single strong sharp peak at 4.466 keV and a small shoulder around 4.474 keV. The XANES spectrum of TPT exhibited a doublet feature, where the white line peak is less symmetric compared to that of TBT. The spectrum of the antifouling paint is not completely identical, but considerably similar to that of TBT, suggesting that TBT is contained in the antifouling paint. This result shows that L_I-edge XANES can be used as a fingerprint to distinguish organotin compounds (TBT and TPT) and inorganic Sn species.

Figure 2 shows Sn L_{III}-edge XANES spectra of the reference materials and the antifouling paint. The featureless L_{III}-edge XANES spectrum of Sn-metal may be caused by strong self-absorption due to the low X-ray energy of the L_{III}-edge relative to that of the L_I-edge. The spectra of other inorganic references, $SnCl_2$ and SnO_2, have two characteristic peaks (3.929 keV and 3.939 keV). The spectra of organotin compounds, TBT and TPT, have a large peak (around 3.932 keV) and a smaller peak (around 3.937 keV). The spectrum of the antifouling paint is similar to TBT, which confirms that TBT is contained in the antifouling paint. It is well known that TBT is soluble in ethanol. Chemical species which is extracted by ethanol from the antifouling paint shows a similar spectrum, suggesting that TBT was extracted in the ethanol (Fig. 2).

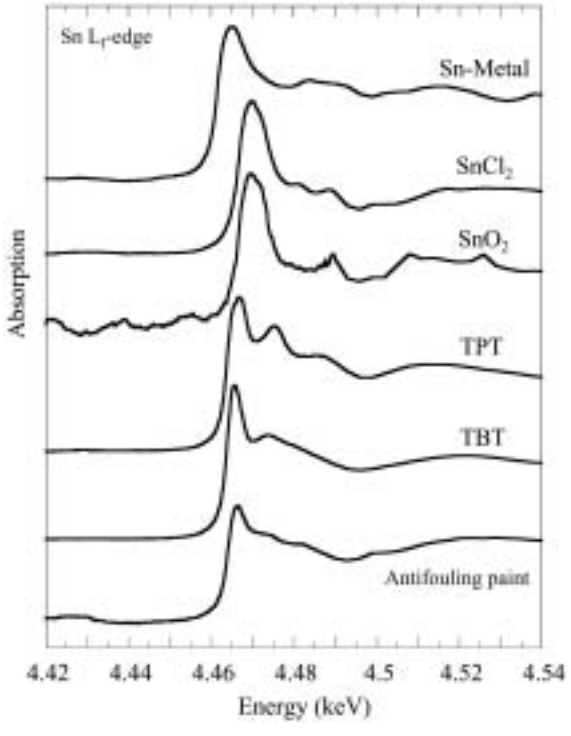

Fig. 1. XANES spectra at Sn L_I-edge for Sn-metal, $SnCl_2$, SnO_2, TBT, TPT, and antifouling paint.

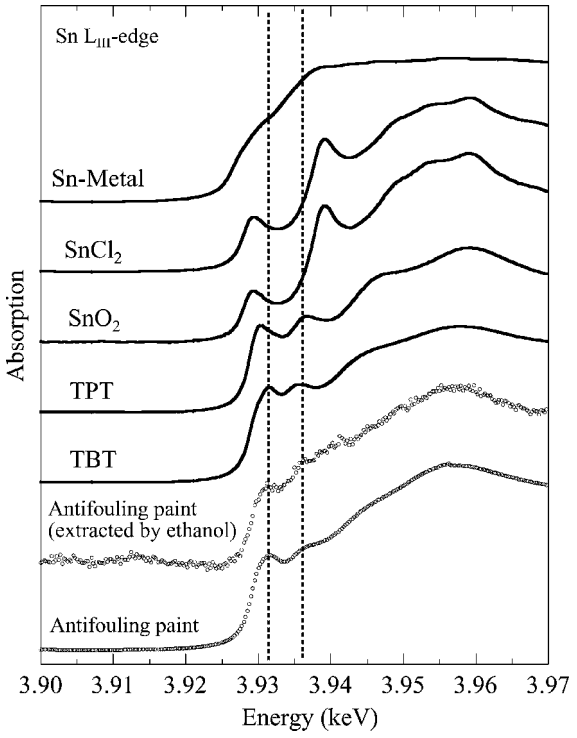

Fig. 2. XANES spectra at Sn L_{III}-edge for Sn-metal, $SnCl_2$, SnO_2, TBT, TPT, and antifouling paint.

The detection limit was estimated using various concentrations of TBT in ethanol sealed by a polyethylene bag. The L_{III}-edge XANES spectra for a solution containing 500 and 50 ppm Sn as TBT were collected 4 times and averaged to reduce random error. As shown in Fig. 3, the spectra of 50 and 500 ppm Sn solution were similar to that of 5 wt% Sn solution (5.0×10^4 ppm). The similarity indicates that the self absorption is not serious for the sample containing 5 wt% of Sn. XANES spectrum for 50 ppm Sn solution cannot be obtained for Sn L_I-edge. These facts suggest that L_{III}-edge is better than L_I-edge from the viewpoint of detection limit. Although the sensitivity may be insufficient for Sn in seawater (0.023–0.061 $\mu g/dm^3$) [13], some sediments containing a relatively large amount of Sn (10–20 ppm) and biological samples accumulating Sn could be detected by fluorescence XAFS.

Deconvolution of a spectrum of a mixture (TBT : TPT = 1 : 1; molar ratio) was preformed based on the normalized XANES spectra of TBT and TPT (Fig. 4). To utilize the energy shift of the white line, the fitting energy region was confined to a region between 3.917 and 3.940 keV. The mixing ratio estimated by the deconvolution (TBT: 49.2%) is similar to the mixture ratio (TBT: 49.0%). This result confirms that the Sn species in the sample can be estimated from XANES spectra if a few organotin compounds coexist in the sample. No spectral change was observed during repeated measurements for L_I-edge and L_{III}-edge XANES, showing that organotin compounds such as TBT and TPT were not altered during X-ray irradiation. These results

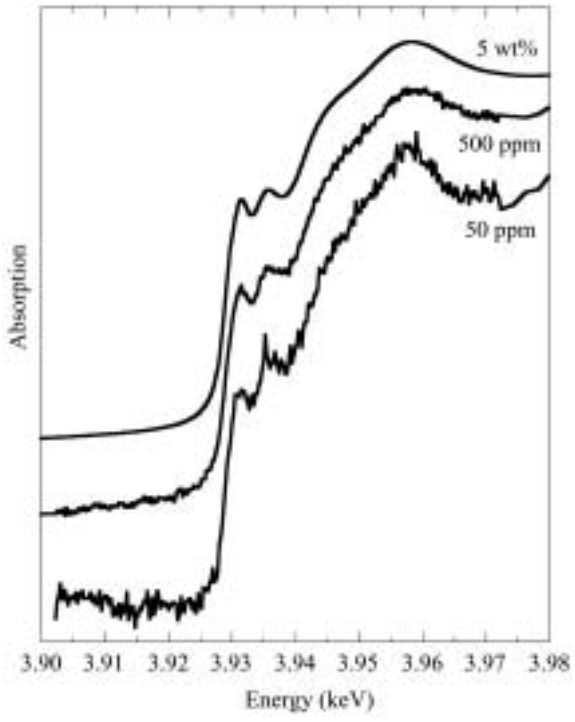

Fig. 3. Sn L_{III}-edge XANES spectra for Sn ethanol solutions containing 5 wt%, 500 ppm, and 50 ppm Sn as TBT in polyethylene bags.

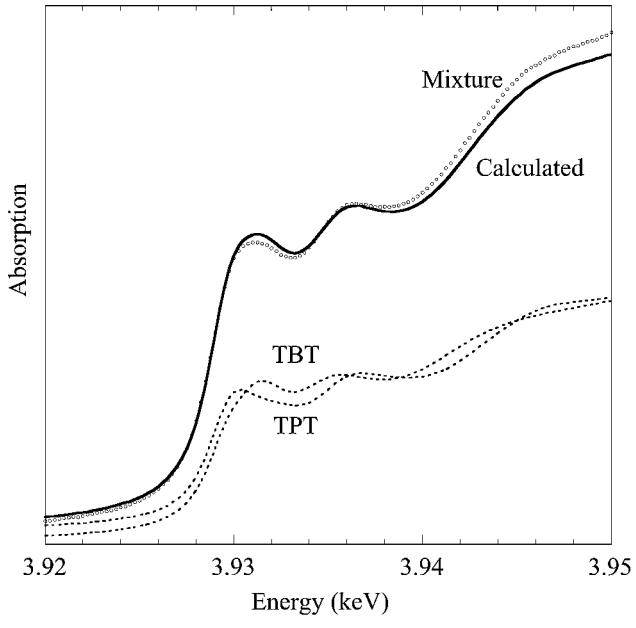

Fig. 4. Deconvolution of Sn L_{III}-edge XANES spectrum of the mixture (TBT : TPT = 49 : 51) and the spectra of 5 wt% TBT and TPT. The solid curve was obtained from a simulation based on the XANES spectra of TBT and TPT.

indicate that a spectroscopic method like XAFS is a powerful tool as a non-destructive method for speciation of tin compounds in the environment.

The radial structural functions (RSF) obtained by absolute values of Fourier transforms of k^3-weighted EXAFS functions for L_I-edge and L_{III}-edge are shown in Fig. 5. The phase shift of RSF was not corrected, since we use RSF as another fingerprint of the Sn species. It is difficult to distinguish $SnCl_2$, SnO_2, TBT, and TPT only from RSF, probably due to the small differences among

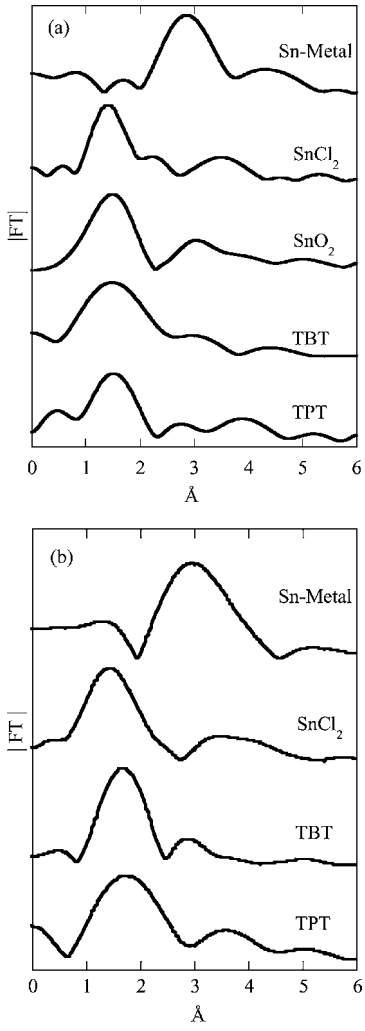

Fig. 5. Radial structural functions (phase shift is not corrected) obtained from EXAFS at (a) Sn L_I-edge and (b) Sn L_{III}-edge.

bond length of Sn to the neighboring atoms in these materials. In addition, the K-edge of Ca (4.038 keV) which is widely distributed in the environment may interfere with the EXAFS of Sn L_{III}-edge (3.928 keV), since the fluorescence by Ca K-edge may inhibit to measure the high energy region of Sn L_{III}-edge EXAFS. These facts suggest that XANES is probably better for Sn speciation in environment if we use Sn L-edge XAFS.

4. Conclusion

This study shows that XAFS, especially XANES, can be a powerful method for the speciation of Sn compounds in the environment. XAFS method dose not require complicated pretreatments like extraction, purification, and derivatization, which are essential in conventional chromatographic analyses. This is a great advantage of XAFS which enables us to exclude the alteration of Sn compounds in the sample during the analysis and pretreatments. Based on the detection limit of the Sn L-edge XAFS technique (ca. 50 ppm), it is thought that the application of the fluorescence XAFS to sediments, biological samples, and antifouling paints that contain a large amount of Sn is possible. Direct observation using XAFS will also be helpful for checking the alteration of organotin compounds during the pretreatment procedures in the conventional analyses.

Abstract

This study used CrO_3-loaded silica as an example to illustrate how the hydration of the samples could affect the structural parameters of an environmental sample. Our results showed that as the moisture content in samples increased, the amplitude of the EXAFS increased, while the oscillation frequency of the EXAFS was virtually unchanged. The hydration of Cr(VI) enhanced the first-shell coordination number (Cr−O); the Debye-Waller factor was also changed. The first-shell coordination number was 4.55 for CrO_3-loaded silica slurry and 2.67 for the dry CrO_3-loaded silica. The Debye-Waller factor (σ^2) was 0.0036 for the slurry and 0.0014 for the dry one. In addition, hydration caused a considerable change in the pre-edge height and the white band of the XANES spectra of Cr(VI).

1. Introduction

Cr(III) is a necessary micronutrient for human, and Cr(VI) is carcinogenic [1]. In nature environment, chromium mainly exists in $Fe(CrO_2)_2$ [1]. Chromium element, Cr_2O_3, CrO_3, H_2CrO_4, chromate and dichromate salts have extensive application in industries of paint, alloy, electroplating, etc. Environmental pollution/contamination by chromium may eventually result in searing to plant, and neurosis, cancer, dermatosis to human [2].

Extended X-ray absorption fine structure (EXAFS) has been used to investigate the molecular environment of target element. This technique is applicable to the study between metal ions and water molecules [3]. The reaction between oxides and water molecules includes hydroxylation, hydration, chemisorption, and charge transfer [4]. Due to the higher charge/radius ratio of metal ions, metal ions were apt to form hydration shell in water [5]. In addition, metal ions in water might cause polarization of water molecules and this resulted in discrete hydration shell [6]. This polarization tended to increase the strength of hydrogen bonding, but reduce the O-H bonding strength of water molecules [6].

The objective of this study was to investigate the effect of hydration on structural parameter of chromium loaded in silica. This research was such designed that the results might be used to explain why both XANES and EXAFS fittings for samples dried at 105 °C were usually unsatisfactory.

2. Experiment

Amount of 62.95 gram CrO_3 of 99.99% purity from Aldrich corporation was end-to-end mixed with 500 gram silica in de-ionized water in a sealed PE bottle for 2 days at 30 rev/min. Part of mixture was then rigorously dried at 105 °C in an oven for 20 days to attain a considerably dry chromium(VI)-loaded silica powder, termed as "dry sample" in this study. The other part of the mixture was only partly dried at 105 °C for 3 days, and this sample was termed as "moistured sample". These samples along with the reference compounds (i.e., CrO_3 and Cr_2O_3) were recorded for their X-ray absorption spectra (XAS) on the wiggler C (BL-17C) beamline at the National Synchrotron Radiation Research Center (NSRRC) in Taiwan. The XAS spectra of "dry" and "moisturized" samples and the references were all recorded in transmission mode at room temperature. The wiggler C beamline had an eletron storage of 1.5 GeV, a current of 120–200 mA, and the scanning span of the monochromator was 4–15 keV. All data were analyzed with WinXAS 2.0 software [7].

3. Results and Discussion

Figure 1 shows the difference between the normalized XANES spectra for the "dry" and "moisturized" samples. Cr(VI) pre-edge spectrum is characterized by an intense peak due to the transition of Cr 1s core electrons to its 3d orbital. This arises from the lack of a center of inversion symmetry in the CrO_4 tetrahedral structure [8, 9]. The area of this peak in the normalized Cr XANES spectrum was demonstrated to be proportional to the Cr(VI)/Cr ratio [9]. Figure 1 indicates that the "moisturized sample" has a higher pre-edge peak than the "dry sample" with the peak intensity ratio of 1.2/1.0, while the corresponding peak area ratio is 1.1/1.0. The "moisturized sample" has slightly greater photon energy of about +1.0 eV energy shift at the normalized absorption of 0.5. This may be explained as the formation of hydrogen bonding between CrO_3 and the hydration because the formation of hydrogen bonding might cause the oxygen in the first coordinated shell to pull electron farther away from Cr, and this would shift the edge jump to higher photon energy. The XANES spectrum of the "moisturized sample" is also characterized with

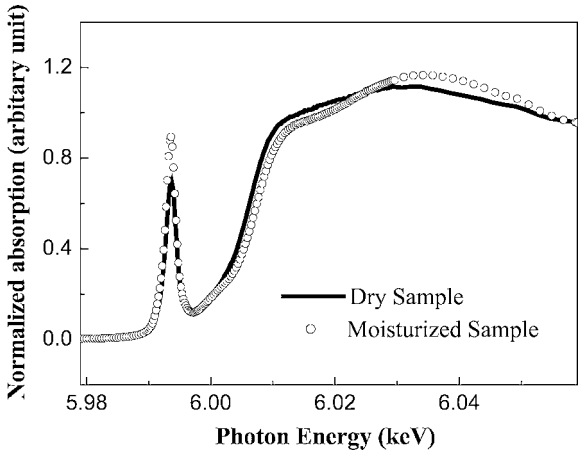

Fig. 1. XANES spectra of dry CrO_3-loaded silica and moisturized CrO_3-loaded silica.

*e-mail: yulin@mail.thu.edu.tw

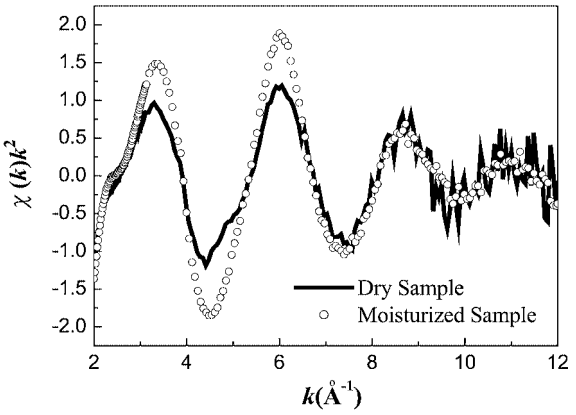

Fig. 2. EXAFS spectra of dry CrO_3-loaded silica and moisturized CrO_3-loaded silica.

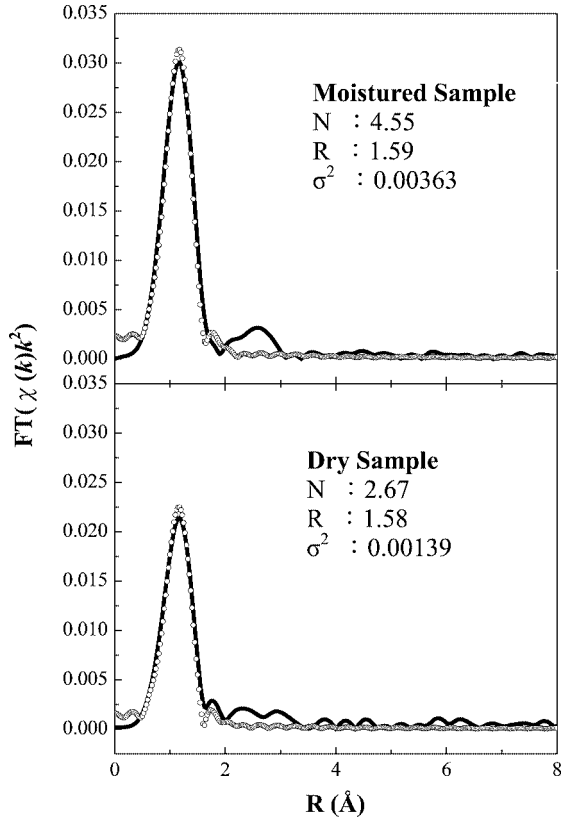

Fig. 3. Fourier transforms fitted for structural parameters of dry CrO_3-loaded silica and moisturized CrO_3-loaded silica.

a greater white line intensity than the "dry sample", that indicates a lower electron density in Cr d orbital.

Figure 2 shows the EXAFS spectra for the "moisturized" and "dry" samples in k space. The EXAFS spectrum of the "moisturized sample" was associated with higher amplitude in the k range of 2–6 $(Å)^{-1}$. However, the frequency of the EXAFS is not changed from dry sample to moisturized sample. Structural results deriving from EXAFS fitting using CrO_3 feff file are shown in each compartment of Figure 3. The coordination number (N) of the first Cr−O shell of the "moisturized sample" is much greater than that of the "dry sample" (i.e., 4.55 vs. 2.67). Therefore we suggest that water molecules might have moved to a position that was close enough to contribute to the coordination number of the first Cr−O shell. The results of the Debye-waller factor (σ^2) also support this suggestion; the "moisturized sample" is characterized with a much greater σ^2 value than the "dry sample": 0.00363 vs. 0.00139.

4. Conclusion

1. The content of moisture in Cr(VI)-loaded silica considerably affected the Cr XAS spectrum.
2. Cr(VI)-loaded silica with greater moisture content was characterized with greater preedge peak height, but the peak area did not seem to be affected by the moisture content.
3. Both the white line intensity in the normalized XANES spectrum and the amplitude of the EXAFS spectrum were enhanced with greater moisture content in Cr(VI)-loaded silica.
4. Both coordination number and Debye-Waller factor of the first coordination shell increased with greaterer moisture content in Cr(VI)-loaded silica. This suggested that water molecules might have moved to a position that was close enough to affect the first-shell molecular environment.

Effect of Water on XAS Spectrum of $Cu(NO_3)_2$ Reference

Nicky Cheng[1], Yu-Ling Wei[1*], Yaw-Wen Yang[2] and Jyh-Fu Lee[2]

[1]Department of Environmental Science, Tunghai University, Taichung City, 407 Taiwan

PACS number: 89.60−K

Abstract

To successfully fit the copper XANES and EXAFS spectra of a copper-containing sample, it is usually desirable to record the XAS spectra of various copper compounds. Nevertheless, $Cu(NO_3)_2$ reference is very hygroscopic, and the fitting results can be misleading if $Cu(NO_3)_2$ containing different amounts of H_2O is used as reference.

This study investigated the effect of water on the XAS spectrum of $Cu(NO_3)_2$ reference. The results, for the first shell (Cu–O), indicated that drier reference $Cu(NO_3)_2$ would have less coordination number. The interatomic distance was 1.95 Å that was independent of the moisture content in $Cu(NO_3)_2$ reference, and there was a slight variation in the Debye-Waller factor for the $Cu(NO_3)_2$ containing different moisture content. For the XANES spectra, it was found that the photon energy for the edge jump could be reduced by as great as 3–4 eV if $Cu(NO_3)_2$ was moisturized. This might have been due to the hydration effect on Cu^{2+}. The white line showed that there was more empty d orbital for the copper in the moisturized $Cu(NO_3)_2$ than for the drier one.

1. Introduction

Although copper is a necessary micronutrient to human, excessive intake of copper through inhalation, ingestion, and skin and eye contact may cause damage to mucous membrane and the upper respiratory tract [1, 2]. Pneumonia, vomiting, and poisoning phenomena can occur, too [1, 2]. In addition, it can cause pathological changes in central nervous system, liver, and kidney [1, 2]. The main man-made sources of copper contaminant include copper smelting, copper mining, metal rinsing, alloy manufacturing, electroplating, pesticide application, waste incineration, and electronics manufacturing [1]. In Taiwan, some heavily polluted areas were investigated and estimated to contain copper contaminant up to the level of more than 10% in weight. To develop an effective method to remedy copper contaminant in soils, solid wastes, and inorganic sludge, it is important to attain the information on copper speciation and molecular environment around copper in the Cu-containing matrices prior to and after remediation/treatment. This information is critical because based on which one can predict the effectiveness of the developed remediation/treatment technology. It is important especially when the long-term stability of the remedied/treated copper contaminant is concerned.

Copper nitrate is one of the frequently used reference compounds for the fitting of Cu XANES and EXAFS spectra. Nevertheless, it is very hygroscopic with solubility of 381/100 by weight in water [3]. This would incur great difficulty in using it as a reference compound. A previous study indicated that mixing of $Cu(NO_3)_2$ into silica and kaolin with de-ionized water, followed by drying at 105 °C for 3 days, resulted in the formation of $Cu(OH)_2$ via the hydroxylation of Cu^{2+} [4]. The Cu XANES fitting performance was not satisfactory [4]. Therefore, the objective of this study was to investigate the effect of hygroscopes of $Cu(NO_3)_2$ on the XAS spectrum of $Cu(NO_3)_2$.

2. Experimental

$Cu(NO_3)_2$ of G. R. grade from Riedel-de-Haën was used for this study. Two $Cu(NO_3)_2$ samples were prepared as follows for XAS measurement. The first $Cu(NO_3)_2$ sample that is termed "dry $Cu(NO_3)_2$" was prepared by grinding the $Cu(NO_3)_2$ chemical, and subsequent drying of the ground $Cu(NO_3)_2$ at 105 °C in an oven till constant weight. The "dry $Cu(NO_3)_2$" was then stored in a desiccator and ready for XAS measurement. The hygroscopic $Cu(NO_3)_2$ was prepared by adding one drop of de-ionized water into suitable amount of $Cu(NO_3)_2$ powder to simulate the hygroscopic phenomena of $Cu(NO_3)_2$ during the sample preparation just before copper XAS measurement. The hygroscopic $Cu(NO_3)_2$ was in a dense slurry form. Besides, $Cu(OH)_2$ of high purity from Riedel-de Haën was also recorded for its XAS spectra.

XAS spectra were all recorded on the wiggler C (BL-17C) beamline at the National Synchrotron Radiation Research Center (NSRRC) in Taiwan. The storage energy was 1.5 GeV, the electric current was 120–220 mA, and the energy spanning 4–15 keV for the monochromator. The edge jump for Cu is 8979 eV. All XAS spectra were recorded in transmittance mode at room temperature. Data reduction was carried out using WinXAS 2.0 [5].

3. Results and Discussion

Figure 1 shows the overplotting of the normalized Cu XANES spectra of "dry $Cu(NO_3)_2$", "hygroscopic $Cu(NO_3)_2$", and $Cu(OH)_2$ compound. It indicated that the photon energy of edge jump of the XANES spectrum of hygroscopic $Cu(NO_3)_2$ is about 3–4 eV less than that of "dry $Cu(NO_3)_2$". In fact, the photon energy for edge jump of the "hygroscopic $Cu(NO_3)_2$", was quite close to that of $Cu(OH)_2$. This is explained by the fact that

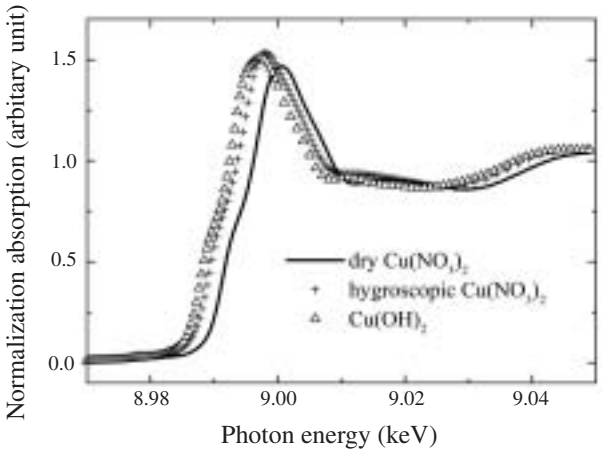

Fig. 1. XANES spectra for dry $Cu(NO_3)_2$, hygroscopic $Cu(NO_3)_2$, and $Cu(OH)_2$.

*e-mail: yulin@mail.thu.edu.tw

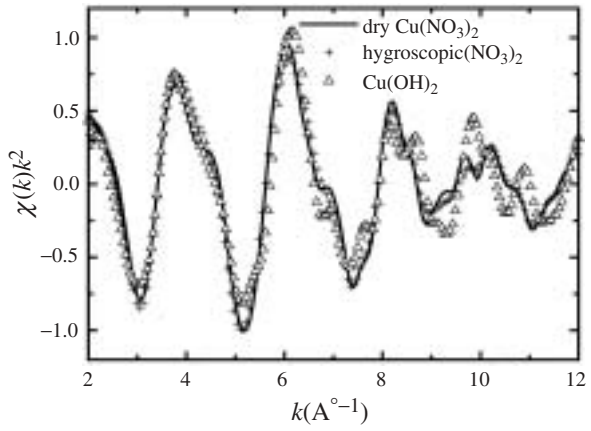

Fig. 2. EXAFS spectra for dry $Cu(NO_3)_2$, hygroscopic $Cu(NO_3)_2$, and $Cu(OH)_2$.

hygroscopic $Cu(NO_3)_2$ would decompose to form Cu^{2+} and $2NO_3^-$. The Cu^{2+} was then hydroxylated into $Cu(OH)_2$ [4]. The white line intensity of XANES spectra for "dry $Cu(NO_3)_2$" and "hygroscopic $Cu(NO_3)_2$" is also different from each other; the hygroscopic one is characterized with higher white line. In other words, the electron density in d orbital was less for the hygroscopic $Cu(NO_3)_2$. This was the reason why XANES fitting of samples involved $Cu(NO_3)_2$ reference was poor in our previous study [4].

Figure 2 presents the overplotting of the k^2-weighed EXAFS in k space for dry $Cu(NO_3)_2$, hygroscopic $Cu(NO_3)_2$, and $Cu(OH)_2$. It shows that there is some slight difference in EXAFS amplitude among these three spectra; while the oscillation frequency is virtually the same for these spectra. One may suggested that molecular environment around copper is only slightly different among dry $Cu(NO_3)_2$, hygroscopic $Cu(NO_3)_2$, and $Cu(OH)_2$. This suggestion will be further supported by the results obtained by comparing the structural parameters among them.

Figure 3 shows the overplotting of Fourier transform of the EXAFS spectra. Not much difference is observed among these spectra. Table I presents the coordination number (N), interatomic distance (R), and Debye-Waller factor (σ^2) of the first shell for dry $Cu(NO_3)_2$ and hygroscopic $Cu(NO_3)_2$ and Figure 4 shows the fitting of EXAFS spectra for dry $Cu(NO_3)_2$ and hygroscopic $Cu(NO_3)_2$. All data of structural parameters indicate that dry $Cu(NO_3)_2$ and hygroscopic $Cu(NO_3)_2$ have quite similar molecular environment, although the electronic state of copper is considerably different between them.

Sample	N	R (Å)	σ^2 (Å)^2
Dry $Cu(NO_3)_2$[a]	3.75	1.95	0.00388
Hygroscopic $Cu(NO_3)_2$[a]	3.94	1.95	0.00378

[a]Use $Cu(NO_3)_2$ feff for Fourier spectra fitting.

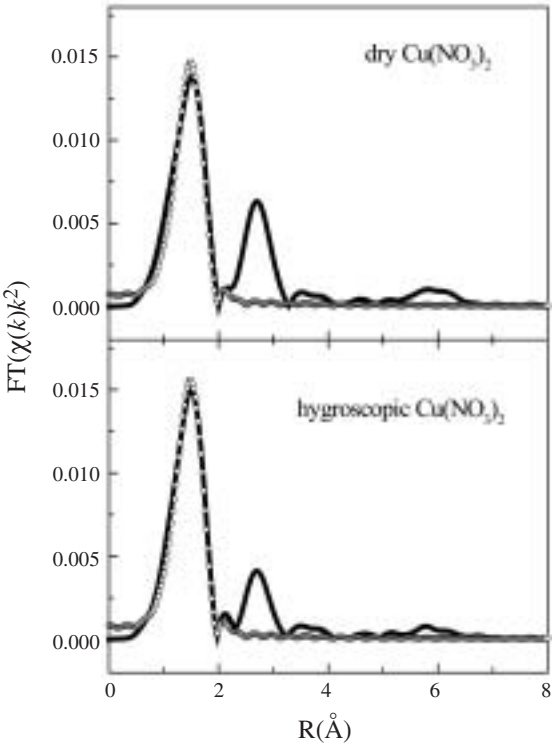

Fig. 4. Fitting of EXAFS spectra for dry $Cu(NO_3)_2$ and hygroscopic $Cu(NO_3)_2$.

4. Conclusion

1. Hydroxylation of hygroscopic $Cu(NO_3)_2$ resulted in partial formation of $Cu(OH)_2$.
2. Water molecules involved in hydroxylation of hygroscopic $Cu(NO_3)_2$ caused a considerable change in copper electronic state, as indicated by the shift of edge jump and the change of white line intensity. This would incur a poor fitting in copper XANES spectra for samples.
3. Molecular environment surrounding copper was virtually similar between dry and hygroscopic $Cu(NO_3)_2$.

Abstract

This study investigated thermally stabilized lead-contaminated silica at 300–900 °C, and the heated samples were leached with combined acid (H_2SO_4 + HNO_3, precursors of acid rain). The leached residues were studied with X-ray absorption spectroscopy (XAS) technique to determine the lead speciation therein. The results indicated that after heating at 300 °C, the main lead speciation in the leached residue was $PbSO_4$ (43%), and PbO and Pb_3O_4 constituted another 53%. For the samples heated at 700 °C and 900 °C, the main lead speciation in the leached residue was PbO (about 77% of the total lead in both leached residues), and $PbSO_4$ only accounted for 22–23% in the residues. No $Pb(NO_3)_2$ was detected in the residues due to its high solubility.

1. Introduction

Lead is a neurotoxin. Chronic intoxication of lead compounds results in body weight loss, poor health, anemia, gastrointestinal distress, and arthralgia [1]. Acute intoxication of lead causes anorexia, vomiting, etc. [1]. Lead level greater than 0.05 mg/L in blood can cause permanent damage to intelligence [1].

The main source of lead contaminant/pollutant in Taiwan has been associated with lead battery manufacturing. Lead compounds were frequently found in atmosphere, waste water stream, and soil nearby the manufacturing plant. In USA soils, lead was frequently found in the US superfund sites [2].

Thermal treatment of heavy metal-containing soils and solid wastes offers an effective alternative for soil remediation and solid waste treatment [3–6].

2. Experimental

The Pb^{2+}-doped silica powder (40,000 mg Pb/kg silica) was prepared by mixing a pre-calculated lead nitrate powder of G. R. grade (Riedel-de Haën) in de-ionized water with pre-weighed silica powder and subsequent drying of the slurry-like mixture at 105 °C for 3 days. Even dispersal of Pb onto the surface of silica powder was achieved by continuous mixing in a rotating mixer (ca. 30 rotations/min) for ten days. The dry Pb^{2+}-doped silica powder was then thermally treated at 300, 700, and 900 °C for four hours in a fixed-bed reactor that was made of stainless steel cylinder. The reactor was electrically heated to the pre-set temperatures before feeding in the dry Pb^{2+}-doped silica powder.

The effect of thermal stabilization on lead leaching was tested by acid leaching of the heated dry Pb^{2+}-doped silica powder. Combined acid of H_2SO_4 and HNO_3 (60 : 40 in weight) in de-ionized water having a pH 5.00 ± 0.05 was used to test the extent of Pb leaching from the heated samples. This test was carried out according to Method S101.60A issued by the Environmental Protection Administration (EPA) of Republic of China. It should be noted that both H_2SO_4 and HNO_3 are main precursors of acid rain. The Pb^{2+}-containing leachates collected from the leaching test were digested according to Method 3010 formulated by USEPA [7]. The concentration of Pb^{2+} in the digested leachates was measured with a flame atomic absorption spectrometer (FAAS). A stock solution from Merck Company containing 1000 mg Pb^{2+} per liter solution was diluted to various extents to prepare the calibration curves. Each curve spanned at least five different Pb concentrations. The lowest correlation coefficient (r^2) was required to be greater than 0.995 for all curves. Five replicate measurements of each diluted stock solution were carried out and the calibration curve was prepared prior to the measurement of a batch of samples. The method detection limit (MDL) was determined to be 0.54 mg Pb/kg silica. The Pb quality control (QC) standard solution was routinely measured to check the stability of the calibration curve. One check of the calibration curve by the standard solution was performed for every 20 unknown samples measured. The X-ray absorption spectroscopic (XAS) spectra were recorded on the wiggler C (BL-17C) beamline at the National Synchrotron Radiation Research Center (NSRRC) located in Hsinchu, Taiwan, Republic of China. The storage energy was 1.5 GeV, the beam current was 120–200 mA, and the energies of the monochromator photon beams are in the range of 4–15 keV. X-ray absorption spectra at the Pb-L^{III} edge (13055 eV) were collected at room temperature in transmission mode for the reference compounds and fluorescence mode for the acid-extracted residues of the thermally treated Pb-containing samples. Data reduction was carried out using WinXAS software [8]. This software is capable to perform species quantification for a multicomponent mixture based on their fingerprint in the XANES region [8]. The species quantification was achieved by simulating the experimental XANES spectrum through a least-squares procedure to refine the sum of a set of reference spectra [8]. Reference compounds that do not seem to exist in the sample often result in negative partial concentration or unreasonable energy shift [8].

3. Results and Discussion

Figure 1 shows the results of lead leaching from the samples heated at 300, 700, and 900 °C. It indicates that thermal treatment at higher temperature reduced lead leaching percentage more effectively (i.e., 5% at 900 °C vs. 26% at 300 °C).

Figure 2 presents the XANES spectra (left column) and their first derivatives (right column) for reference compounds

*e-mail: horix@ms17.hinet.net

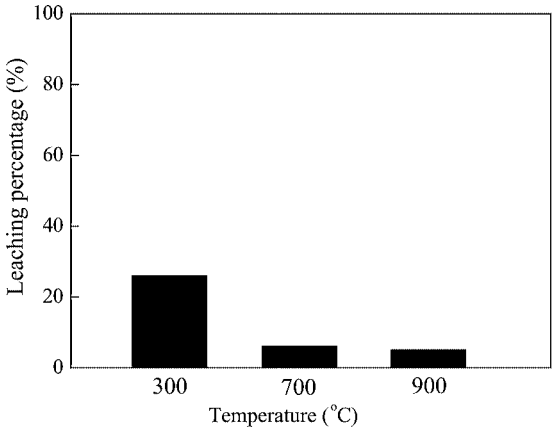

Fig. 1. Leaching percentage of lead from lead-containing samples thermally treated at 300, 700, and 900 °C.

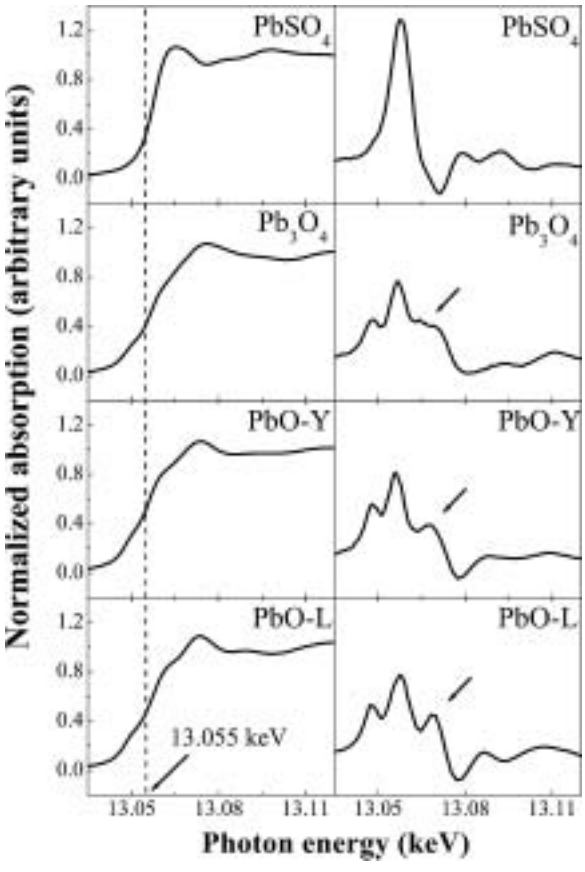

Fig. 2. XANES spectra (left column) and their first derivatives (right column) for the reference compounds.

$PbSO_4$, Pb_3O_4, PbO-yellow, and PbO-litharge. There are distinct differences among the spectra except between that for PbO-yellow and PbO-litharge. Only minor differences are observed between the XANES spectra for both PbO. The white line height for PbO-litharge reference is slightly higher than that for PbO-yellow.

Figure 3 presents the XANES spectra (right side) and their respective first derivatives (left side) for the acid-extracted residues of the thermally stabilized samples. The first derivative of the 300 °C-heated sample residue (see bottom right compartment of Fig. 3) is more similar to that of $PbSO_4$ reference compound (see top compartment of Fig. 2) than that of the 700 °C and 900 °C-heated sample residues. XANES fitting results indicate that the main lead species in the residue of the 300 °C-heated

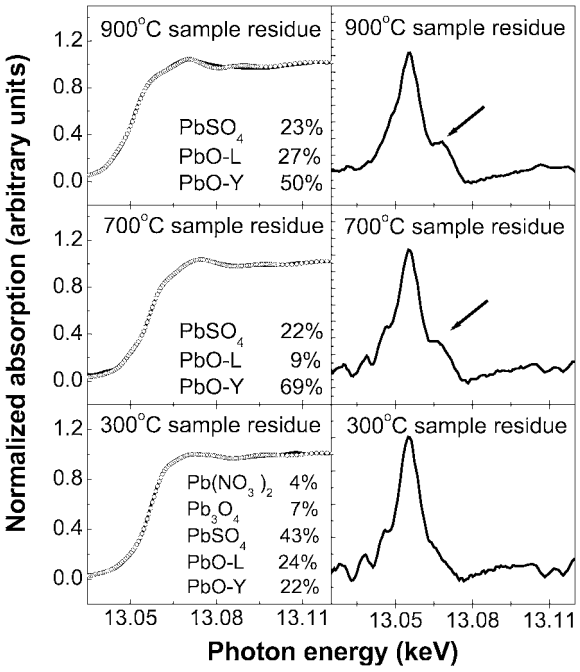

Fig. 3. XANES fitting (left column) and their first derivatives (right column) for the acid-extracted residues of the heated samples.

sample is $PbSO_4$; while that in the residues of the 700 °C- and 900 °C-heated samples is lead oxide (i.e., mostly the PbO-yellow). $PbSO_4$ content in the acid-extracted residues of the heated samples decreases with the thermal treatment temperature (i.e. 43% for 300 °C sample residue, 22–23% for 700–900 °C sample residues). This is reasonable because $PbSO_4$ may decompose into PbO and SO_2/SO_3. As to the lead oxide, thermal treatment at higher temperature followed by the combined-acid leaching resulted in greater transformation of PbO-yellow into PbO-litharge. Furthermore, $Pb(NO_3)_2$ was detected only in the extracted residue of 300 °C sample because it decomposes into PbO at about 500 °C.

Figure 4 depicts the fitting of the corresponding Fourier transforms of EXAFS and the resulted structural information is shown in Table I. The EXAFS spectra were k^2-weighed and were Fourier-transformed in the "k" range of 2.5–10.4. The first peak

Table I. *Structural results based on the EXAFS fitting for the acid-extracted residues of the heated samples.*

	$Pb(NO_3)_2$-doped SiO_2	
sample	N type at R (Å)	σ^2 (Å)^2
300 °C sample residue[a]	1.00 Pb-O at 2.18	0.004
700 °C sample residue[a]	1.45 Pb-O at 2.27	0.002
900 °C sample residue[a]	3.39 Pb-O at 2.24	0.013
PbO-L reference compound[a]	4.00 Pb-O at 2.29	0.006

[a]: fitted by PbO-L feff1.

(covering the range of: 0.4–2.26 Å) of the Fourier-transformed EXAFS spectra was fitted with PbO-litharge feff1 file to obtain the structure parameters of coordination number (N), Pb−O interatomic distance, and the Debye-Waller factor (σ^2) for the first shell. The first-shell coordination number is 1.00 for the 300 °C sample residue, 1.45 for the 700 °C one, and 3.39 for the 900 °C sample residue. This suggests that greater sintering reaction might occur in the 900 °C sample than the 700 °C one. The Debye-Waller factor (σ^2) is also greater for the 900 °C sample residue due to the greater extent of sintering reaction.

4. Conclusions

1. Effectiveness of thermal stabilization of Pb^{2+}-doped silica increased with greater treating temperature. Less Pb^{2+} was acid-leached from the sample thermally treated at higher temperatures.
2. Lead compounds in the acid-leached residues of the thermally treated samples tended to transform from $PbSO_4 + Pb(NO_3)_2$ into PbO-yellow and PbO-litharge. The content of PbO-litharge increases with higher thermal treatment temperature.
3. Both the results of the coordination number and Debye-Waller factor suggest that treatment at 900 °C resulted in greater sintering reaction than that at 700 °C.

Abstract

Aqueous metal complexes are important chemical species in the geosphere, since they often determine the mobility of metals in the environment. While EXAFS spectroscopy is the method of choice to determine the structure of such species in environmental matrices, it often fails when several complexes coexist. In this case, all present complexes contribute to the EXAFS signal, and the deconvolution into single contributions is difficult. We have developed a new algorithm to determine the spectral contributions of the single in mixtures of species, based on a combination of Monte-Carlo Simulation and Target Transformation Factor Analysis (MCTFA). This novel approach requires solely the structure of the interacting ligand as input data, enabling the determination of complexes even in "messy" environmental samples.

1. Introduction

Many attempts have been made in the past to determine structure, chemical behavior and relative distribution of aqueous metal complexes at a given set of geochemical conditions (defined by pH; Eh; concentrations of aqueous ions, solids, gasses; temperature; etc.). EXFAS spectroscopy is one of the most versatile and powerful techniques to determine the often low concentrations in the presence of complex backgrounds typical for geochemical settings. However, if more than one metal complex exists, then the EXAFS signal is the superposition of the contributions of the backscattering atoms of all metal complexes, and only average structural parameter (i.e. radial distances, coordination numbers) can be obtained. In case the EXAFS spectra of isolated complexes can be measured, one can derive the identity and quantity of the complexes in mixtures by Target Transformation Factor Analysis (TFA) and/or Linear Combination Fits (LCF) [1, 2]. Especially for uranyl-organo-complexes, however, species may remain undetected because they cannot be prepared (and measured) as pure species. Under these conditions, the EXAFS spectra of the pure metal complexes may be obtained by Iterative Target Transformation Factor Analysis (ITFA) [3–6]. Starting point for ITFA is a series of EXAFS spectra measured in dependence of one ore more physicochemical parameters, which influence the speciation (relative concentration distribution of species) of the metal complexes. Although ITFA does not depend on EXAFS spectra of pure species, it still depends on speciation data, which may often be provided by thermodynamic data bases and models. If even the data of the relative species distribution are missing, however, ITFA must fail. Therefore, we propose another approach, where only the structure of the metal-binding ligand is required. Our approach varies the position of the metal in relation to the ligand by Monte-Carlo Simulation (MC). For each structural configuration, the theoretical EXAFS spectrum is then calculated and submitted as target test vector to TFA. We have tested this approach using a series of uranyl acetate complexes at varying pH.

2. Experimental

Eight samples were prepared in the pH range 0.10–4.48 at an ionic strength of 1.2 mol/L. For all samples [U(VI)] was 0.05 mol/L and the acetic acid concentration [ac] was 1 mol/L except for the sample at pH 4.48, where [U(VI)] = 0.025 mol/L and [ac] = 0.5 M. The U L_{III}-edge EXAFS spectra of the pH series were measured at the Rossendorf Beamline (ROBL) at the ESRF (Grenoble, France) in transmission mode at room temperature. Crystallographic data of sodium tris(acetato)dioxouranate [7] were used to create the ligand structure for the MCTFA and to calculate the theoretical phase and amplitude functions for EXAFS data analysis (FEFF6).

3. Monte-Carlo Simulation Target Transformation Factor Analysis (MCTFA)

MCTFA combines the advantages of modeling and statistics. The MC simulation allows to model the three dimensional structure of the complexes by using the experimental XAS spectra and the structure of the interacting ligand as constraints [8–10]. TFA allows to check whether the resulting EXAFS spectrum of the calculated complex is a component of the series of measured EXAFS spectra [1, 3, 11].

In the following capital bold letters are matrixes, small bold letters are vectors, and italic letters are scalars. Starting point of TFA is the calculation of the abstract (abs) factor solution for the abstract reproduction of the data matrix $\mathbf{D}_{(r,c)} = \mathbf{R}_{\mathbf{abs}(r,c)}\mathbf{C}_{\mathbf{abs}(c,c)}$ ($\mathbf{D}$ accumulates the c EXAFS spectra of complex mixtures at r measuring points, $\mathbf{R}_{\mathbf{abs}}$ and $\mathbf{C}_{\mathbf{abs}}$ contains eigenvectors) by using Eigenanalysis. The orthogonal factor solution consists of c eigenvectors. Only n (n – number of main components) eigenvectors are necessary to reproduce $\mathbf{D}$. In the second step of TFA, n is determined using the eigenvalues in $\mathbf{\Lambda}$ and the indicator function *IND* [11]. After the factor compression the dimension of $\mathbf{R}_{\mathbf{abs}}$ is (r, n) and that of $\mathbf{C}_{\mathbf{abs}}$ is (n, c). In the third step a EXAFS spectrum is subjected as a test vector $\mathbf{x}_{\mathbf{test}}$ and gives a predicted (pred) vector $\mathbf{x}_{\mathbf{pred}} = \mathbf{R}_{\mathbf{abs}}\,\mathbf{\Lambda}^{-1}\mathbf{R}'_{\mathbf{abs}}\mathbf{x}_{\mathbf{test}}$ ($'$ stands for transponse). The spectrum $\mathbf{x}_{\mathbf{test}}$ is a component of the spectra of the complex mixtures if it is in agreement with the predicted spectrum $\mathbf{x}_{\mathbf{pred}}$. The spectrum $\mathbf{x}_{\mathbf{test}}$ we calculated using MC technique.

The steps of the whole algorithm are as follows: (1) Fit of a spectrum of the series to determine Debye-Waller factors σ_i for the ligand atoms and the energy shift ΔE_0 (2) Eigenanalysis of the EXAFS spectra of mixtures, factor compression. (3) Set up a cube and insert the ligand molecule. (4) Put the metal atom at a random

*e-mail: rossberg@esrf.fr

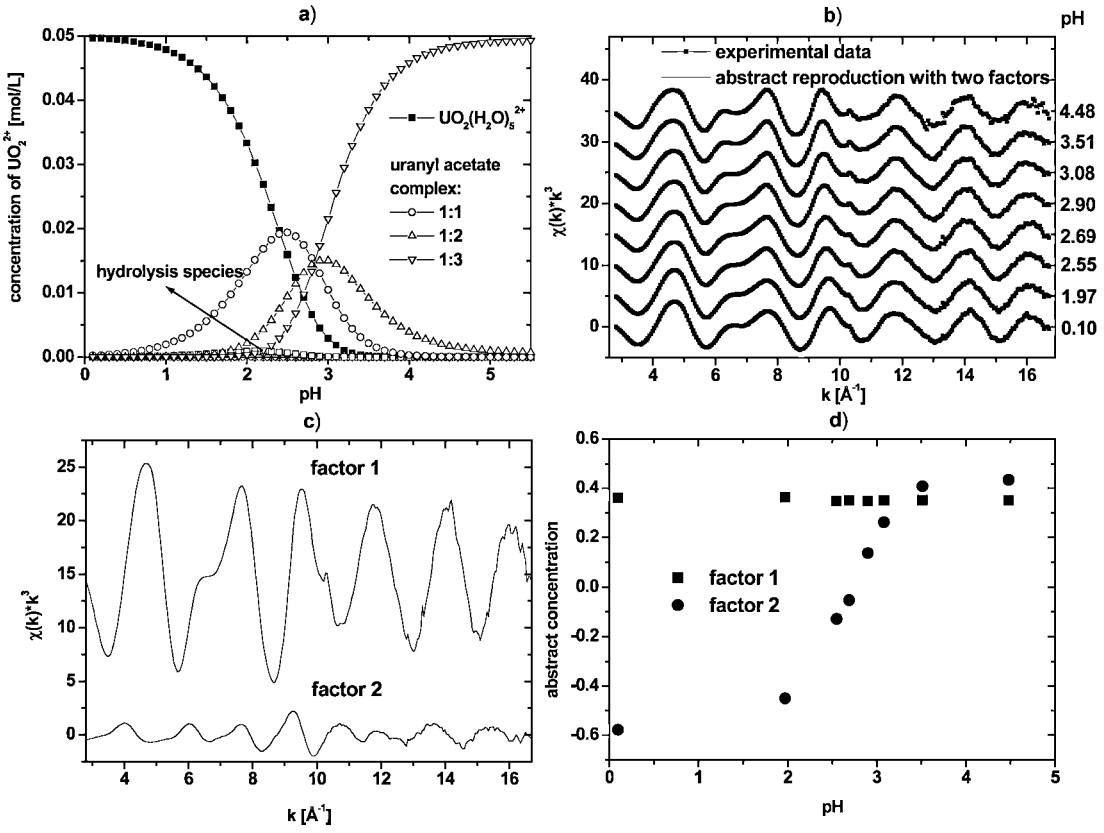

Fig. 1. (a) Speciation for [U(VI)] = 0.05 mol/L, [ac] = 1.0 mol/L, I = 1 mol/L (complex stability constants from [12]); (b) (c) content of data matrix **D** and their abstract reproduction using abstract spectra $\mathbf{R_{abs}}$ and (d) abstract concentrations $\mathbf{C_{abs}}$.

position in the cube. (5) Calculate the distances R_i between metal atom and the ligand atoms. (6) Calculate the theoretical EXAFS spectrum $\mathbf{x_{test}}$ using σ_i, R_i, and ΔE_0. (7) Calculate $\mathbf{x_{pred}}$ using the TFA procedure. (8) Determine χ^2 between $\mathbf{x_{test}}$ and $\mathbf{x_{pred}}$ and normalize χ^2 to the variance $\mathbf{x'_{pred}}\ \mathbf{x_{pred}}$, save the best normalized χ^2. (9) Go to step 4 and repeat m times. (10) Put the metal atom at the position of the lowest normalized χ^2, divide edge length of the cube by a factor, shift the center of the cube to the position of the metal atom, go to step 4 if the edge length of the cube is greater than the expected uncertainty in atomic distances otherwise stop. (11) The metal atom has reached the optimum position towards the ligand.

The algorithm has two advantages: (1) The TFA identifies also the spectrum of the pure complex $\mathbf{x_{test}}$ as a component of the spectral mixtures, therefore the algorithm is sensitive to the pure metal complexes. (2) Only the metal atom is moved during the MC simulation, which drastically reduces the computing time in relation to methods which move the whole ligand. This is especially important when large ligands are investigated.

4. Results and discussion

In the pH interval 0.10-4.48, the U(VI)/ac system contains four complexes (Fig. 1a).

Our previous study using ITFA [3, 5] has shown that only two spectroscopic components (i.e. factors, Fig. 1 b–d) are required to reproduce all spectra: the spectra of uranyl hydrate ($UO_2(H_2O)^{2+}$) and of the 1 : 3 U(VI)/ac complex, while the 1 : 1 and the 1 : 2 complexes can be reconstructed from them (Fig. 2).

From a structural point of view, these two spectroscopic units correspond to uranyl coordinated to a water molecule and uranyl

	O_{eq}	2.47	6.0	8.5
	C_1	2.87	3.1	3.8
	C_2	4.39	3.1	3.8
U(VI)-carboxylate (MCTFA)	O_{ax}	1.78*	2*	1.7*
	O_{eq}	**2.46**	4*	9.5*
	C_1	**2.84**	2*	4.0*
	C_2	**4.34**	2*	4.0*

R – atomic distance [Å], N – coordination number, σ^2 – Debye-Waller factor [Å^2].

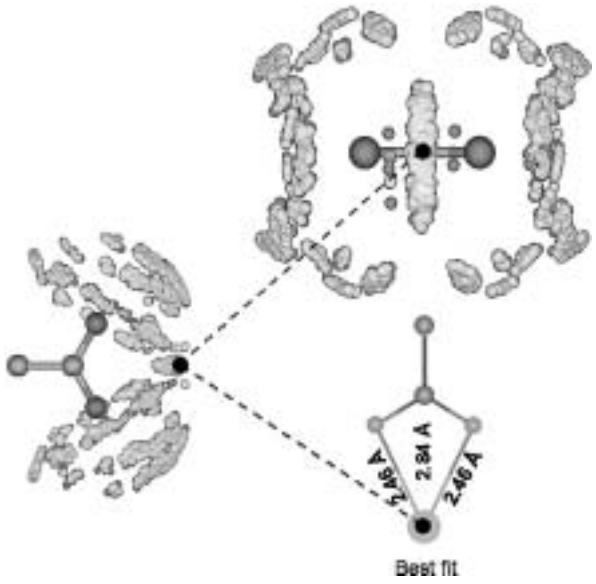

Fig. 3. MCTFA result. Brighter balls indicate U positions with the highest likelihood (best fits), darker balls indicate positions resulting in poorer fits. Structural data for the optimum position (black dot) are given in Table I.

coordinated to a carboxylic group in a bidentate arrangement. For all complexes only the number of this two structural units vary and the short-range structure as determined by EXAFS remains invariable (Table I). Note that this result was obtained by ITFA [3, 5]. In the following we demonstrate, that we can achieve the same uranyl-carboxylate structure by MCTFA, even when we use a much smaller pH range of 0.10–2.69, which does not include the pure end-member spectrum, and with a more restricted chi-range of 2.9–12.3 $Å^{-1}$, representing the typically poorer data quality of environmental samples. For the calculation of the theoretical EXAFS spectrum, we used the distance U-O_{ax}, σ^2 of O_{ax} and O_{eq}, and ΔE_0 determined from the spectrum at pH 2.69. Furthermore, we kept the distances of the two axial oxygen atoms constant, and accounted for the twofold degenerated 4-legged multiple scattering path of the uranyl chain in our calculation. Using these constraints, we achieved the structure of the uranyl-carboxylate unit in 110.000 iterations. The resulting U-O_{eq} distances are identical to those found by conventional EXAFS data analysis of the 1 : 3 U(VI)/ac complex considering an error of 0.02 Å (Table I, Fig. 3). Thus, we are confident that MCTFA may be successfully applied to solve the local structures of a wide range of complexes based solely on the ligand structure, which is often known. Thus, the newly developed method could be extremely useful to decipher the structure of metal complexes in environmental samples where a wide range of organic ligands, from simple organic acids to large biopolymers may be present.

Abstract

An attractive remediation strategy for the removal of highly soluble U(VI) from groundwater is microbial reduction of soluble U(VI) to U(IV) as insoluble uraninite. The feasibility of this remediation strategy depends on the rate and extent of microbial reduction of U(VI) in the presence of ions commonly found in groundwater that can form complexes with uranyl. Recently, Ca in solutions with U(VI) has been shown to inhibit microbial reduction of U(VI). Indirect evidence supports the formation of a Ca-UO_2-CO_3 complex that may be responsible for the limited microbial reduction of U(VI) in the presence of Ca, but direct evidence for the formation of a Ca-UO_2-CO_3 complex is needed for verification. X-ray absorption fine-structure measurements of solutions containing 50 μM U(VI) and 30 mM bicarbonate, with and without 5 mM Ca, were made to determine whether a Ca-UO_2-CO_3 complex was present. These results are discussed.

1. Introduction

Activities associated with the mining and processing of U ores have resulted in vast areas of environmental contamination. Current remediation strategies are based on the removal of soluble U(VI) from the aqueous phase by reducing it to insoluble U(IV) in the form of a uranium oxide precipitate, uraninite. The formation of the insoluble uraninite should minimize the transport of U from contaminated areas. Previous studies have shown that dissimilatory metal-reducing bacteria (DMRB) couple the oxidation of organic matter or of H_2 to the reduction of oxidized metals including U(VI). The feasibility of this remediation strategy depends on the rate and extent of microbial reduction of U(VI) in the presence of ions commonly found in groundwater that can form complexes with U(VI).

Factors that enhance or inhibit bacterial U(VI) reduction are not well understood. Recently, Ca in solutions with U(VI) has been shown to inhibit microbial reduction of U(VI) [1]. Indirect evidence of for a Ca-UO_2-CO_3 solution complex in solution has been demonstrated [2, 3]. Such complexes have been largely overlooked, because most equilibrium speciation models predict the dominant uranyl species in calcareous groundwater to be uranyl carbonates. These species may be responsible for the limited microbial reduction of U(VI). Direct evidence for the formation of a Ca-UO_2-CO_3 complex is needed to help clarify the cause of the limited microbial reduction of U(VI) in calcareous groundwater.

X-ray absorption fine-structure (XAFS) measurements of solutions containing environmentally relevant concentrations of U(VI) (50 μM), bicarbonate (30 mM), and acetate (5 mM) with and without Ca (5 mM) have been made to determine the presence of a Ca-UO_2-CO_3 complex. Our previous study [1] briefly reported results for a similar +Ca solution (with no added acetate) as supporting evidence for the formation of a Ca-UO_2-CO_3 complex. A more thorough analysis of the EXAFS data from two samples that differ only in the presence or absence of Ca is presented here.

2. Experimental Methods

The solution samples were prepared under anoxic conditions. Both solution samples contain 50 μM U(VI), 30 mM HCO_3, and 5 mM acetate. One sample (+Ca) also contains 5 mM $CaCl_2$ while the other sample (−Ca) did not. The U concentration in these samples of 50 μM are similar to the level of U contamination at the NABIR Field Research Center site, Oak Ridge National Laboratory, TN, USA, but are very dilute for EXAFS measurements. For our 3 mm thick sample the change in the absorption coefficient at the U L_3-edge is approximately 2×10^{-4}. This edge step is approximately two orders of magnitude smaller than a standard edge step for a fluorescence measurement. Uranium L_3-edge EXAFS measurements were made at the MR-CAT insertion device (10-ID) beamline [4] at the Advance Photon Source. The insertion device was tapered to reduce the variation in the X-ray intensity (to less than 15%) through the scanned energy range. A Si(111) double crystal monochromator was used to select the X-ray energy. A Rh mirror was used to remove X-rays with higher harmonic energies. The measurements were made in fluorescence mode by using a 13 element solid-state detector (Canaberra with XIA electronics). The incident X-ray intensity was monitored using a nitrogen filled ion chamber. The intensity of the nonfocused beam of approximately 1 mm square at the U L_3-edge is approximately 5×10^{13} photons/s. The integration time for each data point of approximately 12 s resulted in approximately one EXAFS scan per hour. The +Ca sample was scanned 3 times while the −Ca sample was scanned 10 times. The data were processed by using standard procedures and with UWXAFS [5] software package. The averaged $\chi(k)$ data are shown in Figure 1. Theoretical models were constructed with the program FEFF7 [6] and the crystallographic atomic positions of andersonite [7]. Automatic overlap of the muffin tin potentials was used in the FEFF7 calculation as previously reported [8].

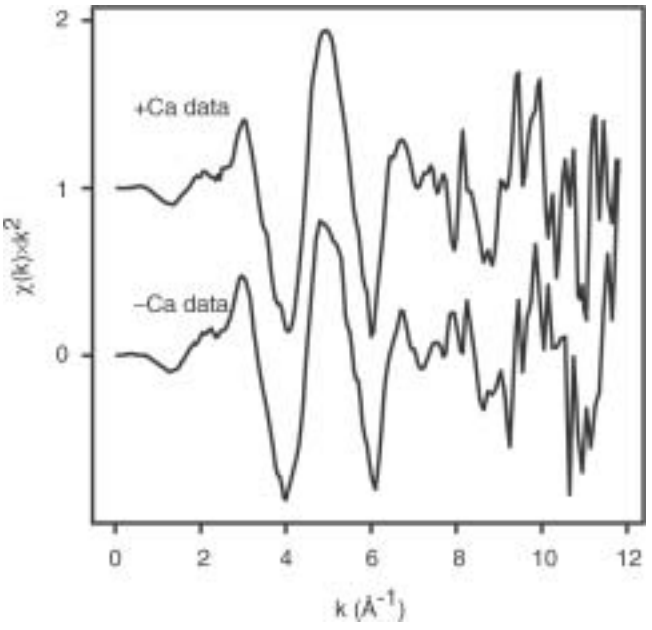

Fig. 1. Averaged $\chi(k) \cdot k^2$ data from the +Ca (2.7 to 10 $Å^{-1}$) and −Ca (2.7 to 9 $Å^{-1}$) samples.

3. EXAFS Data Analysis

Speciation calculations based on formation constants for a proposed Ca-UO_2-CO_3 complex indicated that this complex will be the major (∼98.4%) component in our +Ca sample [1]. The U(VI) is in the form of a uranyl tricarbonate species with an unknown number of Ca atoms, presumably bound to the distant oxygen atoms of the carbonate groups. A ball-and-stick model of this species is shown in Fig. 2. This figure shows the equatorial oxygen (Oeq) atoms in the plane of the page with the axial oxygen (Oax) atoms above and below the uranium atom. The model for this structure contains 4 shells of atoms. The coordination numbers in the model for the uranyl-tricarbonate species are held to the expected values based on the speciation calculations. These coordination numbers are 2 Oax, 6 Oeq, 3 C, and 3 Odist (distant oxygen atoms of the carbonate groups) as shown in Fig. 2.

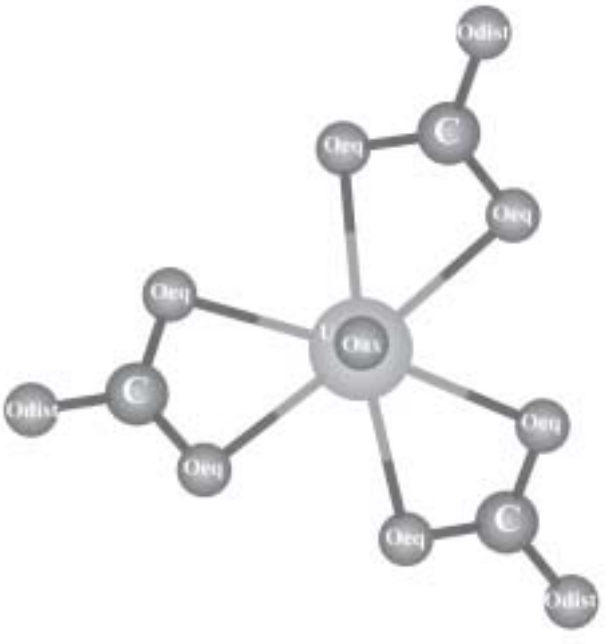

Fig. 2. Ball and Stick figure of $(UO_2)(CO_3)_3$ species. The uranyl moiety (UO_2^{2+}) is made up of the U atom bound with two axial oxygen (Oax) atoms that are located above and below the U atom.

Important U-Oax1-U-Oax2 and U-C-Odist multiple scattering (MS) paths that must be included in the model. The EXAFS variables for these MS paths can be approximately parameterized in terms of the single scattering (SS) path containing the end atoms. For a linear group of three atoms, U-C-Odist, the σ^2-value of the SS path U-Odist has been set equal to the σ^2-value of the MS paths. This is exactly true if the atoms are linear and becomes an approximation as they deviate slightly from linearity. The σ^2-values for the U-Oax1-U-Oax2 MS paths are parameterized as described elsewhere [8]. Based on other Ca-UO_2-CO_3 systems, the U-Ca distance is expected to be about 3.8 to 4.1 Å. This path was added to model our +Ca data. Table I lists the paths included in the model and the EXAFS parameterizations.

Both data sets (+Ca and −Ca) were fit simultaneously by using a k-weight values of 1, 2, and 3 in the Fourier transform. Initially all N, Δr and σ^2 values were constrained to the same values for both data sets. This initial model failed to reproduce both data sets simultaneously. The other extreme, allowing all N, Δr and σ^2 values to vary independently also failed because of our limited data ranges. The minimum freedom needed to describe the data accurately was determined to have equal N and Δr values for both data sets and variable σ^2 values (See Table I).

Table I. *EXAFS parameters for the simultaneous fits to +Ca and −Ca data sets. One S_0^2 value and one ΔE value were also determined in the fit. The two data sets have 6 common variables ($\Delta Roax$, $\Delta Roeq$, ΔRc, $\Delta Rodist$, ΔE, and S_0^2). The −Ca data set has 4 (σ^2oax-, σ^2oeq-, σ^2c-, and $\sigma^2odist-$) independent variables, while the +Ca data set has 7 (σ^2oax+, σ^2oeq+, σ^2c+, $\sigma^2odist+$, $Nca+$ $\Delta Rca+$, and σ^2ca+) independent variables. Therefore, the −Ca and +Ca data sets have averages of 7 and 10 variables, respectively. The −Ca and +Ca data sets have 14 and 16 independent points, respectively. The M.S. path U-C-Odist has a degeneracy of twice the S.S. path U-Odist because there are two equivalent M.S. paths (U-Odist-C and U-C-Odist).*

Path	Model	N	ΔR	σ^2
U-Oax	+Ca	2	$\Delta Roax$	σ^2oax+
	−Ca			σ^2oax-
U-Oeq	+Ca	6	$\Delta Roeq$	σ^2oeq+
	−Ca			σ^2oeq-

	−Ca			3 ± 3
U-Oax1-U-Oax2	+Ca	2	3.64 ± 0.01	0 ± 1
	−Ca			3 ± 3
U-Ca	+Ca	1.4 ± 1.2	4.02 ± 0.03	0 ± 1
U-Odist	+Ca	3	4.11 ± 0.02	8 ± 10
	−Ca			3 ± 3
U-C-Odist	+Ca	6	4.11 ± 0.02	8 ± 10
	−Ca			3 ± 3
U-C-Odist-C	+Ca	3	4.11 ± 0.02	8 ± 10
	−Ca			3 ± 3

Figure 3 shows the Fourier transform of the data and the best-fit models. Under the data and model in the Figure 3 is shown the individual contribution from each path included in the models, illustrating the importance of the MS paths and the overlap of the Odist paths with the Ca path. The best-fit values for all the paths included in the models are listed in Table II.

4. Conclusions

The best-fit value for the number of Ca atoms for the +Ca sample is 1.4 ± 1.2 indicating the presence of a Ca-UO_2-CO_3 complex in this sample. All the other parameters including the σ^2 values and Δr values, are within the uncertainties of previously reported values. Simultaneously fitting the +Ca and −Ca data was necessary to distinguish between the contribution from the Ca atom, the distant oxygen (Odist), and the MS paths (U-C-Odist) of the carbonate groups. Direct evidence of the Ca-UO_2-CO_3 complex and its role in bioreduction of U(VI) in calcareous ground waters like those found at the FRC must be considered in developing a feasible bioremediation strategy.

Abstract

Ironstone deposits are common in the Barberton Mountain Land of South Africa. They are composed of fine-grained goethite with significant amounts of several manganese oxide phases. Fossil bacteria in these rocks are often preserved within the iron and manganese oxide phases, and bacteria may have played a significant role in the formation of the deposits. Manganese minerals, in particular lithiophorite ($(LiAl_2(Mn_2^{+IV}Mn^{+III})O_6(OH)_6)$ and todorokite ($(Ca, Na, K)_x(Mn^{+IV}Mn^{+III})_6O_{12} \cdot 3.5H_2O)$), have been identified by X-ray diffractometry.

These rocks have now been studied by X-ray absorption fine structure spectroscopy. X-ray absorption near edge structure (XANES) spectroscopy showed that the oxidation state of both iron and manganese in these rocks is high. Least squares modeling of the X-ray absorption near edge structure (XANES) spectra shows that most of the manganese is present in the oxidation states +III and +IV, with no detectable manganese as +II. Similarly for iron, only +III oxidation state could be identified in most rocks. Extended X-ray absorption fine structure (EXAFS) studies confirm that both edge-sharing (lithiophorite, todorokite) and corner-sharing octahedra (todorokite) are present and constrains the proportions of these two minerals. Bacteria stabilized the higher oxidation states of iron and manganese during precipitation, acting as an important component of the mineralization.

1. Introduction

Bodies of ironstone deposits are common in the Barberton Mountains of South Africa. These deposits have been interpreted as products of Archean (3.5–3.2 Ga) sea-floor hydrothermal vents. Some of the present authors (Lowe and Byelry [1]) have recently reinterpreted them as modern subaerial deposits. Along with the geological arguments indicating very little deformation for such old rocks, one of the evidence in favor of modern origin of these deposits is the common occurrence of the mineral goethite. Goethite has low thermal stability, easily transforming to hematite at 80 °C–100 °C [2]. In addition to goethite, several manganese minerals are also present in these ironstone deposits.

Analysis of rock specimens from these locations by optical and electron microscopy showed that the iron and manganese minerals were probably of bacterial origin (Figs. 1, 2, and 3). The filamentous structure in Fig. 1 is typical of that reported by many researchers from bacterial deposits [3]. The radial acicular grains are composed or iron. Fig. 2 shows an optical thin section of the same rock. The translucent regions are the tubes whereas the dark opaque regions are filled with manganese minerals. Electron probe micro-analysis of the needles in Fig. 3 indicated them to be todorokite ($(Ca, Na, K)_x(Mn^{+IV}Mn^{+III})_6O_{12} \cdot 3.5H_2O$). Along with todorokite, lithiophorite($LiAl_2(Mn_2^{+IV}Mn^{+III})O_6(OH)_6$) was also identified in the rocks by X-ray diffractometry. Manganese minerals are typically very fine grained, poorly crystalline, and intimately mixed with other phases to such a degree that identification is difficult. In addition, none of the techniques used so far to characterize these rocks identify the oxidation state of either iron or manganese.

Resolution of the ambiguity in the oxidation states and the type of iron and manganese minerals should provide us with important information about the nature of biological oxidation of iron and manganese. This paper reports the results of the X-ray absorption fine structure (XAFS) studies.

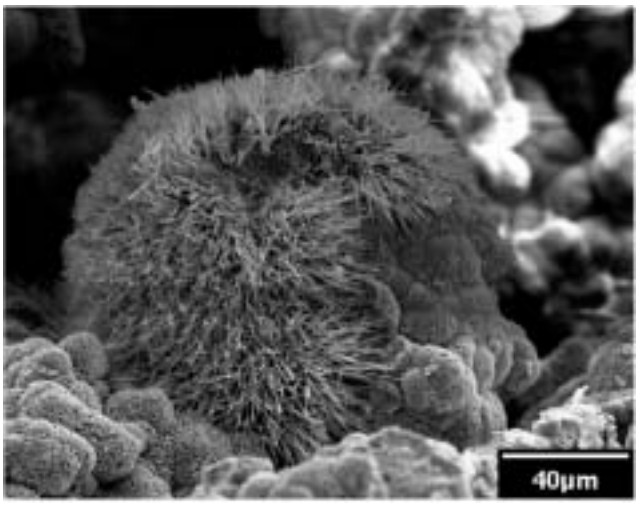

Fig. 3. Needle-like todorokite crystals.

2. Experimental Procedure

2.1. *Sample Locations*

The rocks studied in this investigation were obtained from three locations of the Barberton Mountain Land in South Africa and the details are provided in Table I.

2.2. *X-Ray Absorption Spectroscopy*

Manganese and iron K edge spectra were obtained at the J. Bennett Johnston Sr. Center for Advanced Microstructures and Devices (CAMD), Baton Rouge, Louisiana, USA. The synchrotron ring operates at 1.3 GeV with the ring current typically between 120 and 50 mA. The measurements were made at the Double Crystal Monochromator (DCM) beam line with Ge 220 crystals. The concentration of the elements was such that data could be collected in transmission for iron but both fluorescence and transmission modes had to be used for manganese. The experiments were conducted in air. XANES spectra for manganese and iron were collected from ca. 150 eV below the edge to up to 20 eV below the edge in 3 eV steps; from −20 eV to 60 eV above the edge in 0.3 eV steps; and 60 eV above the edge to 300 eV above the edge in 3 eV steps. For manganese EXAFS, the range over which data could be collected was limited by the iron K edge at 7112 eV. Thus only several hundred eV of data could be collected. The steps were 3 eV below the edge and 2 eV above the edge up to 7112 eV. The data were reduced with WinXAS [4], Athena, and Artemis.

3. Results and Discussion

Fig. 4 shows the iron XANES spectra of some selected ironstones along with those of some standard iron minerals. A synthetic ferrous oxide (from Alfa Aesar) XANES spectrum is also included

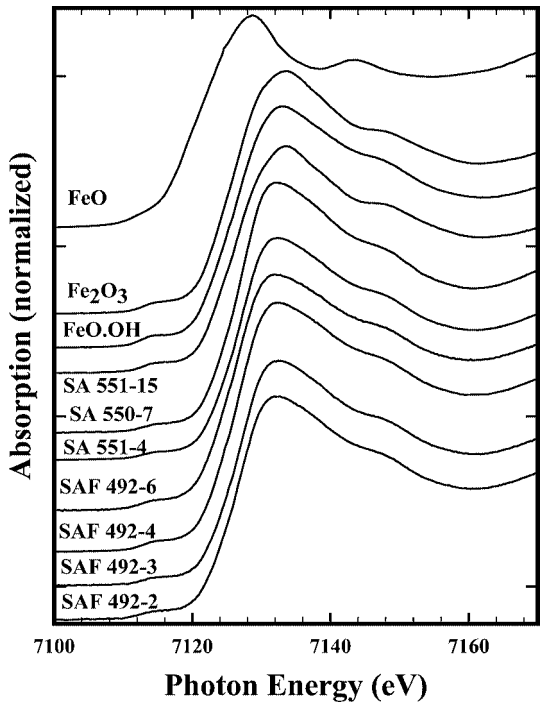

Fig. 4. Iron K edge XANES spectra from standard minerals and ironstones.

to show that no ferrous iron is present in any of these rocks. The locations of the pre-edge peak (7112.58 eV vs. 7113.22 eV), the edge (7126.42 eV vs. 7126.96 eV), the white line maxima (7133.07 eV vs. 7133.5 eV), and the minor peak (7145.65 eV vs. 7146.28 eV) beyond the white line are different for goethite and hematite. A comparison of the XANES spectra of the standard minerals with those of the ironstones shows that SA 551-15 (see Table I) contains hematite whereas the rest contains goethite. For example, least squares analysis of the spectrum SAF 492-2 indicates that 90% of it is goethite.

Fig. 5 shows the manganese K edge EXAFS spectra of some representative minerals from the ironstone deposits. The pseudo-radial distribution functions show three main peaks up to the distance of 3.5 Å. These are due to Mn-O, Mn-Mn_e and Mn-Mn_c shells [5], where the e and c subscripts stand for edge sharing and corner sharing configurations, respectively. SAF-492-2 does not have any corner sharing octahedra, indicating that it has edge sharing octahedra only and, thus, it is a layered structure. X-ray diffractometry previously identified lithiophorite, a mineral with a layered structure, in this specimen and thus confirms the structure determination by EXAFS. SA 550-7, has a strong Mn-Mn_c shell, suggesting a high degree of corner-sharing. X-ray diffractometry identified todorokite in this specimen, and the EXAFS data confirms the presence of a corner-sharing MnOx mineral in this specimen. The ratio of the peak heights of the shells Mn-Mn_e and Mn-Mn_c relates to the degree of corner-sharing in a

Elevation	Approximately 5,100 feet above sea level	Approximately 5,200 feet above sea level	Approximately 5,400 feet above sea level
Sample number	SAF 492-X SA 552-X	SA 550-X	SA 551-X
Minerals identified	Goethite, kaolinite, lithiophorite, todorokite	Mostly goethite	Goethite and hematite

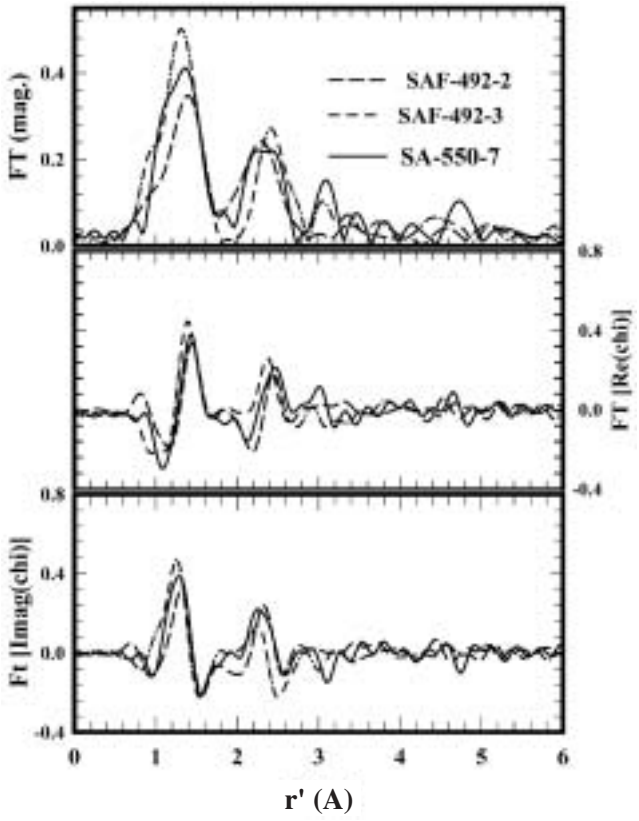

Fig. 5. Manganese K edge EXAFS spectra from some selected ironstones.

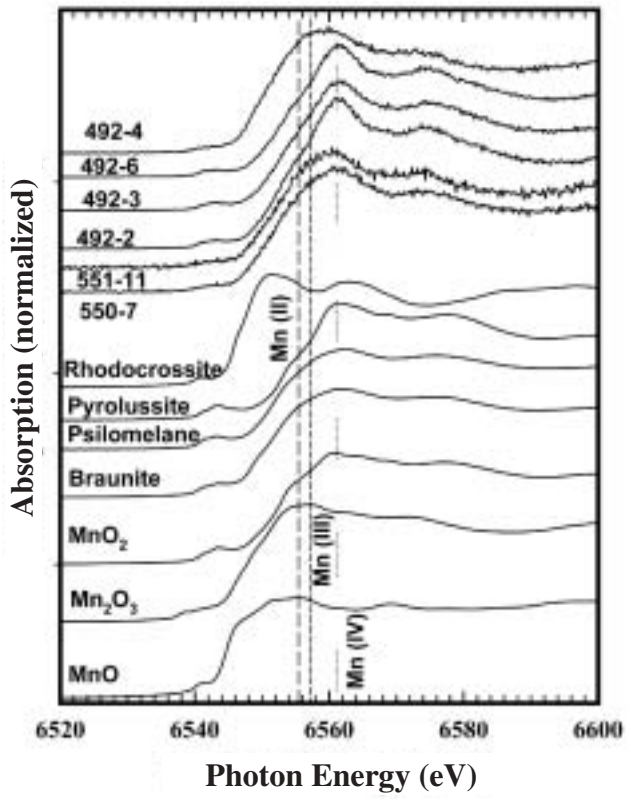

Fig. 6. Manganese K edge XANES spectra of some standard minerals and ironstones.

MnOx mineral [5]. This ratio is different in each of the specimens shown in the figure. If it is assumed that this ratio is constant in one mineral, then SAF492-3 could be a mixture of the minerals lithiophorite and todorokite.

Fig. 6 shows the manganese K edge XANES spectra of some of the representative minerals, along with those of some MnOx minerals and synthetic standards. The formal oxidation state of the manganese in these minerals ranges from +II to +IV, and the coordination from six to four. Least-squares modeling of the X-ray absorption near edge structure (XANES) spectra shows that most of the manganese is present in oxidation states +III and +IV, with no detectable manganese as +II.

X-ray absorption fine structure (XAFS) studies show that the oxidation state of iron and manganese in these rocks is high. They are +III for iron and +III and +IV for manganese. Iron and manganese oxidizing bacteria are common in nature. Such bacteria precipitated these minerals or their pre-cursors. Ehrlich [3] has proposed a manganese cycle in nature where the initial precipitate of bacterial oxidation is an amorphous MnO_2 which diagenetically alters to more crystalline varieties of minerals such as todorokite and lithiophorite. Hematite may also be a product of diagenetic alterations. Observations of thin sections of these rocks (Fig. 1) under the optical microscope indicated that the iron oxides formed first, with the voids later filled by the manganese minerals. The bacteria thus acted sequentially, depositing the iron oxides first followed by the manganese oxides.

4. Conclusions

The oxidation state of the iron and manganese minerals is high in the ironstones from the Barberton Mountain Land of South Africa. The present manganese minerals are probably diagenetic alteration products of initial amorphous MnO_2.

Abstract

In situ high-temperature and high-pressure XAFS experiments were performed at the Ni K-edge, at the ID22 μ-beamline of the ESRF (Grenoble, France). The experimental setup consists of an externally heated "Bassett-modified" hydrothermal diamond-anvil cell. The sample chamber is loaded with a water-saturated haplorhyolitic glass: $(NaAlSi_3O_8)_{47}(KAlSi_3O_8)_{21}(SiO_2)_{32}$, together with an aqueous $NiCl_2$-solution (0.35 M) and an air bubble. The experiment is carried out to a temperature (T) of 780 °C, and the corresponding hydrostatic pressure (P) is calculated to be around 520 MPa, based on the equation of state of water. μ-XANES spectra are then collected *in situ* in the silicate melt and in the aqueous phase. Spectroscopic data are first interpreted in terms of speciation. At the experimental P-T conditions, nickel is essentially four-coordinated in the hydrous melt, whereas its coordination is 5 in the glass. Moreover, based on the theoretical description of the absorption edge, the XANES spectra are used to derive the "fluid/melt" partitioning coefficient for nickel (0.22 ± 0.05), as well as the density of the hydrated melt ($0.9 \pm 0.5\,g/cm^3$).

1. Introduction

Structural and thermodynamical properties of hydrous silicate melts are of major interest for understanding fundamental geological processes related to explosive volcanic eruptions. Particularly, information concerning trace element speciation, and "fluid/melt" partitioning behavior, is required for understanding the transport properties as well as the geochemical processes controlling the formation of deep Earth magmas. Also, information concerning the density of hydrous silicate melts is required to better understand the dynamic properties related to the ascension of "highly-hydrated" magmas. One way to obtain such information is to perform *in situ* experiments using a hydrothermal diamond-anvil cell. That method is particularly adapted for the study of hydrous silicate melts [1], and can typically reach temperatures to 1000 °C and pressures to 1–2 GPa.

2. Experimental

In situ high-temperature and high-pressure experiments are performed using a "Bassett-modified" hydrothermal diamond-anvil cell (HDAC). The sample chamber is loaded with a water-saturated glass of haplorhyolitic chemical composition: $(NaAlSi_3O_8)_{47}(KAlSi_3O_8)_{21}(SiO_2)_{32}$. Then, an aqueous $NiCl_2$-solution (0.35 M) is added with an air bubble in the sample chamber (see Fig. 1, left). The H_2O "liquid/vapor" homogenization temperature, measured before and after the heating run, is 295 ± 10 °C. Consequently, at the experimental temperature (i.e., 780 °C), the pressure is calculated to be around 520 MPa, based on the equation of state of water [2]. At the melt state, the silicate phase forms hydrated, and nearly-spherical "globules" in equilibrium with the aqueous phase [1, 3] (see Fig. 1, right).

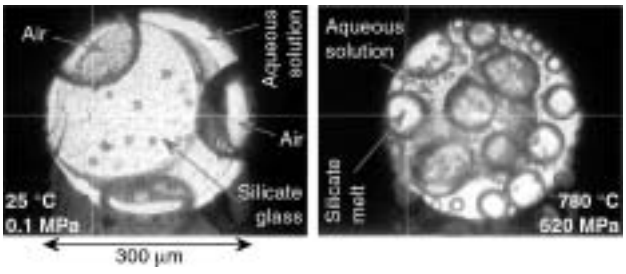

Fig. 1. Haplorhyolitic melt in an aqueous $NiCl_2$-solution (0.35 M), exposed to high temperature and high pressure.

During the experiment, μ-XANES spectra are collected at the Ni K-edge in fluorescence mode (ID22 beamline, ESRF, France); an optical monitoring of the sample being systematically performed before and after data acquisition. We used Si(111) double crystals monochromator, and Kirckpatrick-Baez focusing mirrors, so that the spatial resolution of the incident X-ray beam was 3×5 µm. Also, XANES spectra were collected using 0.1 eV steps in the pre-edge region and 0.5 eV steps in the main edge crest region.

3. Results and Discussion

The normalized Ni K-edge XANES spectra collected for the hydrated melt and the quenched glass are first interpreted in terms of nickel speciation. *Ab initio* calculations were performed using the FEFF 8.28 package assuming the crystal structure of NiO (6-coordinated Ni) and $NiCr_2O_4$ (4-coordiated Ni); the XANES spectra being calculated using Hedin-Lundqvist potentials and default values for all options.

Based on experimental [4] and theoretical approaches, the absorption edge XANES spectra as well as the position of the first "EXAFS" oscillation (gray line), traduce essentially the presence of NiO_4 moieties in the hydrous silicate melt

*e-mail: munoz@oreka.com

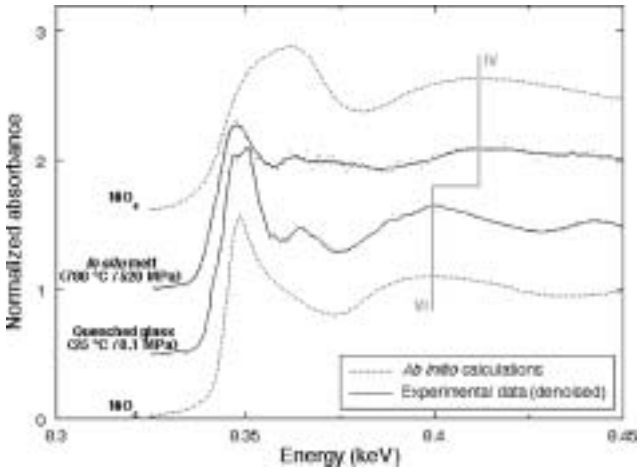

Fig. 2. Comparison between the Ni K-edge theoretical XANES spectra for NiO_4 and NiO_6 clusters, and the experimental spectra collected *in situ* for the hydrated silicate melt and for the quenched glass.

(see Fig. 2). This important result shows that quenched glasses are not appropriate images of their corresponding melts. Also, the coordination numbers of nickel in hydrous melts as well as in anhydrous melts [5] are similar, suggesting that water does not highly affect the local structural environment of nickel under *in situ* conditions.

The sample density (ρ) as well as the mass fraction of nickel (x_{Ni}) are then extracted from the μ-XANES spectra (edge jumps uncorrected) using the following equation [6]:

$$\alpha.\Delta\mu = \rho.x_{\mathrm{Ni}}.\Delta(\mu/\rho)_{\mathrm{Ni}} \quad (1)$$

in which $\Delta(\mu/\rho)_{\mathrm{Ni}}$ is the variation of the mass absorption coefficient before and after the edge, $\Delta\mu$ is the experimental edge jump at the Ni K-edge (modeled using an arctangent; see Fig. 3), and α is an "attenuation factor" due to the experimental setup. More precisely, this attenuation factor traduces the thickness of the sample, but also the non-linearity of the absorption coefficient due to the absorption of the X-ray beam by the diamonds, as well as the fluorescence detection at the rear of the HDAC.

In order to determine x_{Ni} and ρ under *in situ* conditions for the aqueous phase and the silicate phase, respectively, the attenuation factors are previously determined, based on the edge jumps of the different XANES spectra collected under ambient conditions:

- Concerning the aqueous phase, the nickel content and the density are well known before the experiment.
- Concerning the silicate phase, the density of the hydrous quenched glass can be estimated around $2.2\,\mathrm{g/cm^3}$ (see [7]). Also, the nickel content is determined after the experiment, using μ-PIXE (Particule Induced X-ray Emission) mapping (see [3]). Analyses were performed using the nuclear microprobe facility of LPS (CEA, Saclay, France).

Consequently, the "fluid/melt" partitioning coefficient obtained for nickel is 0.22 ± 0.05. Despite its important compatible character (i.e., crystal vs. melt; e.g., [8]), this result suggests a non-negligible mobilization of nickel by the aqueous fluid during the ascension of magmas.

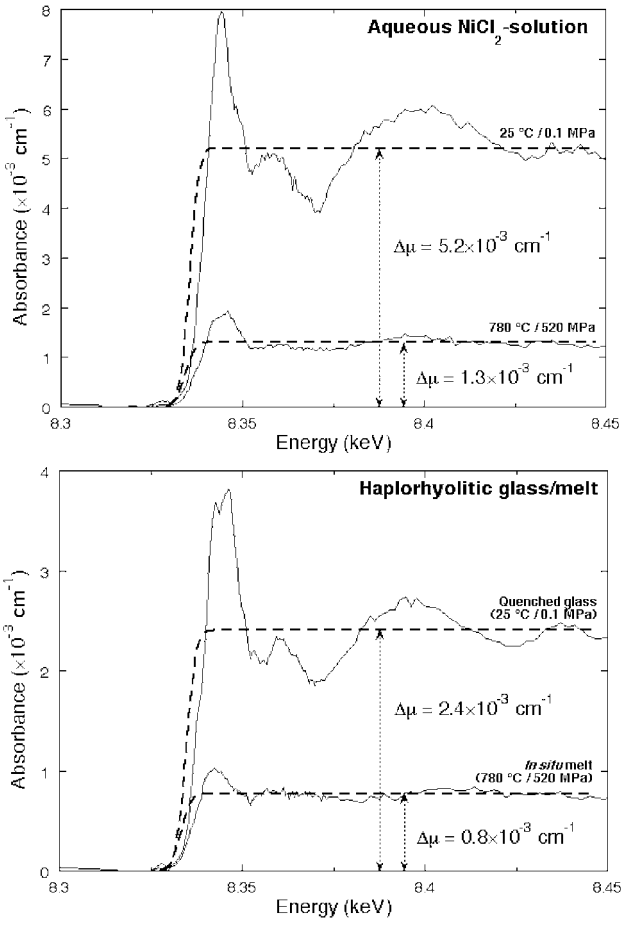

Fig. 3. μ-XANES spectra collected at the Ni K-edge for the aqueous $NiCl_2$-solution (up), and the haplorhyolitic phase (down), exposed to *in situ* (high-temperature/high-pressure) and ambient conditions.

Also, the density of the hydrous haplorhyolitic melt at 780 °C and 520 MPa is estimated to be $0.9 \pm 0.5\,\mathrm{g/cm^3}$, suggesting a particularly important proportion of water in the melt structure. This study represents the first attempt to measure a hydrous melt density well above the glass transition temperature, involving a major contribution to a better understanding of the structural and macroscopic properties of highly-hydrated magmas in conditions prior to explosive eruptions.

Abstract

The sorption of Au at the goethite-water interface is studied. In order to better understand sorption models for cations on mineral surfaces, reverse Monte-Carlo (RMC) simulations [1] were used to analyse EXAFS spectra. A starting model is constructed based on the (110) mineral surface separated by a layer of water molecules. Some of metal cations at the mineral-water interface are replaced by absorbed gold cations. All atomic positions are allowed to vary on both the mineral surface and in the water layer during the RMC simulations. Partial pair distribution functions and corresponding EXAFS spectra are computed and refined by a Metropolis algorithm. The final RMC model matches most EXAFS features (including short- and medium-range environments). The usual EXAFS parameters (coordination number, coordination distance and Debye-Waller factor and higher moments) are retrieved from the partial pair distribution functions by moment analysis. In case of Au at the the goethite-water interface four Au-O coordinations are found at an average distance of 1.99 Å with a second moment of 0.0013 Å^2. Two iron next-nearest neighbors show a broad distribution between 3.2 and 3.8 Å with an average coordination distance of 3.49 Å, a coordination number of 3 and a second moment of 0.013 Å^2. The results of the RMC simulations are compared with results of conventional EXAFS analysis methods.

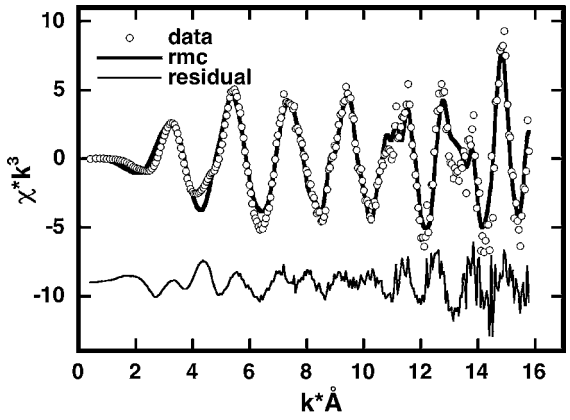

Fig. 1. EXAFS spectrum for Au sorbed on goethite surface at pH = 7 analyzed by RMC.

1. Introduction

Sorption of heavy metals onto finely divided minerals (such as clays or iron oxy-hydroxides) is an essential process in environmental geochemistry [2]. Toxic metals can then be fixed and locally concentrated because of sorption phenomena. This is also the case for strategic metals such as gold, which can be pre-concentrated on iron oxy-hydroxides, especially onto soils in tropical countries. X-ray absorption fine structure experiments are conducted to understand the sorption of gold onto iron oxy-hydroxides better, specifically, the speciation and connectivity of the gold moieties with the mineral surface [3]. Usually, the information for nearest neighbors is relatively easy to obtain, whereas for next-nearest neighbors it is much more difficult to extract, because of static disorder effects and overlapping signals. Here, simulations are required to analyze the experimental information, such as that provided by molecular dynamics or Reverse Monte Carlo (RMC) methods. In this study, we present the first application of a RMC simulation of an EXAFS spectrum applied to environmental sciences.

2. Experimental Methods

The EXAFS spectrum was chosen from a set of one hundred collected for various iron oxy-hydroxides [3] onto which trivalent gold was sorbed from an aqueous chlorine solution at various pH, Au/Cl molalities, conditions and mineral surfaces (bohemite, ferrihydrite and goethite). The goethite sample studied here is representative of the others in terms of the EXAFS signal: goethite was equilibrated at pH 7 with a gold chlorine solution (0.1 M [Cl] and 9.5 10^{-4} M [Au]). The gold concentration is 1.4 wt% corresponding to 0.09 μmol/m^2.

Au L_{III} edge EXAFS spectra were collected at 77 K using a 13-element solid state Ge detector available on beamline 4-3 at SSRL (Stanford, USA) (see fig. 1). We used Si (220) double-crystal monochromators with slits and a vertical aperture of 1 mm. The energy resolution is mostly limited due to a core hole lifetime of ∼8 eV. Scans were collected with 0.5 eV steps in the XANES and 0.05 Å^{-1} in the EXAFS region to 16 Å^{-1}. Photo-reduction was monitored by observing the drastic change in the XANES due to the formation of metallic gold induced by the beam. Gold photo-reduction was found to be less than 10% after averaging 10 scans (due to a rather quick data collection at low temperature). This is confirmed by a wavelet study of this spectrum [4], which established the lack of gold next-nearest atoms in the medium range environment of gold. Multiple-scattering events (related to the presence of square planar Au(III)O_4 moieties) are observed to interfere with the single-scattering contributions arising from iron next-nearest neighbors. However, this interference is significant only for the low k-range of the EXAFS signal (below 5 Å^{-1}) but this feature will be anyway considered in the RMC model.

The "rmcxas" package [1] was used to analyze the unfiltered EXAFS spectrum by RMC. The (110) surface of goethite was selected as model because it absorbs 90% of the gold. The initial configuration was constructed using a double (110) goethite surface, separated by a layer of water (randomized) (see fig. 2). Some Fe atoms at the mineral/water interface were replaced by

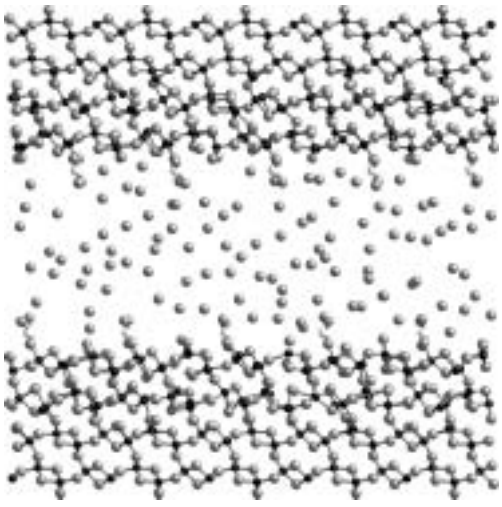

Fig. 2. RMC model of the goethite/water interface after refinement (Au: white, Fe: black, O: grey).

Au. Protons were neglected because they do not contribute to the EXAFS spectra. The simulation box is 54.6 × 30.1 × 54.1 Å large and contains 5680 atoms, including 20 Au atoms. During each RMC cycle, all atomic positions were allowed to vary up to 0.05 Å on both the (110) surfaces (10 Å deep into goethite) and in the water layer. After 260 cycles, the calculated model (using feff8 standards) matches all EXAFS features between 1 and 10 Å (the range of the pair distribution function). Most of the residual signal can clearly be attributed to multiple-scattering events within the AuO_4 polyhedra (details are provided in [4]).

3. Results and Discussion

A conventional EXAFS analysis of the EXAFS spectra was conducted assuming 4 shells:

- two for oxygen nearest neighbors: single- (SS) and multiple scattering (MS) of order 3 and 4, centered near 1.99 and 3.1 Å, respectively (3.9(3) atoms),
- two for iron next-nearest neighbors (SS), centered near 3.1 and 3.3 Å (total 2.0(5) atoms), respectively (attempts to model with an unique shell failed).

The RMC simulation results are consistent with this conventional analysis but significant additional information can be obtained in the medium range environment (see fig. 3):

- 3.5(7) O atoms located at 1.99 Å for the first neighbors with $\sigma^2 = 0.0013(12)$ Å^2,
- 2.0(4) next-nearest Fe atoms, centered near 3.49(3) Å with $\sigma^2 = 0.013(4)$ Å^2.

The agreement for the first neighbors is excellent. However, a significant underestimation (−0.3 Å) of the Au-Fe distances is observed for the conventional model, probably due to disorder effects in the complex medium range environment around Au at the mineral/water interface. Even more importantly, RMC results suggest that there is a broad distribution of Au-Fe distances (between 3.2 and 3.7 Å). This would mean that the shortest Au-Fe distance obtained by conventional methods is significantly affected by MS contributions arising from first neighbors (despite this contribution was also modeled using a separate shell during the whole refinement). This is again in agreement with a wavelet analysis of such spectrum [4], which evidenced a strong interference between both signals but could only be quantified

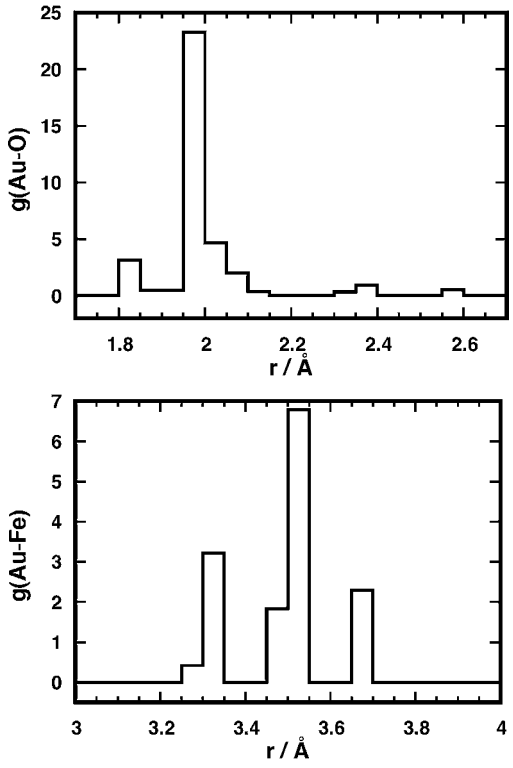

Fig. 3. Partial pair distribution functions for Au-O (top) and Au-Fe (bottom) as obtained by RMC analysis.

by the RMC discussed here. The RMC simulation also suggests that significant Au-O pairs (SS) interfere with Au-Fe pairs (SS) in the 3–3.5 Å range and these distant Au-O pairs were most likely modeled as Au-Fe pairs in the conventional EXAFS least-square model. From these RMC results, a dramatic change in the Au-O-Fe angles can be deduced (+20–40°), which affects the AuO_4-FeO_6 connectivity model (less edge-shared polyhedra as compared to when conventional EXAFS models are undertaken).

In conclusion, RMC simulations open new perspectives in environmental sciences, as they are based on a physical 3D models for sorption reproducing the experimental EXAFS information. Despite of the intrinsic limitations of RMC methods, structural information in the medium range environment probed by EXAFS can be quantitatively derived. Overlapping signals for cations and anions in the medium range structure of Au are evident. Also, the presence of a broad distribution of cation-cation distances is observed which cannot be detected by conventional EXAFS analyses. As a result of these disorder effects, the average cation-cation distances are underestimated by ca. 10%, which change drastically the models for the inter-polyhedral connectivity. This is of major importance for the analysis of EXAFS spectroscopy because it reveals methods to extract information on medium-range structures probed by EXAFS in complex materials. One important future development of the RMC analysis of EXAFS spectra is the computation of higher order distribution functions to include MS signals.

Abstract

XAFS spectroscopy using synchrotron radiation is an extremely suitable technique to study local atomic and electronic structure of mixed $Th_{1-x}U_xO_2$ and $Th_{1-x}Pu_xO_2$ oxides. Despite of XAFS technique overall success, a *pico-meter* barrier (10^{-2} Å) exists in XAFS data analysis. Here we present the dependence of the mixed oxide structure on composition, probed by XAFS with *picometer accuracy*. Complimentary XAFS spectra were measured at the Th, U, and Pu L-edges. We found that opposite to the lattice parameter obtained by XRD, the distances given by XAFS for the first and second shells do not follow completely neither Vegard's law nor the virtual crystal approximation (VCA). The Th-O, U-O and Pu-O distances obtained vary slightly upon dilution. These values are close to the ones expected from Vegard's law but are always smaller than the ones expected in VCA. The U-U(Th) and Th-Th(U) distances vary strongly upon dilution and the values are close to the ones expected from the VCA model but are always smaller than the ones expected by the Vegard law. The average lattice parameter calculated from XAFS data agrees well with a random distribution of metal (Th, U, Pu) and with one calculated from XRD data. With this complementary XAFS data on the local structure around two selected metal ions it is then possible to give a better view on the mixed oxides structure, the distribution of the two metal ions and local distortions in such medium crystal structure studied by XRD.

1. Introduction

In the last decade, there has been a renewal of interest in studying the feasibility of thorium based fuel reactors as a potential advanced fuel for Generation IV nuclear energy systems that can be operated to relatively high burn-ups, and producing less minor actinides than uranium based fuel [1, 2]. Solid solutions of uranium and thorium oxide are being developed as fuel for the thermal breeding reactors and high temperature gas cooled reactors.

The lattice constant of $Th_{1-x}U_xO_2$ and $Th_{1-x}Pu_xO_2$ solid solutions changes linearly with x in the whole region, a feature commonly referred to as Vegard's law [3, 4]. Such behaviour does not exclude a bimodal distribution of nearest-neighbour (NN) distances in the solid solutions as diffraction methods do not provide sufficient information on the local structure in disordered crystals [5]. It is somewhat surprising that the XAFS analysis well developed for solid solutions [6] has not yet been extensively exploited in the study of actinide dioxide solid solutions ($Th_{1-x}U_xO_2$, $U_{1-x}Pu_xO_2$, etc.).

2. Experimental details and data analysis

A series of solid solutions of $Th_{1-x}U_xO_2$ ($x = 0.0$, 0.11, 0.24, 0.37, 0.49, 0.65, 0.81, 0.91, 1) and $Th_{1-x}Pu_xO_2$ ($x = 0.0$, 0.13, 0.32, 0.66, 1.0) were prepared respectively in IPN (Orsay, France) and at CEA (Valhro, France) according the previously described procedure [2]. All the samples were characterized by using XRD. The lattice constant of $Th_{1-x}U_xO_2$ and $Th_{1-x}Pu_xO_2$ solid solutions changes linearly with x in the whole region in a good agreement with the literature data [2–4].

The XAFS measurements of $Th_{1-x}U_xO_2$ and of $Pu_{1-x}U_xO_2$ were performed on the D44 (XAS4) "hot" beam line of the LURE DCI synchrotron radiation facility (Orsay, France). A standard transmission scheme with a Ge (400) double crystal monochromator and two ion chambers containing argon gas was used. The powders of $Th_{1-x}U_xO_2$ and of $Th_{1-x}Pu_xO_2$ solid solutions were finely ground and mechanically mixed with cellulose powder. The adjusted thickness of the samples permits us to reach a value for the absorption jumps between 0.2 to 0.8 depending on the composition of the solid solutions.

The XAFS were treated using the "EDA" software package following the standard procedure [7]. The experimental XAFS spectra $\chi(k)k^2$ were Fourier transformed (FT) with a Kaiser-Bessel window in the 0–15 $Å^{-1}$ range. In all the FT's of the experimental spectra (Fig. 1) there are two main peaks located at 1.9 Å and 3.8 Å with a smaller pre peak at 3.2 Å, and lower peaks from 4.5 to 6 Å.

We have analysed the Th, U and Pu L_3-edge XAFS of the solid solutions to determine the change bond lengths in the first and second coordination shells as a function of solid solutions composition. Representative FT of the Th L_3-edge XAFS are shown in Fig. 1. As a general feature, the first peaks in the Th, U

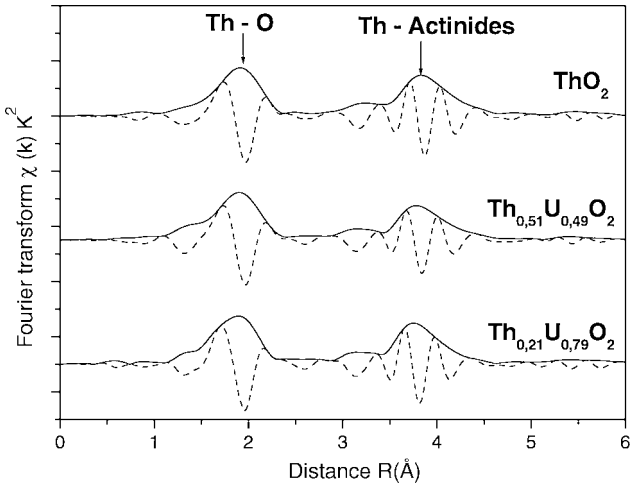

Fig. 1. Fourier Transforms of the experimental XAFS $\chi(k)k^2$ (Th L_3-edge) of ThO_2, $Th_{0,51}U_{0,49}O_2$ and $Th_{0,21}U_{0,79}O_2$.

*E-mail: purans@science.unitn.it

and Pu FT of the solid solutions are sharp and show a small, but significant and gradual shift to those in the respective standards (ThO_2 and UO_2). The second peak is also sharp and shows a more visible gradual shift from one end member to the other.

The single-shell XAFS spectra were fitted using single-scattering curved-wave formalism with picometer accuracy [8]. The XAFS data were analyzed using two different approaches: the phases and amplitudes were either calculated or obtained experimentally from a crystalline reference. Theoretical backscattering amplitudes and phases were calculated by the FEFF8 code using different clusters that mimic the possible environment of the An^{4+} ions in solid solutions, respectively [9].

3. Results and discussion

The interpretation of the XAFS spectra in $Th_{1-x}U_xO_2$ and $Th_{1-x}Pu_xO_2$ solid solutions is analogous to the pure oxides (see XAFS analysis of ThO_2, UO_2 and PuO_2 in ref. [10–13]) due to the very small differences in the scattering amplitude and phase shift functions of thorium, uranium and plutonium atoms: here the visible differences are only caused by the change of the lattice constant with the composition and by the very small differences in the scattering amplitude and phase shift functions of thorium and uranium (plutonium). The first effect is responsible for the shift in the energy position of the features of the FT while the second one for the small decrease of the second peak amplitude of the FT. We estimate that at room temperature the thermal broadening (Debye Waller factor) contributes $\sigma_2 = 0.005\,\text{Å}^2$ to the DW factor in the Th-O and U-O near-neighbour distribution.

3.1. *First-neighbor environment*

From the XAFS fitting data in the first coordination shell we conclude that the distances $R_{\text{U-O}}$, $R_{\text{Th-O}}$ and $R_{\text{Pu-O}}$ vary linearly upon dilution in the solid solutions (Figs. 2 and 3). The values ($R_{\text{Th-O}}$, $R_{\text{U-O}}$ and $R_{\text{Pu-O}}$) are closer to the ones expected from Vegard's law (Pauling model – the partial molar volume of each constituent is independent of concentration) than to the ones expected from the VCA. We estimate an uncertainty of 0.003 Å

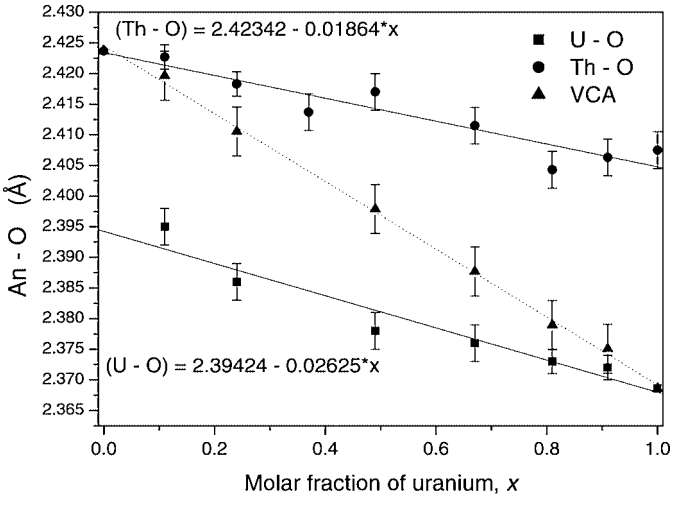

Fig. 2. Variation of the interatomic distances Th-O (● upper line) and U-O (■ bottom line) with the composition $Th_{1-x}U_xO_2$. The variation of crystal lattice parameter ($a/2$) follows Vegard's law (middle dotted line – XRD data). The average weighted distances (▲) calculated from the distances Th-O (●) and U-O (■) are also shown.

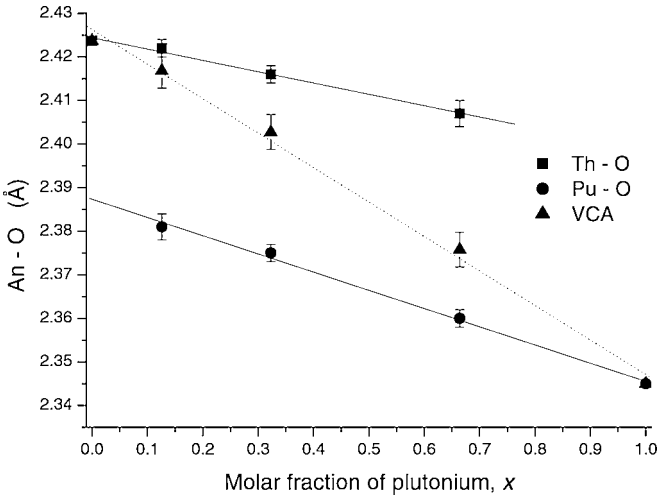

Fig. 3. Variation of the interatomic distances Th-O (■ upper line) and Pu-O (● bottom line) with the composition $Th_{1-x}Pu_xO_2$. The variation of crystal lattice parameter ($a/2$) follows the Vegard law (middle solid line – XRD data). The average weighted distances (▲) calculated from the distances Th-O (■) and Pu-O (●) are also shown.

in the near-neighbour distances, corresponding to a factor of 2 increase in the reliability of-fit parameter from a minimum value, expected in the dilute alloys (10 mol%) where the error is ∼0.005 Å. The total decrease in $R_{\text{Th-O}}$ in $Th_{1-x}U_xO_2$ from pure ThO_2 to pure UO_2 (linear interpolation to 0 mol% Th in UO_2) is 0.019 ± 0.003 Å, or ∼35% of the difference between $R_{\text{Th-O}}$ and $R_{\text{U-O}}$ in the end-point compounds (impurity limit). At the same time the increase in $R_{\text{U-O}}$ from pure UO_2 to the impurity limit of U in ThO_2 is 0.026 ± 0.003 Å, or ∼47% of the difference between $R_{\text{Th-O}}$ and $R_{\text{U-O}}$ in the end-point compounds. For comparison in $Th_{1-x}Pu_xO_2$ from pure ThO_2 to pure PuO_2 (linear interpolation to 0 mol% Th in PuO_2) is 0.025 ± 0.003 Å, or ∼32% of the difference between $R_{\text{Th-O}}$ and $R_{\text{Pu-O}}$ in the end-point compounds which is in good agreement with the value (35%) obtained for $Th_{1-x}U_xO_2$. So the local compressibility of [ThO_8] cluster is characteristic in these two solid solutions. At the same time the increase in $R_{\text{Pu-O}}$ from pure PuO_2 to the impurity limit of Pu in ThO_2 is 0.0425 ± 0.005 Å, or ∼54% of the difference between $R_{\text{Th-O}}$ and $R_{\text{Pu-O}}$ in the end-point compounds which is the highest "compressibility" observed.

3.2. *Second-neighbour environment*

On the contrary to the first shell, the U-U(Th) and Th-Th(U) distances vary strongly upon dilution and the values are close to the ones expected from the VCA model but are always smaller than the ones expected by the Vegard law. We estimate an uncertainty of 0.005 Å in the second-neighbour distances, corresponding to a factor of 2 increase in the reliability-of-fit parameter from a minimum value, expected in the dilute alloys (10 mol%) where the error is ∼0.005 Å. The total decrease in $R_{\text{Th-U(Th)}}$ from pure ThO_2 to pure UO_2 (linear interpolation to 0 mol% Th in UO_2) is 0.067 ± 0.003 Å, or ∼71% of the difference between $R_{\text{Th-Th}}$ and $R_{\text{U-U}}$ in the end point compounds. At the same time the increase in $R_{\text{U-Th(U)}}$ from pure UO_2 to pure ThO_2 (linear interpolation to 0 mol% U in ThO_2) is 0.080 ± 0.003 Å, or ∼86% of the difference between $R_{\text{Th-Th}}$ and $R_{\text{U-U}}$ in the end point compounds. The total decrease in $R_{\text{Th-Pu(Th)}}$ from pure ThO_2 to pure PuO_2 (linear interpolation to 0 mol% Th in PuO_2) is 0.105 ± 0.010 Å, or ∼84% of the difference between $R_{\text{Th-Th}}$ and $R_{\text{Pu-Pu}}$ in the end point

compounds. At the same time the increase in $R_{\text{Pu-Th(Pu)}}$ from pure PuO_2 to pure ThO_2 is 0.105 ± 0.010 Å, or ∼84% of the difference between $R_{\text{Th-Th}}$ and $R_{\text{Pu-Pu}}$ in the end point compounds.

Abstract

Natural actinides (U and Th) are harmful for the crystalline structure of natural minerals, due to their irradiation. Natural minerals can then become amorphous to X-ray diffraction ("metamict") after being irradiated throughout a long period of time (10^8 years). Then, they are used as natural analogues of ceramics for nuclear waste storage. XAFS studies were performed in zircon, monazite and titanite to understand the effect of radiation damage on the local structure around Th, U, Zr and P and compared to available molecular dynamics (MD) simulations. In zircon, a local expansion around actinides (when substituting for Zr) is found. The radial expansion is a function of the metamictisation degree: up to ∼4 Å in crystalline zircon and larger in the metamict counterparts. *Ab-initio* calculations (FEFF7) were performed around Zr (∼23 000 sites) and around U (1000 to 3000 sites) in various crystalline and alpha-decay damaged zircon MD simulations. The calculated averaged EXAFS spectra confirms this expansion, which validates the use of the potentials used in the simulations as well as the alpha decay damage model considered in these MD simulations. Tetravalent actinides were found to be 8-coordinated in the undamaged structure, whereas their coordination drops to 7 in the damaged structures. In contrast to zircon, no local expansion around actinides in monazite was detected, despite some polymerization around P is measured (related to radiation damage). Finally, in some phases (such as titanite), actinides are found as oxyde-type clusters (ThO_2, UO_2). Consequently, actinides do not "systematically" substitute for major actions in these structure, in contrast to the common belief in mineralogy.

1. Introduction

Natural minerals may model long-term radiation effects by receiving very small amounts of radiation during hundreds of million years [1]. These mineral analogues offer a possibility to study the real effect of "*in-situ*" damage on the structure of ceramics receiving strong amounts of radiation. In the hope of identifying an adequate matrix to contain high activity nuclear wastes, a broad range of minerals of different structure is studied by XAFS methods (experimental and *ab-initio* XANES and EXAFS methods) and molecular dynamics. We studied the structural environment of several analogues such as zircon, monazite, zirconolite and titanite and compared experimental information to these reconstructed from molecular dynamics to (1) better understand the influence of radiation damage on crystals, (2) help validate the models used in molecular dynamics to simulate radiation damage and (3) provide accurate information on the way disorder effects influence the short-, and medium range environment probed by XAFS methods in these highly disordered materials.

*Corresponding author, e-mail: farges@univ-mlv.fr

2. Experimental Methods

A set of natural minerals that suffered radiation damage were investigated, including zircon ($ZrSiO_4$), monazite ($CePO_4$), zirconolite ($CaZrTi_2O_7$) and titanite ($CaTiSiO_5$). We have selected various samples of these minerals that contain significant amounts of natural actinides (Th and U from 0.01 to 30 wt.%). These samples (suffering severe radiation damage) are coming from various localities throughout the world (Sri Lanka, Madagascar, Brazil, South Africa, Canada etc.). They were thoroughly characterized using various methods (X-ray diffraction, electron microprobe, etc.) to differentiate between samples that suffered only from radiation damage to that suffered subsequent weathering. XAFS spectra for major elements were collected at the Si K- (zircon), P K- (monazite), Zr K- (zircon) and $L_{III/II}$-edges (zircon) to help validate the structure of these materials simulated by molecular dynamics. Then, XAFS spectra were collected for minor to trace amounts of actinides (L_{III}-edges of Th and U) to understand the effect of radiation damage on the local structure of the remaining actinides. XAFS spectra for soft X-ray energies were collected at the SA32 spectrometer (Super-Aco, Orsay, France) using a Ge(111) monochromator. We used total electron-yield detection to collect the spectra. Hard X-ray XAFS spectra (Zr K-edges and Th/U L_{III}-edges) were collected at SSRL (Stanford, USA) on beamline 11-2, using a Si(220) double-crystal monochromator. We used a Stern-Heald type fluorescence detector (filled with Xe) with Sr filters to filter the elastic scattering. EXAFS spectra were collected with 0.05 $Å^{-1}$ steps. Molecular dynamics simulations were performed for the zircon structure only, assuming several levels of radiation damage (recoil of 4 and 5 keV, respectively) with various U contents (1 atom, 4% and 12% of Zr atoms replaced by U). Simulations were performed using periodic conditions assuming 139,964 atoms. Details on the calculations (potentials etc.) are given elsewhere [2]. *Ab-initio* EXAFS calculations were undertaken using the FEFF7 code [3] at the Zr K-, and U L_{III}-edges on thousands of clusters provided by molecular dynamics and averaged to compare with the experiment.

3. Results and Discussion

The Zr $L_{II/III}$-edge XANES spectra of metamict zircon show a shift in the first EXAFS oscillation (Fig. 1) as compared to crystalline zircon. This confirms that Zr undergo a $8 \rightarrow 7$ coordination change with increasing radiation damage. Fourier Transforms of the Zr K-edge EXAFS spectra and their models (Fig. 2) show that the Zr-O average interatomic distance

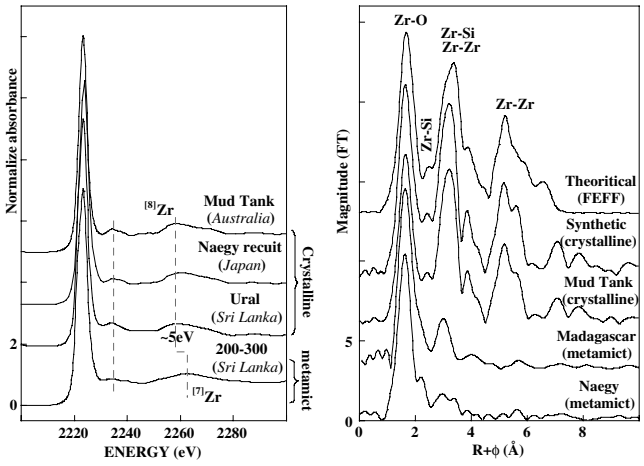

Fig. 1. Zr L_{III}-edge XANES (left) and FT's of Zr K-edge EXAFS (right; with k^3-weighting, $k = 1.5$–$13.5\,\text{Å}^{-1}$ and Kaiser-Bessel window) for crystalline and metamict zircons.

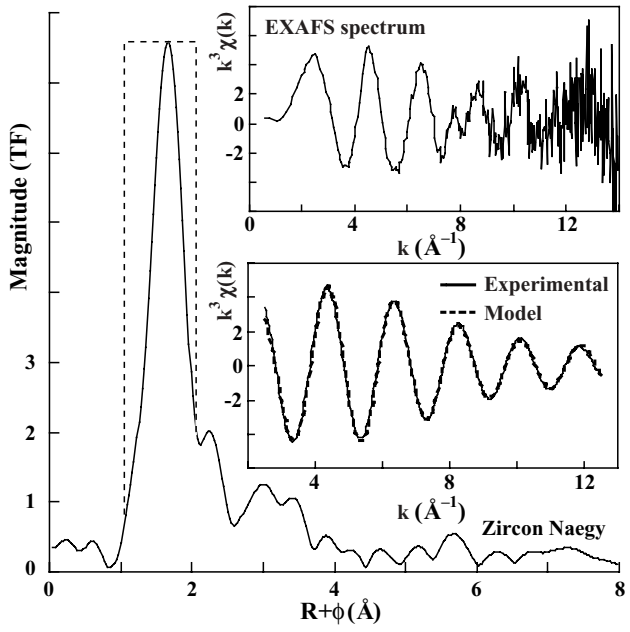

Fig. 2. Fourier transform of the EXAFS spectrum (inset, top) collected at Zr K-edge in a metamict zircon and the data modelling (inset, bottom).

decreases from 2.20 to 2.15 Å with increasing radiation damage, in agreement with [4]. The structure obtained from the MD simulations of the damaged regions in zircon is in agreement with the experiment for metamict zircons. In the damaged region, zirconium is surrounded, on the average, by 6.9 atoms at 2.14 Å (first neighbors are widely distributed from 2.0 to 2.4 Å). The average Zr K-edge *ab-initio* EXAFS was computed (using FEFF 7) from the MD simulation around Zr. The cumulant expansion model of that FEFF7 spectrum resulted in ∼7 atoms at 2.14 Å, suggesting that disorder effects were properly taken into acccount in the EXAFS models for the natural zircon samples.

In addition, next nearest neighbors are observed around Zr in the EXAFS spectra for natural metamict minerals. These contributions can be modeled as (edge-shared) Si second neighbors near 3.10 Å and more distant (despite relatively noisy) Zr-Si contributions (near 3.73 Å). The EXAFS modelisations based on MD simulations for Zr in damaged zircon confirm the presence of Zr-Si contributions (at 3.15 Å) and Zr-Zr contributions near 3.75 Å. The overall good agreement for the EXAFS models computed for the natural samples and the MD-simulations suggests that the MD models are representative of naturally occuring radiation damage. This agreement also confirm that disorder effects in the model of the experimental EXAFS for the next-nearest neighbors were properly taken into account (using cumulant expansion theory).

Analysis of the P K-edge EXAFS spectra in monazites suggests that the P-P pairs near 2.5 Å increases significantly in magnitude with radiation damage. Then, some polymerization of the PO_4 tetrahedra occurs as a consequence of increasing radiation damage. In contrast, any large structural reorganization due to radiation damage is observed around the other major elements such as Th.

Concerning minor, to trace amounts of actinides (Th and U) in natural minerals, we studied first the insertion of these cations in the crystalline minerals before studying the radiation damaged ones (Fig. 3). In crystalline minerals, the analysis of the EXAFS spectra suggests that Th and U are 8-coordinated with Th-O and U-O at 2.41(2) and 2.38(2) Å. Therefore, these cations keep their preferred coordination environment, even if the main site they occupy (e.g., the Zr site in zircon) is not fully adapted (in size and in redox) to these actinides sizes. However, the analysis of the EXAFS for the medium range structure around minor amounts of Th and U (0.05–0.2 wt.%) in zircon shows the presence of relatively longer (Th,U)-Zr bonds (3.7 Å) as compared to the ones in the original zircon (3.6 Å). This suggests the presence of a structurally «expanded» region up to 4 Å from the central actinide. This expansion is due to the insertion of a larger actinide in the site of a smaller Zr (see model on Fig. 4). However, in the 4–5.5 Å range around the central actinide, a relatively «contracted» region is observed, based on the measured EXAFS distances compared to the ones in the original zircon structure. Above 5.5 Å, the undistorted original structure of the host mineral is observed (Fig. 4). These regions around actinides were also observed in the MD simulations, validating then our EXAFS interpretations. These results also help us understanding the point defects that are created in the zircon structure when minor actinides replaces major zirconium atoms

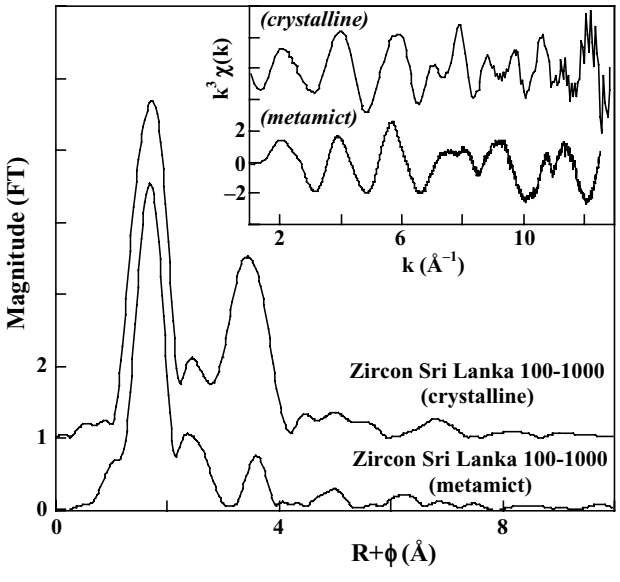

Fig. 3. FT's of the U L_{III}-edge EXAFS (inset) spectra for zircons: crystalline (top) and damaged (bottom).

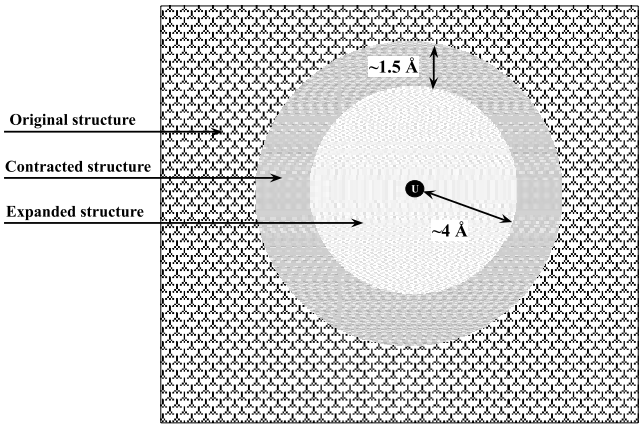

Fig. 4. Schematic representation of the local structure around actinides in crystalline zircon, as observed from EXAFS experiments and MD simulations.

(see Fig. 4). The influence of radiation damage on the local structure around these actinides was measured using Th/U-L_{III} EXAFS spectroscopy and compared to MD simulations (considering a 4 and 5 keV cascade). The agreement between the experimental information and the MD simulations was also excellent, suggesting that the MD methods reproduce faithfully natural radiation damage. We have found, in addition, that in both experiment and MD simulation, tetravalent actinides (Th and U) are 7-coordinated (EXAFS-derived Th-O and U-O distanced averaging anharmonically at 2.37 and 2.35 Å). To our knowledge, this is the first time that such a coordination environment is reported for tetravalent actinides.

In some other phases (titanite for instance), we observed that actinides do not replace a major cation in the structure but are present as actinide oxide-type clusters (ThO_2, UO_2; see Fig. 5). We think that subsequent heat treatment can be at the origin of migration of the actinides from its host matrix (as substituted) to some oxide-type cluster.

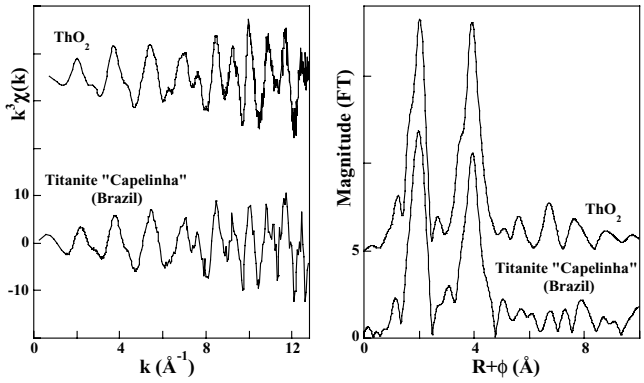

Fig. 5. EXAFS spectra collected at Th L_{III}-edge in a titanite sample from Brazil compared to ThO_2 and their Fourier transform.

4. Conclusions

Combination of XAFS and molecular dynamics of radiation damage in minerals analogues of ceramics for nuclear waste suggests that MD simulates adequately radiation damage, consistent with the observation of very old (10^8 years) metamict minerals. Also, important and unique information about the complex structure of the metamict state was extracted as well as on the sites of actinide in minerals that are geochemically important phases for dating or tracing major geologic events (such as volcanology). Finally, a better understanding on the way disorder affects EXAFS spectra is obtained.

Abstract

The oxidation state and local environment of Fe atoms in a series of vitrified lead-rich industrial wastes, as a function of the ash content, is studied using EXAFS and NEXAFS measurements at the Fe-K edge. The Fe-K EXAFS results reveal that the Fe-O distance and the coordination number in the 1st nearest neighbour shell decrease with increasing ash content in the vitrified product. Information on the iron's valence state and the role of Pb^{2+} ions in the glass matrix is drawn from the characteristics of the pre-edge features and the position of the absorption edge in the NEXAFS spectra.

1. Introduction

The solidification and stabilization of lead oxide-contaminated ash, which is a toxic industrial waste, is a process that allows for its safe disposal. The aim of this work is to determine the local environment of the Fe atoms (whose structural role depends on its oxidation state and the PbO concentration) in the glass matrix of lead-rich industrial wastes, using XAFS spectroscopies. The NEXAFS spectra of transition metals have a weak pre-edge peak (about 10 eV below the absorption edge), which is assigned to $1s \rightarrow 3d$ transitions. The intensity and energy position of this peak, as well as the energy position of the absorption edge, are sensitive to the oxidation state [1] and bonding geometry of the Fe atom [2]. Therefore, conclusions can be drawn on the oxidation state and bonding geometry of the Fe ion.

2. Experimental Details

The under study samples were produced with an incineration process that involves co-melting of lead contaminated ash (it consists mainly of iron oxides and $PbO \cdot PbBr_2$), with the appropriate quantities of vitrifying (SiO_2) and flux (Na_2O) agents at high temperatures (1400 °C), followed by fast cooling in order to form vitrified materials [3]. The under study vitrified products contain various concentrations of fly ash (ranging from 10% to 60%) and a SiO_2/Na_2O ratio equal to 2.33. A crystalline (powder) iron oxide, hematite α-Fe_2O_3 was also studied as a reference samples. The EXAFS and NEXAFS measurements were conducted at room temperature, using the KMC2 double-crystal monochromator of the electron storage ring BESSY-II in Berlin. The NEXAFS and EXAFS spectra were recorded at the Fe-K-edge, using a fluorescence yield detector (Si-PIN photodiode). The NEXAFS spectra were recorded in the energy range 7035–7150 eV, at an angle of incidence $\theta = 45°$.

3. Results and Discussion

The characteristics of the NEXAFS spectra were determined via fitting using a sigmoidal (Boltzman function) to simulate transitions to the continuum [4] and a Lorentzian to fit the pre-edge peak. Prior to fitting, the spectra were normalized for the transmission function of the monochromator, using the signal from an ionization chamber positioned in front of the sample, and were subjected to background subtraction and normalization to the atomic limit.

In the Fe-K-edge NEXAFS spectra, the intensity of pre-edge peak increases with increasing ash content (Fig. 1). It has been reported that the position of the pre-edge peak is a measure of the $Fe^{+3}/\Sigma Fe$ ratio [1] while its intensity, which is inversely proportional to the coordination number of the absorbing atom [2], is greater in non-centrosymmetric complexes (due to the large electric allowed dipole component from 3d-4p mixing) than in centrosymmetric complexes (where the $1s \rightarrow 3d$ transition has an electric quadripole nature). Therefore, the observed increase in the intensity of the pre-edge peaks indicates that the local environment around the Fe ion is becoming less symmetric as the ash content increases, i.e. the Fe atom tends to occupy tetrahedral sites. In addition to that the position of the pre-edge peak is independent of the ash content, indicating that, the $Fe^{+3}/\Sigma Fe$ ratio remains constant despite the changes in the concentration of the fly ash. Given that only Fe^{+3} ions can occupy both tetrahedral and octahedral sites in the glass matrix, the alteration in the

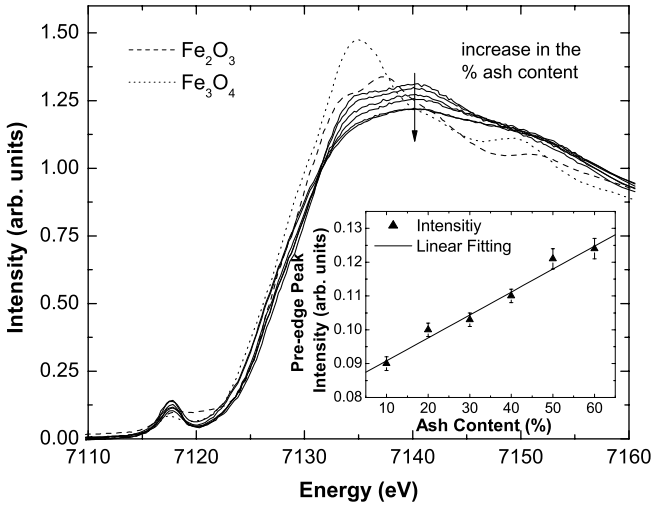

Fig. 1. NEXAFS Fe-K edge spectra of the under study samples. The dependence of the intensity of the pre-edge peak on the ash content is depicted in the inset of the graph.

*e-mail: paloura@auth.gr

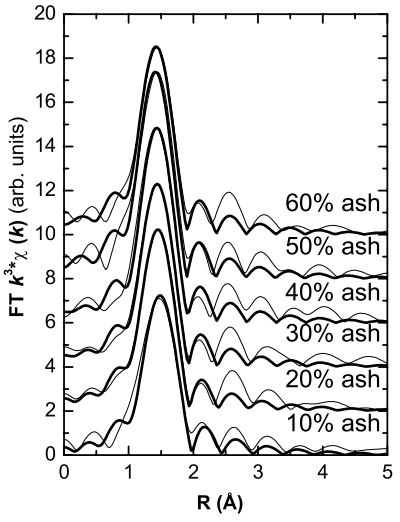

Fig. 2. The Fourier transforms (FT) of the $k^3\chi(k)$ spectra. The raw data and the fitting are shown in thin and thick solid lines, respectively.

local environment around the Fe atom (verified by both EXAFS and NEXAFS analysis) can be assigned only to Fe^{+3} ions. The energy position of the absorption edge (E_{abs}), in all the under study samples, is insensitive to the ash content and appears at energies higher than that in α-Fe_2O_3 and Fe_3O_4 (7126.2 and 7124.6 eV). This violet shift of the E_{abs} can be attributed to structural differences (distortion) in the Fe-O polyhedrons, due to the polarizability of the Pb-O bond, which in turn depends on the PbO concentration [5], [6].

The EXAFS spectra were normalized for the transmission function of the monochromator and subjected to subtraction of the atomic absorption using the AUTOBK [7] program. After their correction for self-absorption effects [8] and for energy shifts induced by the monochromator, the spectra were fitted using the FEFFIT [7] program. The model for the fitting was constructed using he FEFF8.0 program. The raw and fitted Fourier transforms of the k^3-weighted $\chi(k)$ spectra (calculated in the k-range 2.9–9.7 $Å^{-1}$) at the Fe-K-edge, are shown in Fig. 2. The Fe-K edge spectra were fitted using one shell and assuming the hematite (Fe_2O_3) model (octahedral structure). The fitting parameters were the bond length, the coordination number and the value of the Debye-Waller factor while the amplitude ($S_O{}^2$) was kept fixed to the value 0.85.

The EXAFS analysis reveals that as the ash content incorporated into the glass matrix increases, both the coordination number and the Fe-O distance decrease from 5.1 to 3.9 and 1.94 Å to 1.88 Å, respectively (Table I). These two distances are characteristic of octahedral and tetrahedral coordination and indicate the preferential occupation of tetrahedral sites by the Fe atoms, as the ash content increases.

The structural role of iron depends on its oxidation state; Fe^{3+} can form intermediate oxides, while Fe^{2+} acts as a glass modifier. Mossbauer spectroscopy measurements conducted in the under study samples [9] revealed that all glasses contain both Fe^{+2} and Fe^{+3} ions, and that Fe^{+2} ions occupy only octahedral sites, while the Fe^{+3} ions occupy both tetrahedral and octahedral sites. Furthermore, the Fe^{+2}/Fe^{+3} ratio remained constant in all vitrified products, i.e. it did not vary with the increase in the ash content. Therefore, the change in the environment around the Fe atom can be attributed to the different structural role of the Pb^{+2}, that strongly depends on the concentration of PbO and increases with the increase of the ash content.

Table I. *EXAFS results; R_1, N_1 and DW_1 correspond to the coordination number, interatomic distance and Debye-Waller factors in the 1st nn shell, respectively.*

Sample name	N_1 (±10%)	R_1 (Å) (±0.01)	DW_1 (Å^2)
10 ash%	5.1	1.94	7.3
20 ash%	4.5	1.92	5.6
30 ash%	4.1	1.89	4.5
40 ash%	4	1.88	3.2
50 ash%	4.3	1.88	4.7
60 ash%	3.9	1.88	4.2

4. Conclusions

A series of vitrified lead-rich solid industrial wastes has been studied by XAFS spectroscopy, in order to determine the effect of different ash concentrations in the formation of the glass matrix. The NEXAFS analysis reveals that the $Fe^{+3}/\Sigma Fe$ ratio is not affected by the increase in the ash concentration. Furthermore, the local environment around the Fe atom tends to become less ordered as the ash concentration increases. This is also affirmed by the EXAFS analysis where the Fe-O distance and the coordination number in the 1st nearest neighbour shell decrease, indicating that the environment around the Fe atom changes from octahedral to tetrahedral. Because the ratio Fe^{+2}/Fe^{+3} is constant, this change can be attributed to the presence of Pb^{+2} ions whose structural role into the glass matrix is different when the concentration of PbO increases. The different structural role of the Pb atom and the strong polarization of the Pb-O bond, can account for the violet shift of the absorption edge in the NEXAFS spectra.

Abstract

X-ray absorption fine structure combined with fluorescence spectrometry was used for the speciation of trace amounts of lead and arsenic adsorbed. The Pb^{2+} species were effectively adsorbed on a layered material $Mg_6Fe_2(OH)_{16}(CO_3)\cdot 3H_2O$ from 100 ppb–1.0 ppm test aqueous solutions. A eutectic mixture of $PbCO_3$ and $Pb(OH)_2$ coagulated in the case of a 1.0 ppm Pb^{2+} solution, and in contrast, the major species was ion-exchanged Pb^{2+} in the case of the adsorption from the 100 ppb aqueous solution. The arsenic species were effectively adsorbed on intercalated Fe-montmorillonite from 50 ppb–16 ppm test aqueous solutions. In this concentration range, As^{3+} in the solution was oxidized upon adsorption. The adsorbed structure was suggested to be $[As^{V}(OH)_2(\mu\text{-}OFe)_2]$ both in the cases of adsorption of As^{3+} and As^{5+}.

1. Introduction

Speciation of toxic elements, such as Cr^{6+}, Cu^{2+}, Zn^{2+}, As^{3+}, Cd^{2+}, Hg^{2+}, and Pb^{2+} in the environment is important to the understanding of their effects to human health and to investigate the removal and reuse methods. XAFS gives direct information for the speciation of non-crystalline site. Higher-energy-resolution XAFS spectra are desirable for precise speciation. To improve energy resolution, the fluorescence X-rays emitted from a toxic element in the sample were analyzed by a high-energy-resolution Rowland-type spectrometer. This method is free from the problems associated with photon-counting losses (SSD) or spectral broadening effects at higher photon energies (Pb K-edge) [1].

Basic polyhydroxide compound of layered structure $Mg_6Fe_2(OH)_{16}(CO_3)\cdot 3H_2O$ (**1**) was found to be effective for lead(II) adsorption, especially when the flow rate of lead test solution was high [1]. Layered material was also good for arsenic (arsenite, arsenate) adsorption, especially in the case that iron material was intercalated between the layers of montmorillonite.

2. Experimental Section

2.1. *Samples*

Standard lead(II) compounds were used as received and diluted to 5.0 wt% of Pb by mixing with boron nitride. An ion-exchanged standard sample was prepared from lead(II) nitrate aqueous solutions on NaY zeolite (JRC-Z-Y4.8, $Na_{58}Al_{58}Si_{134}O_{384}\cdot 240H_2O$). The cation exchange ratio was 85.5%. An adsorbent **1** was synthesized by adding NaOH to the aqueous solution of $MgCl_2$ and $FeCl_3$ [1]. The specific BET surface area was 110 $m^2\,g^{-1}$. The interlayer spacing was 7.79 Å based on X-ray diffraction (XRD) measurements. A 1.0 ppm or 100 ppb lead(II) nitrate solution was adsorbed at a flow rate (space velocity) of 50 min^{-1} on adsorbent **1**.

Standard As^{III} and As^{V} compounds were used as received and diluted to 2.0 wt% of As by mixing with boron nitride. An adsorbent was prepared by the following procedure. 8.14 ml of a 0.43 M $Fe(NO_3)_3$ solution and 9.33 ml of a 0.75 M NaOH solution were mixed and left undisturbed in the dark at 290 K for 24 h. 0.5 wt% of Na-montmorillonite (Kunipia F, $Na_{1.5}Ca_{0.096}Al_{5.1}Mg_{1.0}Fe_{0.33}Si_{12}O_{27.6}(OH)_{6.4}$) was suspended in distilled water and the reaction mixture was added. The resultant powder obtained was dried for 72 h at 313 K. The Fe loading was 15.3 wt%. The sample is denoted as Fe-montmorillonite. 20 ml of 1–16 ppm solutions of $As^{III}{}_2O_3$ or $KH_2As^{V}O_4$ was adsorbed on 50 mg of Fe-montmorillonite in a 30-ml tube at 290 K for 12 h. 500 mg of Fe-montmorillonite was packed and 50–200 ppb solutions of $As^{III}{}_2O_3$ were flowed at a rate of between 1.4–2.1 ml min^{-1}. All the samples were pressed into 20 mm-diameter disks for X-ray measurements.

2.2. *X-ray Emission and Absorption Measurements*

The X-ray measurements utilizing a fluorescence spectrometer were performed on the Undulator Beamline 10XU of SPring-8 (Sayo). The storage ring energy was 8.0 GeV and the ring current was 100–50 mA. A Si(111) double crystal monochromator and a Rh-coated double mirror set were used. All the measurements were performed at 290 K. The X-ray fluorescence from the sample was analyzed by a Rowland-type spectrometer ($R = 220$ mm) equipped with a Johansson-type Ge(555) crystal (50×50 mm^2, Crismatec) and a scintillation counter (Oken). The energy resolution was 1.1 eV at the Cu $K\alpha_1$ emission (8 keV) including the contribution of the beamline [2] and 0.3 eV at the V $K\alpha_1$ emission (5 keV) based on the peak width of emission and the pre-edge absorption peaks [3].

The Pb $L\alpha_1$ emission spectrum was measured for Pb^{2+} adsorbed on compound **1** (Pb 0.12–1.0 wt%) and reference Pb compounds with the excitation energy set at 13064.3 eV. The fluorescence spectrometer was tuned to the center of the Pb $L\alpha_1$ peak and the Pb L_3-edge XAFS spectrum was measured. The Undulator gap and the piezoelement were optimized to maximize the X-ray beam flux at each data point.

The As $K\alpha_1$ emission spectrum was measured for arsenic adsorbed on the Fe-montmorillonite (As 0.13–0.48 wt%) and reference As compounds with the excitation energy set at 11885.0 eV. The fluorescence spectrometer was tuned to the center of the As $K\alpha_1$ peak and the As K-edge XAFS spectrum was measured. Measurements for standard As samples and a part of As adsorbed onto Fe-montmorillonites were carried out in transmission mode to evaluate the energy resolution and signal-to-background ratio of the spectra obtained in each mode.

*e-mail: yizumi@chemenv.titech.ac.jp

2.3. *XAFS Data Analysis*

Background subtraction of the raw XANES spectrum was performed by using a Victoreen parameter. The subtraction was not necessary in the case of XANES utilizing the fluorescence spectrometer. A smooth spline function was calculated in the postedge region, and then the spectrum was normalized. An EXAFS curve fitting analysis was performed using empirical phase-shift and amplitude parameters for the Pb-O and As-O bonds extracted from the EXAFS spectra of PbO_2 and $K[AsO_2(OH)_2]$ and theoretical phase-shift and amplitude parameters of the As•••Fe bond generated using the *ab-initio* calculation code FEFF 8.2 [4] for the coordinates of $AsFeO_4$ crystal [5].

3. Results and Discussion

3.1. *Pb Lα_1 Emission and L$_3$-edge Absorption Spectra*

The Pb Lα_1 emission peak appeared at 10551.5 eV for 0.12 wt% Pb adsorbed on compound **1** from a 100 ppb Pb^{2+} solution. The full width at a half maximum (FWHM) obtained by the peak fit using a pseudo-Voigt function was 11.7 eV. The core-hole lifetime width of Pb L_3 is 5.81 eV and the energy resolution of spectrometer was evaluated to be 10.1 eV, including the contribution of the beamline.

Normalized Pb L_3-edge XANES spectra are depicted in Figure 1. The rising edge for standard Pb^{II} inorganic compounds shifted by 2.8–4.3 eV toward higher energy compared to 13040.6 eV for Pb^0. The rising edge for lead (0.12–1.0 wt%) adsorbed on compound **1** appeared within the range 13042.9–13044.2 eV (a–c), demonstrating that the adsorbed lead state was II. The rising edge and maximum point energies for the spectrum for 1.0 wt% Pb on compound **1** (13044.2 and 13056.3 eV, respectively; Figure 1a) prepared from 1.0 ppm test solution resembled only that for $2PbCO_3{\cdot}Pb(OH)_2$ (13044.0 and 13055.5 eV, respectively; g).

The samples of 0.30 and 0.12 wt% Pb on compound **1** were both prepared from 100 ppb Pb^{2+} solution, and the two spectra (b) and (c) resembled each other. Based on the rising edge and the maximum point energies, these two spectra (13043.0 ± 0.1 eV and 13054.3 ± 0.7 eV, respectively) resembled only that for PbY (13043.4 and 13054.4 eV, respectively; d).

The comparison of post-edge peak at 13094–13097 eV and the unresolved shoulder peak at 13049 eV supported above assignments of lead species in Figure 1a–c. Most of the Pb^{2+} coagulated as a eutectic mixture of $PbCO_3$ and $Pb(OH)_2$ on compound **1** in the case from a 1.0 ppm solution. The hydroxyl groups should be derived from the buffering effect of basic surface of compound **1**. The formation of pure $PbCO_3$ by the reaction with intercalated/dissolved carbonate or pure $Pb_6O_4(OH)_4$ by the reaction with surface hydroxyl groups should be negligible. In contrast, in the case of the 100 ppb solution, the major lead phase was ion-exchanged Pb^{2+} via the surface reaction $-OH + Pb^{2+} \rightarrow -OPb^+ + H^+$. A shoulder peak at 13049 eV (Figure 1b and c) suggests a minor contribution from a coagulated eutectic mixture of $PbCO_3$ and $Pb(OH)_2$ on compound **1**. Pb L_3-edge EXAFS was measured for the sample of Figure 1a. The Pb-O bond was found at 2.4 Å and the coordination number (N) was ≈3 [6].

3.2. *As Kα_1 Emission and K-edge Absorption Spectra*

The As Kα_1 emission peak appeared at 10544.7 eV for 0.48 wt% As adsorbed on Fe-montmorillonite from a 16 ppm test solution of As^{5+}. The FWHM obtained by the peak fit using a pseudo-Voigt function was 5.72 eV. The total core-hole lifetime width for As Kα_1 is 3.08 eV and the energy resolution of the spectrometer was evaluated to be 4.8 eV, including the contribution of beamline. Note that this value will be an overestimation in the case that As^{5+} and As^{3+} co-exist as adsorbed in the sample. The corresponding value of energy resolution was estimated to be 1.3 eV for an arsenic metal sample.

Normalized arsenic K-edge XANES spectra are depicted in Figure 2. The maximum point energy above the edge shifts from 11867.1 for the arsenic metal (a) to 11868.5 for $As^{III}{}_2O_3$ (b) then to 11872.1 eV for $K[As^{V}O_2(OH)_2]$ (c). The maximum point energy for (d)–(g) was similar to the case of (c). The spectrum pattern of the arsenic adsorbed from the 16 ppm arsenate solution (d) closely resembled that of $K[AsO_2(OH)_2]$. Unexpectedly, spectra (e)–(g) for the samples prepared from the arsenite solution were more similar to (c) than they were to (b). Hence, in the case

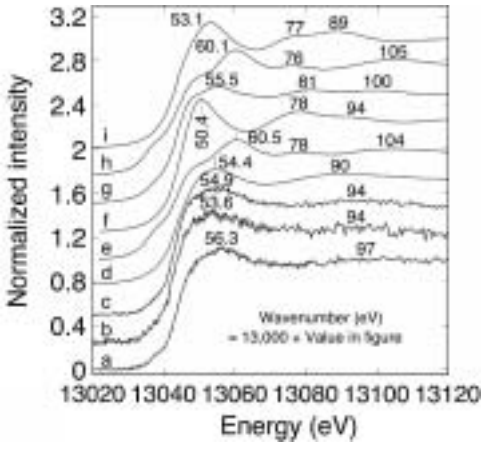

Fig. 1. Normalized Pb L_3-edge XANES spectra for Pb^{2+} on (1) measured utilizing a secondary fluorescence spectrometer (a–c). The Pb content was 1.0 wt% adsorbed from 1.0 ppm Pb^{2+} solution (a) and Pb 0.30 (b) and 0.12 wt% (c) from 100 ppb solution. Reference XANES spectra for PbY zeolite (d), PbO (e), $Pb(NO_3)_2$ (f), $2PbCO_3{\cdot}Pb(OH)_2$ (g), $Pb_6O_4(OH)_4$ (h), and $PbCO_3$ (i). (d)–(i) were measured in the conventional transmission mode.

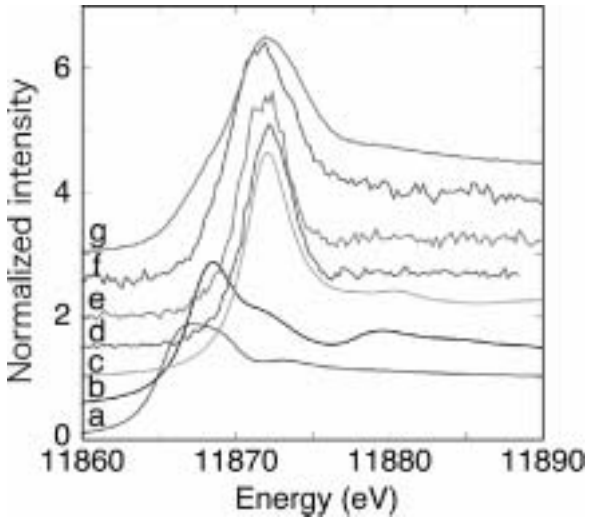

Fig. 2. As K-edge XANES spectra measured at 290 K for As metal (a), As_2O_3 (b), KH_2AsO_4 (c), and As adsorbed (d–g) on Fe-montmorillonite (Fe 15.3 wt%) from test solutions of 16 ppm of KH_2AsO_4 (d), 16 ppm of As_2O_3 (e), 200 ppb of As_2O_3 (f), and 50 ppb of As_2O_3 (g). Spectra (a)–(c) and (g) were measured in transmission mode and (d)–(f) were measured in fluorescence mode utilizing a secondary fluorescence spectrometer.

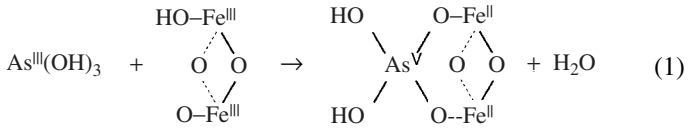
of the arsenic adsorbed from arsenite solutions in the range of 50 ppb–16 ppm, most of the As^{3+} was oxidized to As^{5+} upon adsorption. A minor peak for adsorbed As^{III} appeared as a shoulder feature at 11868.8–11869.8 eV in (e) and (f). Arsenic K-edge EXAFS was measured for arsenic adsorbed from 200 ppb–16 ppm on Fe-montmorillonite. The As-O and As•••Fe distances were 1.68 Å ($N \approx 3$) and 3.22–3.25 Å ($N \approx 2$), respectively. Also based on the crystallographic structure of FeO(OH) where $[FeO_6]$ octahedral are connected at the edge, the mechanism of oxidative adsorption of As may be formulated as equation **1**. $[AsO_2(OH)_2]^-$ was also suggested for spectrum d adsorbed from arsenate [9–11].



(1)

4. Conclusions

X-ray absorption fine structure combined with fluorescence spectrometry was successfully applied to trace amounts of lead and arsenic adsorbed from aqueous solutions containing 50 ppb–16 ppm of lead or arsenic. Based on Pb L_3-edge XANES, it was found that a eutectic mixture of $PbCO_3$ and $Pb(OH)_2$ coagulated in the case of the 1.0 ppm Pb^{2+} solution, whereas the major species was ion-exchanged Pb^{2+} in the case of adsorption from 100 ppb Pb^{2+} solution. Both arsenate and arsenite species were adsorbed on Fe-montmorillonite (Fe 15.3 wt%) from 50 ppb– 16 ppm solutions containing of As. In this concentration range, As^{3+} in solution was oxidized to As^{5+} upon adsorption. Because the As^{3+} is more toxic [8, 9], Fe-montmorillonite effectively trapped trace amounts of As^{3+} in solution and detoxified it.

Abstract

We have applied fluorescence XANES for the study of the oxidation state of Ce in natural solid materials. High sensitivity and high energy resolution of 19-element semiconductor detection system enables us to obtain XANES spectra of trace Ce in natural samples. In this study, we report an application of the method to soil horizons, where presence of Ce(IV) was found in the depth between 0.60 and 1.50 m in the soil horizon presumably due to the oxic condition in the layer compared with the shallower regions. The fact is consistent with the preferential enrichment of Ce in the soil relative to other REE (rare earth elements), which is called as the positive Ce anomaly in the REE patterns (REE pattern: relative abundances of REE in samples against reference materials such as chondrite, shale, etc). There is a correlation between the abundances of Ce(IV) and Mn(IV), suggesting that the oxidation of Ce by Mn(IV) oxides is responsible for the relative enrichment of Ce among REE. If we assume that Ce(IV) has been mainly produced by water-rock interaction, the Ce(IV)/Ce(III) ratio coupled with Ce abundance data suggests that considerable amount of REE is incorporated into the soil during its formation from primary minerals.

1. Introduction

Cerium is an important element in geochemistry to elucidate redox environment and chemical processes during formation of natural samples [1]. This is primarily due to the preferential enrichment or depletion of Ce relative to other REE often observed in natural samples. The anomalous behavior of Ce is called as the Ce anomaly which is a useful index in REE pattern (= relative abundances of rare earth elements (REE) normalized by proper materials such as chondrite or shale that represents the bulk compositions of the earth). An example of the (positive) Ce anomaly in REE pattern is found in a soil sample at 1.42 m depth as shown in Fig. 1. Usually, REE patterns become smooth curves, which reflects similar chemical characteristics among REEs. However, the anomalous value of Ce is often recognized in the REE pattern. This phenomenon has been considered to occur by chemical reactions including Ce(IV) during the formation processes of the sample, because other REE (except for Eu) behaves exclusively as trivalent ion in natural systems. However, few studies have identified the Ce(IV) species by direct physico-chemical methods due to the low sensitivity for the speciation study of Ce in natural samples. Recently, we have applied XANES for the determination of the Ce(IV)/Ce(III) ratio in natural samples such as ferromanganese nodules [2], weathered granites [3], cherts [3], zircons [4], and apatite fossils [5]. In this study, we have applied the method to a soil-water system using a well-controlled experimental paddy field in NIAES (National Institute for Agro-Environmental Sciences) in Tsukuba, Japan. In the paddy field, soil water samples at different depths can be extracted to determine concentration of dissolved REE that can be compared with the abundance in the soil. In the field, we can assume that the soil water comes from overlying horizon, since water flow in the field is usually downward. This enables us to simplify the input and output of the REE in the soil horizons.

2. Samples and experimental procedures

The experimental paddy field (size: 10 m × 50 m) in NIAES is located in Tsukuba, Japan, which was particularly designed to study the migration of trace elements in paddy soils [6]. The site of the paddy field consists of fine-textured Gray Lowland Soil. The parent material of the soil layer is mainly tephra (fine volcanoclastic materials) which deposited in late Pleistocence. The layer at the depth between 0 and 0.60 m is alluvial soil dressed in 1974. The Kanto Loam layer (late Pleistocene) is at the depth between 0.60 and 1.30 m, while a transitional zone is located between 1.30 and 1.70 m depth. The deeper layer (>1.70 m) is Joso Clay layer and sandy sediment of the Ryugasaki Formation (late Pleistocene). The paddy field is flooded from May to September. Porous ceramic cups are placed at the depths of 0.20, 0.50, 1.0, 1.5, 2.0 and 2.5 m to collect soil water and the cups are connected to vacuum pumps.

Cerium L_{III}-edge XANES spectra were measured at BL-12C line at the Photon Factory (Tsukuba, Japan) using a 19-element Ge detector [7], with which we can obtain XANES spectra of trace amount of Ce in soil samples (Ce: 20–60 ppm). Some spectra were taken by a similar method at BL01B1 at SPring-8, Japan [8]. Relative energy to peak top of white line of Ce(III) species (e.g., Ce(III)-oxalate; Fig. 3) at 5726 eV was used to show XANES spectra in this study. Manganese and Fe K-edge XANES were also measured by a similar method. REE abundances in soil and water samples were measured by ICP-MS as described in Takahashi *et al.* (2002) [9].

3. Results

REE patterns in the soil samples examined in this study are shown in Figs. 1a and 1b. Each sample is named by the average depth indicated in the brackets in Fig. 1. The soil horizon name is also shown in Fig. 1. It is observed that the Ce anomaly is not

*E-mail: takahasi@geol.sci.hiroshima-u.ac.jp

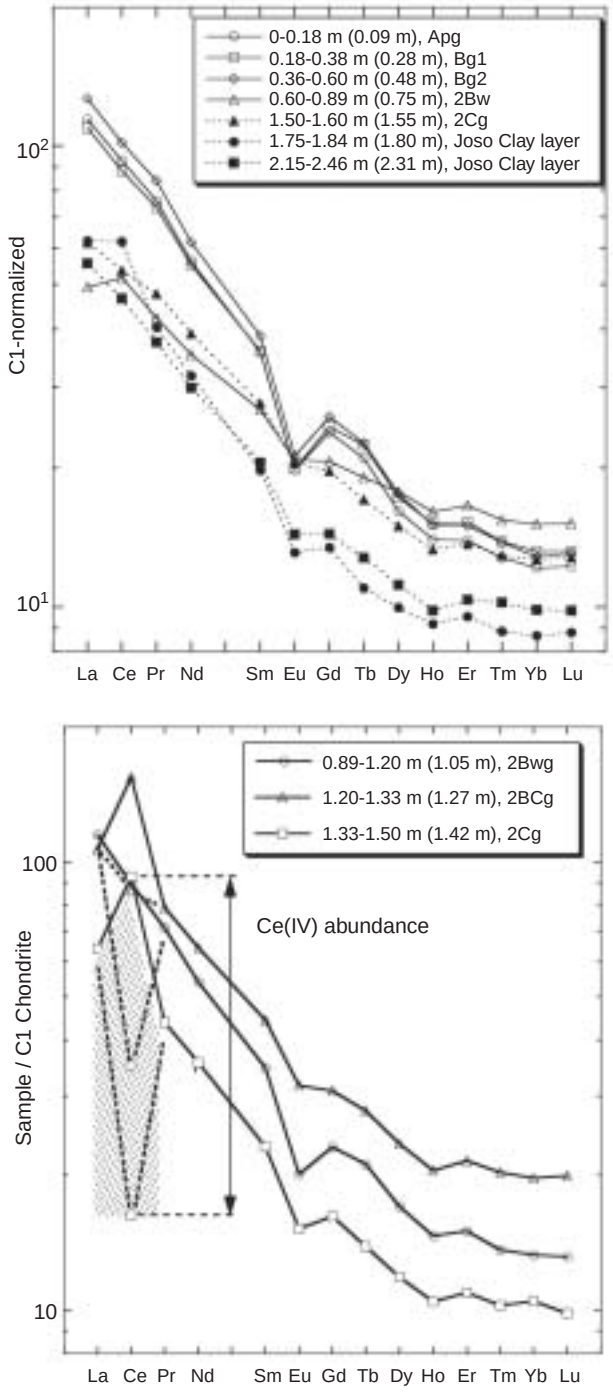

Fig. 1. (a) REE patterns of soil samples at various depths in the experimental paddy field in NIAES. REE abundances of C1 chondrite [15] were employed for the normalization. Soil horizon name (e.g., Apg) is also indicated in the figure. (b) REE patterns of soil samples at 1.05, 1.27 and 1.42 m depths with Ce(III) abundances (dotted curves) based on the Ce(IV)/Ce(III) ratio determined by XANES.

found in the horizon above 1.20 m depth except for the 0.75 m sample of the horizon 2Bw (Fig. 1). Actually, only the horizon at 0.75 m depth (2Bw) is not gleyed, rather oxic horizon, which is consistent with the appearance of the positive Ce anomaly in the horizon. The redox condition is rather anoxic ($Eh < 0$ mV) above 0.30 m during the flooded period in the paddy field due to the high content of organic carbon, while lower layer containing less amount of organic carbon is more oxic compared with the overlying region [8, 9]. This shows that the fractionation of Ce from other REE does not occur in these horizons above 0.30 m, since these horizons are not very oxic to produce Ce(IV). Between

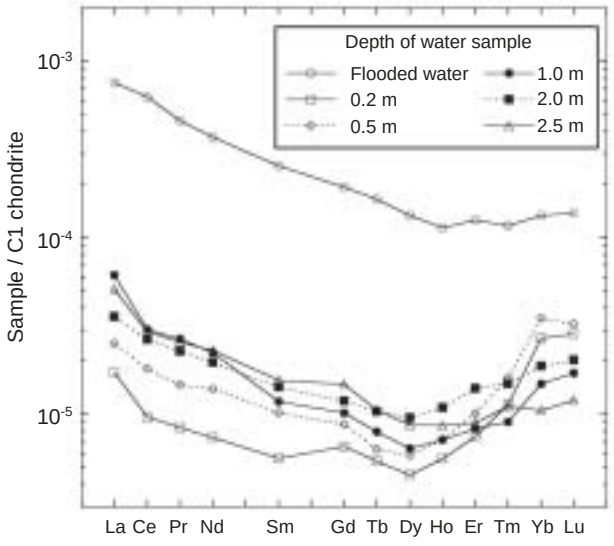

Fig. 2. REE patterns of soil waters at various depths in the experimental paddy field in NIAES. Europium abundances could not be determined due to large abundances of Ba in water samples, since the signal of BaO interferes with Eu in ICP-MS measurements.

1.20 and 1.84 m depth except for the 1.55 m sample, distinct positive Ce anomalies are observed. REE abundance in soil water samples recovered during flooded period (August, 2001) are much lower than those in flooded water, showing that reactions with soil particles undergo to determine REE abundance in soil waters (Fig. 2). Water samples at 0.20 m, 1.0 m, and 2.5 m depths show slightly negative Ce anomalies, while flooded water does not show the Ce anomaly. This suggests that the preferential removal of dissolved Ce from other REE in the soil horizons occurs in the depth due to the formation of Ce(IV) species.

It has been difficult so far to elucidate more information about Ce and REE migration only from REE patterns. Based on the Ce(IV)/Ce(III) ratio determined by XANES, we can extract more information about REE behavior. XANES spectra of Ce(III) reference materials can be well simulated by a pair of an arctangent function and a Lorentzian function whose centroid is shown at 0 eV as relative energy in Fig. 3 [5]. Cerium(IV) can be simulated similarly by three pairs of an arctangent function and a Lorentzian function. The centroid of the three Lorentzians are at 3 eV, 11 eV, and −6 eV, though the third one is subtle peak. Some XANES spectra of Ce in the soil samples are shown in Fig. 3, where XANES spectra of soil samples can be deconvoluted by those of Ce(III) and Ce(IV) reference materials. Cerium(IV) percentages obtained from the deconvolution are shown in Fig. 3.

4. Discussion

In the soil samples at shallow region (0.09 m, 0.28 m, and 0.48 m depths samples), XANES results show that Ce(III) is predominant, which is consistent with the speculation suggested by REE patterns. In the deeper region, considerable amount of Ce has been oxidized to Ce(IV) during water-rock interaction. Iron and Mn abundances, major constituents in soil, increase with depth in the soil horizons and show maximum at 1.27 m [8], which seems to be correlated with the degree of the positive Ce anomaly. This suggests that formation of Ce(IV) in soil can be related to the oxidation of Ce(III) by MnO_2 phase and possibly by Fe_2O_3 phase

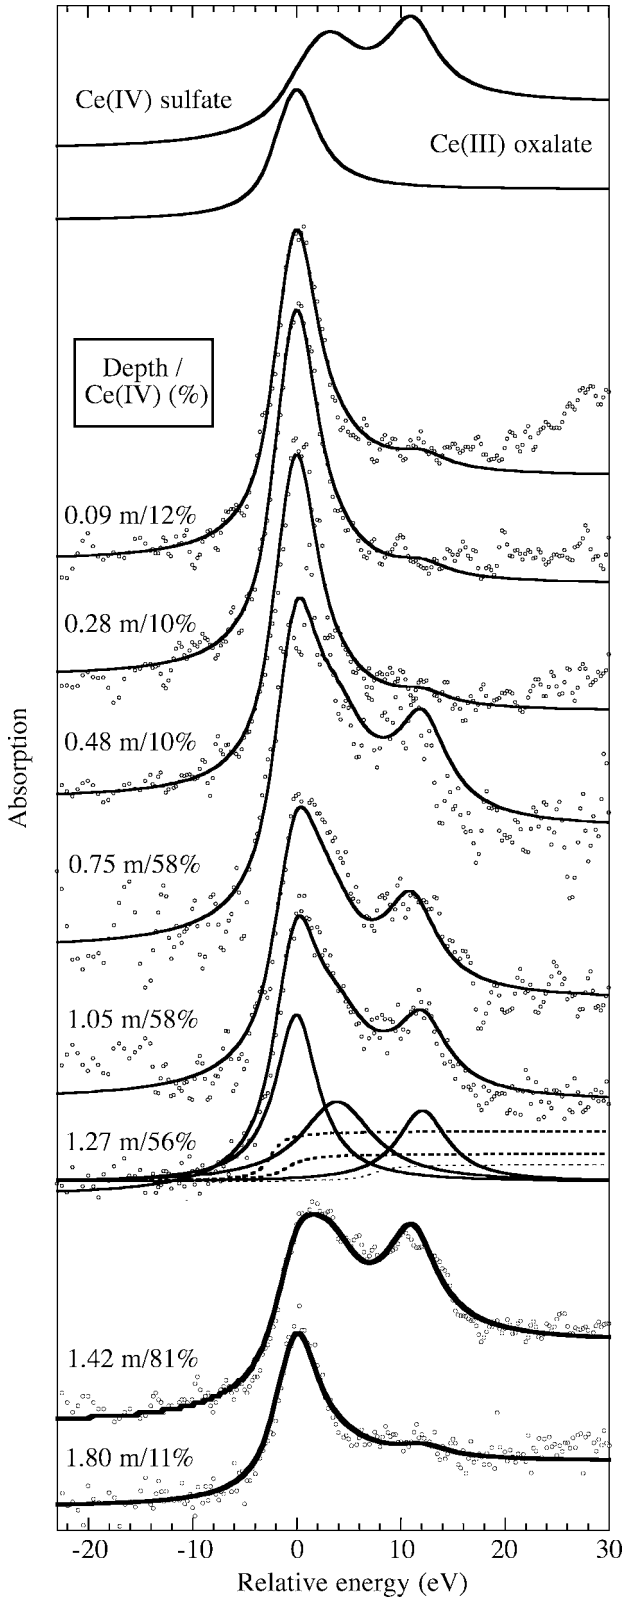

Fig. 3. Cerium L_{III}-edge XANES spectra of the soil samples with those of Ce(III) oxalate and Ce(IV) sulfate shown as reference materials.

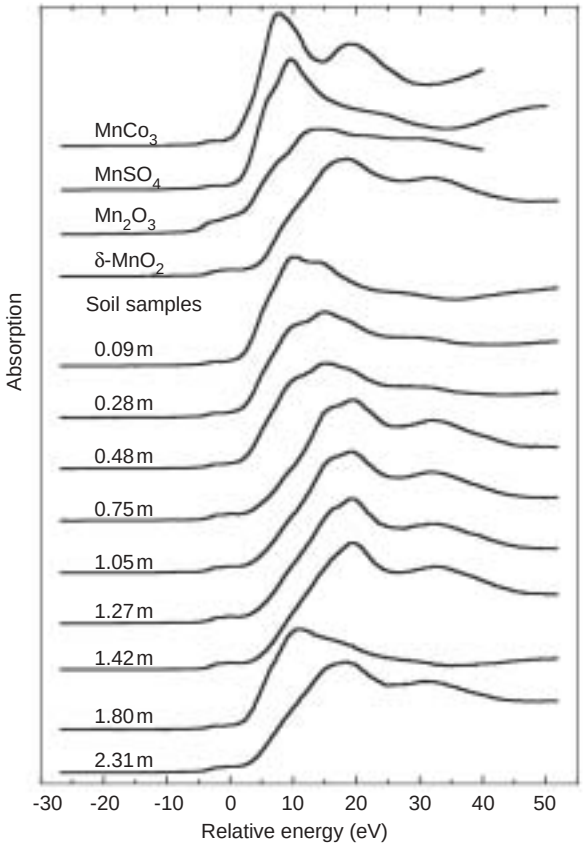

Fig. 4. Manganese K-edge XANES spectra of the soil samples with those of Mn reference materials.

as implied in various studies (e.g., Kawabe *et al.* [14]). In order to support the speculation, oxidation states of Fe and Mn were also studied by XANES. Iron K-edge XANES spectra of all samples examined in this study show similar spectra to ferrihydrite (spectra are not shown), showing that there is not strong correlation with Ce(IV) and Fe(III) (hydr)oxide abundances. On the other hand, the absorption edge of Mn shifts to higher energy with an increase in depth between 0 and 1.50 m depth (Fig. 4). This shows that Mn in the soil horizon takes higher oxidation states in the deeper horizons up to 1.50 m depth. The spectra of the samples at depth between 0.60 and 1.50 m are similar to that of δ-MnO_2, showing that δ-MnO_2 is main Mn phase in the horizon. This coincides with the fact that the amount of Ce(IV) is larger at the depth between 0.60 and 1.50 m. The lower horizon (1.80 m depth) is very reductive, since the horizon is at the top of the Joso Clay layer where ground water table exists during the non-flooded period. This is also reflected in the XANES spectra, that is, the 1.80 m depth sample contains lower abundance of Ce(IV), while Mn K-edge spectrum of the sample shifts to lower energy, showing that Mn(IV) oxides is not included in the horizon. These results suggest that the oxidation of Ce by Mn(IV) oxides is a main mechanism to produce Ce(IV) in the soil horizon. The oxidation of Ce(III) by δ-MnO_2 in natural aquifer has also been indicated in the case of ferromanganese nodules where Ce is completely oxidized by the oxidative sorption on δ-MnO_2 in marine environment [2]. Although it has been suggested that the oxidation of Ce(III) is also caused by iron (hydr)oxides [14], present results show that the oxidation by Mn oxides are more plausible mechanism to produce Ce(IV) in the soil horizon.

It has been suggested that Ce(IV) is produced by Mn(IV) oxides during water-rock interaction. Normally, the Ce anomaly is not found in igneous rocks due to the low content of Ce(IV) in magma [1, 2, 12, 13]. Therefore, it is expected that Ce(III) is predominant species in primary rocks before being subject to weathering to produce soil. This indicates that the presence of Ce(IV) provides the evidence of influence of water-rock interaction on the formation of the soil. Based on the Ce(IV)/Ce(III) ratios, Ce(III) abundances in soil samples showing

the positive Ce anomalies (1.05, 1.27, and 1.42 m depths samples) are plotted in the REE patterns (dotted curves in Fig. 1b). The REE patterns using Ce(III) abundances show negative Ce anomalies. As written above, such negative Ce anomalies cannot be produced during igneous rock formation processes. Tetravalent Ce fraction must be accreted to the soil as a consequence of water-rock interaction accompanied with the oxidation of Ce(III). For example, a fraction of Ce indicated as an arrow in Fig. 1b must have been added to the 1.42 m depth sample by water-rock interaction. Cerium(III) abundance estimated from the Ce(IV)/Ce(III) ratio is regarded to be closer to the Ce abundance originally retained in the primary rocks before subject to water-rock interaction to produce the soil sample. This means that at least shaded area in the Fig. 1b has been accreted to the soil during water-rock interaction, since original REE pattern is unlikely to exhibit any Ce anomalies (Fig. 1b). This suggests that considerable amount of REE has been incorporated into the soil during water-rock interaction. If the Ce(IV)/Ce(III) ratio is not available, it is not possible to discuss such a meaning of REE abundances in soils. For example, one may think that REE abundances of soil have been produced only as a result of removal of REE from primary rocks. However, this is not the case for the samples studied in this work based on the estimation by REE patterns coupled with the Ce(IV)/Ce(III) ratio. The Ce(IV)/Ce(III) ratio coupled with the degree of Ce anomaly shows that most of Ce has been incorporated into the soil during the formation process of soil from primary rocks.

Abstract

Microbial metal reduction is relevant for developing bioremediation strategies for contaminated sites containing toxic metal compounds, but the molecular mechanisms involved and the regulation of those mechanisms are poorly understood. Metal reduction capability is microbe specific, yet the involvement of metalloproteins in the transport of electrons from electron donor molecules to electron acceptor molecules (i.e., to the metals to be reduced) is common to all metal-reducing organisms. A thorough understanding of the mechanisms involved in metal reduction by microbes, with a focus on their metalloproteins, will provide valuable information about the metal reduction capability of the organisms and could provide general insight into the mechanisms of metalloprotein expression and regulation in other microbial systems as well. We are developing methods for the efficient separation, detection, and quantification of metalloproteins. Electrophoretic methods for protein separation have been combined with X-ray fluorescence mapping and XAFS to determine the abundance and local chemical environment of iron within a cytochrome.

1. Introduction

Microbial metalloproteins mediate critical processes such as metal reduction, tolerance to radiation, and degradation of organic contaminants. Elucidating the involvement of metalloproteins in biochemical networks is crucial to the development of bioremediation strategies for waste sites containing toxic organic and metal compounds, because currently the molecular mechanisms involved in microbial metal reduction and the regulation of those processes are only partially understood. To elucidate metalloprotein expression within whole cells and microbial communities, we have begun developing new technologies and strategies to enable coupling of X-ray fluorescence (XRF) imaging, XRF elemental analysis, and XAFS with electrophoretic methods.

2. Metalloproteins

Metalloproteins have been estimated to represent one-third of the proteins synthesized by biological systems. As the name suggests, these proteins include a metal atom or atoms in their three-dimensional structures. Typically, one or more relatively small metal atoms are associated with a much larger protein molecule. Metalloproteins participate in many of the essential reactions of metabolism and energy production, including reactions with potential bioremediation applications such as reduction of toxic metals and radionuclides and degradation of hazardous organic contaminants. In respiratory energy production, metalloproteins pass electrons down a controlled thermodynamic gradient to a final electron acceptor by altering the valence states of the metals. In the absence of oxygen, organisms can produce metalloproteins essential for the reduction of available metal ions, including contaminant metals found in soils, sediments, and aquatic systems. The metalloproteins that mediate these respiratory electron transfers are primarily cytochromes that carry Fe atoms coordinated in porphyrin rings. Other metals, notably Cu and Mn, also participate in such processes. For example, the terminal step of oxygen-dependent respiration involves cytochrome c oxidase, an enzyme containing Cu and Fe.

Beyond metal reduction, metalloproteins from various organisms also catalyze the oxidation of chelating agents (thereby halting dispersal of heavy metals and radionuclides mobilized by them) and the degradation of organic pollutants. Metalloproteins are also undoubtedly involved in microbial processes controlling the fixation and general cycling of carbon.

Current methods for identifying and characterizing new metalloproteins in complex mixtures are slow and laborious. Isotopic labeling of proteins with specific metal tags enables detection only of metalloproteins containing that specific metal (e.g., Fe). *In situ* labeling with radiolabeled metals can be problematic if the cell's uptake and metabolism of the radiolabeled molecules are inefficient. Staining methods for detection of metalloproteins, such as the heme stains, also allow for the detection of only one type of metalloprotein. The sensitivity of these specialized stains is also limited, necessitating the use of relatively large amounts of proteins (often over 100 μg of pure protein) for detection. New methods must be developed, therefore, to achieve high-throughput, global discovery and characterization of individual metalloproteins of different types in the complex mixtures of proteins produced by organisms.

3. Electrophoretic Separation of Proteins under Nondenaturing Conditions

The global detection and characterization of metalloproteins requires, in addition to the detection and characterization methods provided by XRF and XAFS, a method for separating complex mixtures into distinct protein components. Although many metalloproteins retain their metal moieties under denaturing conditions, we hypothesize that separation under nondenaturing conditions will preserve even the protein-metal interactions that might be disrupted by denaturation.

Separation of native proteins (i.e., nondenatured functional proteins with minimally disrupted protein structure) by one-dimensional (1-D) gel electrophoresis in cellulose acetate, starch, or polyacrylamide has been used effectively to characterize

*Corresponding author. e-mail: kemner@anl.gov

hundreds of enzyme activities and isozyme polymorphisms [1, 2]. Such 1-D separations of nondenatured proteins can be achieved by using 1-D zone electrophoresis or isoelectric focusing in starch or polyacrylamide. For zone electrophoresis, buffer and gel conditions are selected to optimize differences in the mass-to-charge ratio of the sample proteins. Selection of the ionic strength and pH of the running and sample buffers influences the charge separation, while selection of the separation matrix concentration, which influences the final pore size of the gel, affects the mass separation. Separation by isoelectric focusing, in contrast, depends only on differences in the net charges of the proteins, independent of their masses.

A 2-D separation based on two independent parameters, analogous to the separation by isoelectric point and size used in denaturing 2-D electrophoresis (2DE), would obviously overcome co-migration of proteins and dramatically increase the number of distinct proteins detectable. We recently developed such a method for the 2-D separation of proteins under nondenaturing conditions and applied the method to the analysis of proteins from the metal-reducing microbe *Shewanella oneidensis* [3].

4. Detection of Metalloproteins in Polyacrylamide Gel Strips

Although the XRF technique is a very powerful probe for identifying a variety of elements in a microbial system, the information provided is only the average for all of the free metal ions and the metalloproteins at the point of interaction with the X-ray beam. To investigate the interaction between a metal and one of the specific proteins expressed by the microbe, the size of the X-ray probe must be comparable to or smaller than the dimensions of the spatially resolved protein of interest. For the 1-D and 2-D gel systems discussed here, 0.1- to 1.0-mm X-ray beams are required to analyze the resolved protein bands in the polyacrylamide gels. Production of high-intensity X-ray beams of this size with an undulator X-ray source has been accomplished simply with the use of apertures the size of the desired spot.

In a preliminary experiment, a sample containing 0.5 μg of cytochrome c was resolved by using isoelectric focusing in immobilized pH gradient (IPG) strips. The portion of the gel containing the protein was cut out and mounted on a sample holder compatible with existing mounting devices at the Materials Research Collaborative Access Team (MRCAT) insertion device beamline at the Advanced Photon Source (APS) [4]. With a single-element solid-state XRF detector, a strong Fe Kα fluorescence signal was easily detected after less than 10 s of irradiation with a 10.5-keV X-ray beam. This result demonstrated that the necessary sensitivity exists for detection of the metal atoms in metalloproteins resolved in gels. In a subsequent experiment, various amounts of catalase (20, 100, and 200 μg) were resolved by isoelectric focusing on replicate IPG strips. One strip was stained for protein, and the others were then "imaged" in 1-D by XRF by translating the strip through the X-ray beam. Normalized integrated intensity of the Fe Kα fluorescence at the protein location on the strip is plotted versus the mass of metalloprotein applied to the IPG strips in Fig. 1. Results of linear regression analysis of these data conservatively indicate a 4 μg detector, 20-s integration time, and 10-keV X-ray probe energy. Realistic improvements to the experimental setup for better detection sensitivity include (1) measurement near resonance for Fe fluorescence detection (factor of ∼2), (2) use of all 13 elements of the solid-state detector at the MRCAT beamline (factor of 3.6), and (3) increased data collection time from 20 s to 600 s

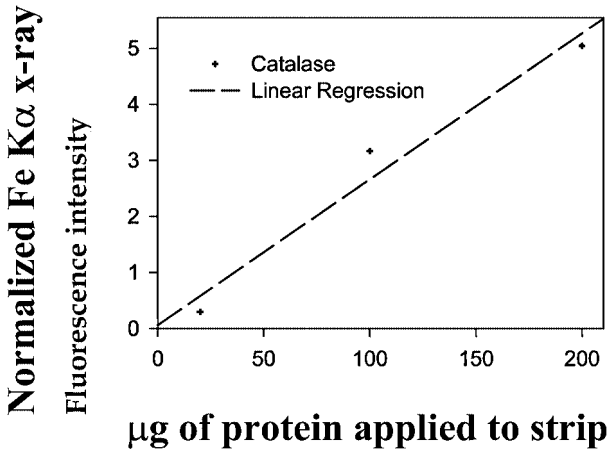

Fig. 1. Normalized integrated Fe Kα fluorescence intensity at the protein location on the IPG strip versus the mass of metalloprotein applied.

(factor of 30). These improvements would result in increased elemental detection sensitivity of >200-fold for a metalloprotein similar to catalase. This translates to sensitivity of better than 20 ng for metalloproteins with concentrations of Fe similar to that of catalase.

We evaluated this technique for investigating samples from microbial cultures. Specifically, we compared the reproducibility and accuracy of XRF elemental mapping for identifying the presence of cytochrome c7 (a triheme Fe-centered metalloprotein) overexpressed by an *Escherichia coli* culture (100 μg of total protein). In addition, 50 and 100 μg of purified cytochrome c7 (as calibration standards) and 200 μg of material from an *E. coli* control culture (i.e., not overexpressing cytochrome c7) were also measured. XRF measurements of the spatial distribution of the Fe Kα fluorescent intensity on a 1-D gel were performed at the MRCAT [4] beamline. A 10.5-keV X-ray beam (0.77mm × 1.0 mm) was used as a probe, and the fluorescent X-ray intensity was monitored with three elements of a multielement solid-state detector. Measurements were made on all samples at room temperature and at atmospheric pressures. Results for the relative intensities of the Fe Kα fluorescence radiation relative to the position on the gel are shown in Fig. 2. These results clearly illustrate (1) correlated elevations in Fe Kα fluorescence intensity for the cytochrome c7 standard and the *E. coli* overexpressing cytochrome c7 (at ∼59,000 μm, marked "A" on the strip),

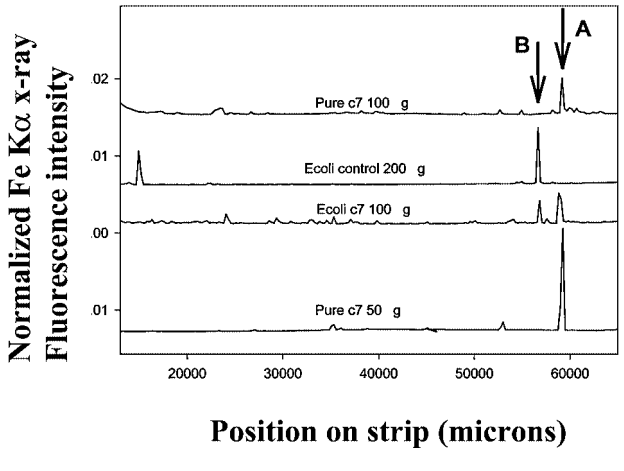

Fig. 2. Relative Fe Kα X-ray fluorescence intensities for cytochrome c7 standards and *E. coli* cell lysates relative to their positions on 1-D IPG gels.

(2) reproducibility (i.e., collocation of the Fe peak at ~59,000 μm, marked "A" on the gel strip, for two replicate samples), and (3) the presence of additional, reproducible Fe fluorescence radiation in both the overexpressed cytochrome c7 and control *E. coli* samples (at ~57,000 μm, marked "B" on the gel strip). These results clearly demonstrate that this approach enables identification of overexpressed metalloproteins in cultures. Observation of Fe peak at ~57,000 μm in both types of *E. coli* samples further demonstrates that this technique does not necessarily require a metalloprotein to be overexpressed in order to be detected.

5. XAFS Analysis of Proteins Separated on Nondenaturing Gels

In many instances, although identification of the presence of metalloproteins is extremely valuable, additional information concerning the structure and function of the metal center of the metalloprotein is desirable. The atoms that coordinate the metals of a protein alter their chemistry. For example, in cytochromes, Fe is bound by four equatorial nitrogen atoms from the porphyrin ring, plus axial ligands from the protein or the solvent. In some cases, a sulfur atom provides the axial ligand. XAFS spectroscopy can be an extremely valuable tool for probing the local chemical and structural environment of the metal within metalloproteins. To investigate the possibility of coupling the XAFS technique to procedures discussed above, we have made Fe XAFS measurements on a catalase protein after isoelectric focusing on polyacrylamide on a plastic backing (IPG strip). XAFS data were collected at room temperature in the fluorescence mode with an ion chamber in the Stern-Heald geometry [5, 6] by using a Lytle detector with an Mn filter. Linearity tests [7] indicated less than 0.5% nonlinearity in the experimental setup for a 50% attenuation of the incident radiation. Incident and transmitted X-ray intensities were monitored with ionization chambers with 100% free-flowing nitrogen gas at atmospheric pressures. Results of the fitting of the data ($\Delta k = 2.5$–$8.0\,\text{Å}^{-1}$, $\Delta r = 1$–$3\,\text{Å}$, 7 floating variables, and 2 degrees of freedom) to theoretical standards generated with the FEFF program [8] are shown in Fig. 3. Results from fitting analysis of these data indicate an average of 4 N/O and 1 N/O (at 1.98 Å and 2.05 Å, respectively) and 8 carbons (at 3.05 Å), plus additional carbons and multiple-scattering effects (at 3.2–3.4 Å), contributing to the local environment of the Fe. These results are consistent with previous XAFS studies of other purified and concentrated catalase proteins [9–11].

For future work, a low-temperature sample holder will be designed to reduce radiation effects that might alter the proteins being measured with XAFS. To increase the sensitivity of the XAFS technique to lower concentrations of metalloproteins, future XAFS measurements will also be made with a 13-element solid-state fluorescence detector.

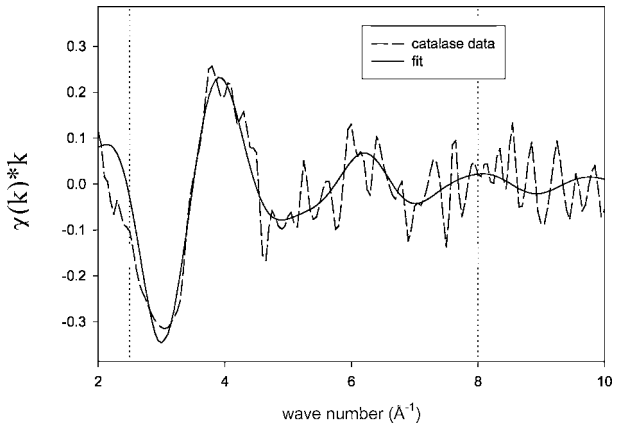

Fig. 3. Theoretical fitting (dashed line) of XAFS chi data (solid line) from catalase spatially isolated on an IPG strip.

6. Summary

In summary, we have described the results of the development of new approaches to identify and characterize metalloproteins. Specifically, we have described the integration of XRF mapping, XRF elemental analysis, and XAFS with electrophoretic methods. Further development of these integrated techniques to enable high-throughput analysis of frozen samples (to reduce the effects of radiation damage) holds great promise for the investigation of proteomic expression in a wide variety of biological systems.

Abstract

It is important to understand the chemical states of heavy metals in solid waste from municipal incinerator (MSWI) fly ash as both the toxicity and behavior in the environment of heavy metals differ with their chemical states. In this study, direct speciation of lead, antimony and zinc in MSWI fly ash was conducted by XAFS spectroscopy. Three kinds of fly ash from continuous stoker-type MSWIs and a kind of fly ash from an ash melting plant (AMP) were investigated. XAFS measurements were carried out on beam line BL01B1 at SPring-8. The lead, zinc and antimony spectra were collected in fluorescence detection mode at room temperature with a Si (111) or Si (311) monochromator. According to Pb LIII-edge XANES spectra, lead was estimated to be predominantly $PbCl_2$ in MSWI fly ashes and PbO in AMP fly ash. Zinc was estimated to be speciated predominantly as $ZnCl_2$ in MSWI fly ashes and a mixture of $2ZnCO_3{\cdot}Zn(OH)_2$, ZnO and ZnS in AMP fly ash. Antimony K-edge XANES spectra indicated that Sb is five-valent in all the fly ashes.

1. Introduction

In Japan, about 50 million tons of municipal solid waste (MSW) is generated every year and more than 75% of MSW is incinerated. The MSW incineration (MSWI) is an excellent technology from the viewpoint of weight and volume reduction of MSW and public sanitation. However, about 5 million tons of bottom ash and 1.2 million tons of fly ash are generated every year during this treatment. MSWI fly ash has recently attracted much attention because of its amount of heavy metals with low boiling point and the presence of trace organic contaminants such as dioxins.

It is important to understand the chemical state of heavy metals in MSWI fly ash on its recycling and detoxification because the toxicity and behavior of metal contaminants in the environment depend on their chemical state. Determining the chemical state of heavy metals in MSWI fly ash is required to prevent the pollution of soils and aquifers near disposal sites.

Determining the chemical speciation of heavy metals at low concentration levels in MSWI fly ash is impossible with physical techniques available in the laboratory, such as XPS or XRD [1, 2]. Chemical fractionation with solvents has been used [3, 4], but these methods are destructive and the initial chemical state may change during the sequential extraction. X-ray absorption fine structure (XAFS) spectroscopy enables quantitative metal speciation to be performed in diluted and chemically complex systems and, therefore, represents a method of choice to study fly ash.

2. Materials and Methods

2.1. *Samples*

Fly ash 1 and 3 were sampled from the electrostatic precipitators of two different continuous stoker-type MSWIs. Fly ash 2 was sampled from the bag filter, which is a dust collector, in a continuous stoker-type MSWI. Fly ash 4 was sampled from the bag filter in an ash melting plant (AMP). Fly ash 2 and 4 contain a lot of calcium compounds because calcium hydroxide is injected before the bag filter for acid gas removal.

The fly ash samples were dried at 105 °C overnight for chemical analysis, but not for XAFS measurements.

For chemical analysis, 100 mg powder was digested for 60 minutes in an acid mixture of 5 ml HNO_3 (15.8 M), 2 ml HCl (11.4 M) and 3 ml HF (27.7 M) using a microwave oven (MDS-2000: CEM corp.) [5]. Then, the acidic solution was neutralized by 18 ml boric acid and set in the microwave oven for 5 minutes. Finally the heavy metals in the filtered solution were analyzed by inductively coupled plasma atomic emission spectroscopy (ICP-AES) (Shimadzu, ICPS-8000).

As target elements, lead and antimony were selected from the viewpoint of their toxicity and zinc was selected from the viewpoint of its recycling. The following compounds were selected as reference materials for XAFS analysis on the basis of the likely chemical form of heavy metals in fly ash.

Zinc compounds: Zn, ZnO, ZnS, $2ZnCO_3{\cdot}3Zn(OH)_2$ (basic zinc carbonate), $ZnSO_4$ and $ZnCl_2$; Antimony compounds: Sb, Sb_2O_3, Sb_2O_5 and SbOCl; Lead compounds: Pb, PbO, $PbCO_3$, $PbCl_2$, PbS, $PbSO_4$ and PbO_2. These materials were provided by Wako Pure Chemical industries, Soekawa Chemicals, and Nacalai Tesque. The specification of the fly ashes and their content in target elements are presented in Table I.

2.2. *XAFS Measurements*

Zn-K, Sb-K, and Pb-LIII edge XANES experiments were carried out on beamline 01B1 at SPring-8 (Hyogo, Japan), which operates at a ring energy of 8 GeV and a stored current from 60 to 100 mA. The main optics is the standard SPring-8 bending magnet system, which contains two mirrors and a fixed-exit double crystal monochromator. The Zn-K and Pb-LIII edge XANES spectra were measured with a Si (111) two-crystal monochromator, and Sb-K edge XANES spectra with a Si (311) two-crystal monochromator. Higher harmonics were reduced by reflection on the two mirrors. XANES spectra of reference materials and fly ash samples were recorded in transmission mode using ionization chambers and in fluorescent mode using a Lytle

Table I. *The specification of fly ash and the content of target elements.*

Sample	Fly Ash 1	Fly Ash 2	Fly Ash 3	Fly Ash 4
Processed materials	MSW	MSW	MSW	Ash
Operation	Continuous	Continuous	Continuous	Continuous
Furnace type	Stoker	Stoker	Stoker	melting furnace
Dust collector	ESP	BF	ESP	BF
Acid gas removal	Wet scruber	Lime injection	Wet scruber	Lime injection
Pb (mg/kg)	11000	6100	8000	10000
Zn (mg/kg)	24000	26000	18000	32000
Sb (mg/kg)	1800	1200	1400	940

detector, respectively. Sample absorbance was measured every 0.3 or 0.5 eV. The energy was calibrated by setting the pre-edge peak of a Cu foil at 8980.3 eV.

Data reduction was performed using the analysis program developed by Tanaka [6] at the Kyoto University Data Processing Center. The normalization procedure has been reported previously [6]. Pattern fitting analysis of XANES spectra was conducted using the commercial REX2000 software (Rigaku co Ltd), assuming that the unknown spectra were linear combinations of the reference spectra in our library [7]. Within the validity of this assumption, the precision on the percentage of species in the powdered samples is estimated to about 2%.

3. Results and Discussion

3.1. *Chemical State of Lead*

Figure 1 shows the Pb-LIII edge XANES spectra of the four fly ash samples and reference materials. The XANES spectra for the MSWI fly ashes 1–3 have a similar shape, in contrast to the AMP fly ash 4. Upon comparing the unknown XANES spectra to the set of known spectra, lead was estimated to be predominantly speciated as $PbCl_2$ in MSWI fly ash 1–3 and as PbO in the melting plant fly ash 4.

Two pattern fitting analyses were performed, differing in the exclusion, or not, of lead sulfide. Although the presence of sulfate

on the surface of fly ash has been reported in the literature from XPS and XANES analysis [1, 8], $PbSO_4$ is not considered to be present in these fly ashes by XANES spectra. Therefore it is assumed that PbS is a possible species. Results reported in Table II show that $PbCl_2$ accounts for ~47 to 87% of Pb in the three MSWI fly ashes. This species is consistent with the high concentration of HCl in the flue gas of MSWI. MSWI fly ash 2 and 3 possibly contain PbS as the second most abundant Pb species. When PbS was excluded from the spectral fit, $PbCO_3$ made up ~20–34% of total Pb. In the AMP fly ash 4, ~59% and ~28% of total Pb was found to be speciated as PbO and $PbCl_2$, respectively. The low values of the residual parameter (*R*) indicate that satisfactory fits of model predictions to experimental data were obtained for all sample spectra.

The chemical states of lead in fly ash were not influenced by the dust collector type or acid gas removal method. Although the flue gas before acid gas removal in AMP was rich in HCl, PbO is the dominant species in the AMP sample. Therefore, Pb speciation is determined by other parameters, such as the furnace temperature and/or the initial chemical state in waste fed into the furnace and particles carried over from the furnace.

3.2. *Chemical State of Zinc*

Figure 2 shows Zn-K edge XANES spectra of the four fly ash samples and reference materials. MSWI fly ash 2 and 3 have similar spectra, and MSWI fly ash 1 a slightly different one. The spectrum of AMP fly ash 4 has a distinct shape and peak position from the three other spectra. Comparison with reference spectra suggests that Zn exists primarily as a Zn chloride phase in MSWI fly ash 1–3. The spectral features at 9667 eV and 9672 eV correspond in position to those of $ZnFe_2O_4$ and $ZnAl_2O_4$. Consistent with these observations, the assumption of 40 to 75% $ZnCl_2$ yielded optimal fits to these spectra with R values of 2.4 to 4.8.The inferred minor species are ZnS in MSWI fly ash 2 and 3, and ZnO and Zn-spinel in MSWI fly ash 1. Adding $ZnFe_2O_4$ and $ZnAl_2O_4$ as component species to the spectral fit of MSWI fly ash 1 reduced the fraction of $ZnCl_2$ from 74% to 40%. The likely presence of oxygenated Zn species is consistent with Jakob *et al.*'s results [9], which reported the presence of zinc and silica or

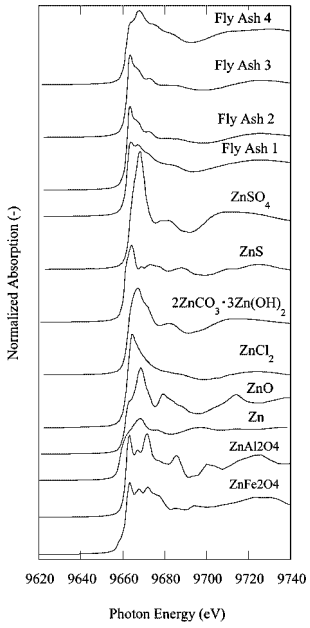

Fig. 2. Zn-K edge XANES spectra of four fly ash samples and reference materials.

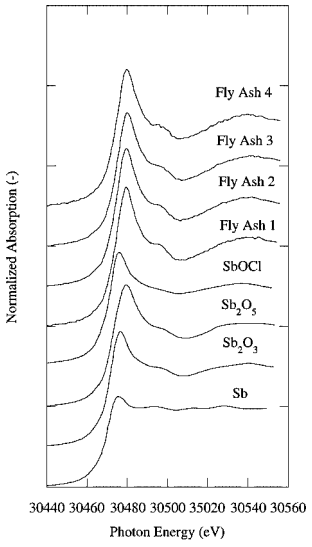

Fig. 3. Sb-K edge XANES spectra of four fly ash samples and reference materials.

aluminum double oxides in ash samples using XRD. In the AMP fly ash 4 sample, two phase compositions gave statistically similar results. One in which Zn is present as a mixture of ZnO, ZnS and $2ZnCO_3{\cdot}3Zn(OH)_2$ in similar proportions, and another consisting of a mixture of $ZnFe_2O_4$ (53%), ZnO (30%), $2ZnCO_3{\cdot}3Zn(OH)_2$ (13%), and $ZnCl_2$ (4%). In this sample, the amount of$ZnCl_2$ is very small, if present at all. These results were in agreement with leaching tests which showed that water soluble fraction of Zn in this ash was about 0.2%. The fact that the reconstructions of Pb spectra were better than those of Zn spectra (R-values were lower for the first set of spectra), partly results from the featureless shape of Pb spectra (i.e., they carry less structural and chemical information and, hence, are easier to simulate).

In conclusion, the chemical states of Zn and Pb in the MSWI fly ashes present similarities. Pb and Zn are essentially in the form of chloride and oxide in the first ash, and in the form of chloride and sulfide and the second and third ashes. This result suggests that the nature of the metal species is determined by the thermo-chemical conditions in the stoker.

3.3. *Chemical State of Antimony*

Figure 3 shows the Sb-K edge XANES spectra of the four fly ash samples and reference materials. The samples XANES spectra have almost the same shape, which suggests that they contain the same Sb species. The position of the peak maximum is at 30480 eV like in Sb_2O_5, and 30476 eV higher than in Sb_2O_3. Therefore, Sb is five-valent in the ash samples. This interpretation is confirmed by the height of the normalized white line, which equals1.60 in Sb_2O_3, 1.68 in Sb_2O_5, and 1.66 to 1.73 in the ashes.

Consequently, the oxidation state, and possibly the chemical form as well, of antimony in fly ash does not vary with the furnace type, waste fed into the furnace and particles carried over from the furnace, the dust collector type and the method used for acid gas removal. Although it has been predicted from thermodynamics that antimony is speciated as Sb_2O_3 or SbO_2 in MSWI fly ash [10, 11], we found here that Sb is five-valent with Sb_2O_5 being a possible species.

4. Conclusion

1) Lead and zinc are predominantly present as metal chloride in the MSWI fly ashes 1–3.
2) The second most abundant species are lead and zinc oxide in MSWI fly ash1, and metal sulfide in MSWI fly ashes 2 and 3. This indicates that the behavior of lead is similar to that of zinc and vice versa.
3) In AMP fly ash 4, metal chlorides are less abundant and the Zn and Pb speciation are dominated by oxide, and possible hydroxide or carbonated (Zn), forms.
4) Overall, these results indicate that the chemical forms of lead and zinc in fly ash is independent from type of the dust collector, the method of acid gas removal, and HCl concentration in flue gas.
5) Antimony is five-valent in all samples. Its speciation is thought to be unique and identical to Sb_2O_5. In a similar manner as Zn and Pb, Sb speciation is constant and independent from the burning or dust collection process.

Acknowledgement

The synchrotron radiation experiments were performed at the SPring-8 facility following the approval of the Japan Synchrotron Radiation Research Institute (JASRI) (Proposal No. 2000B0309-NX-np and 2001A0367-CX-np).The authors warmly thank Mr. Takehiko Murakami, Mr. Kazuo Yasui and Mr. Toshiyuki Kawai for their assistance during the measurement.

Abstract

The chemical states of Cu, Zn, and As in sewage sludge have been investigated by X-ray absorption fine structure (XAFS) spectroscopy. XAFS spectra show that Cu and Zn of 150 ppm–200 ppm form sulfides of 2+, and As of less than 250 ppb exists as 3+ in the sludge under anaerobic state. The *in-situ* XAFS measurements reveal that under aerobic states, Zn sulfide is partially dissolved and As is partially oxidized to 5+ although Cu maintains sulfide form. The stability of these compounds in the sewage sludge is discussed.

1. Introduction

The chemical forms of heavy metals, such as Cu and Zn, in sewage depend on the sewage treatment process including condensation and aerobic treatments. The condensed heavy metals in sewage sludge potentially prevented us to apply the sludge to beneficial use, although their concentrations are very low. Chemical states of the heavy metals are very important information for developing highly safe and reliable techniques of removing or stabilizing the heavy metals. Sequential extraction method by Stover *et al.* [1] has been used for estimating the chemical forms of heavy metals in sewage sludge. However, this technique is an indirect method in which compounds of heavy metals would be chemically destructed.

X-ray fluorescence X-ray absorption fine structure (XAFS) technique has been applied to investigating the chemical states of trace elements in environmental matters, such as contaminated soil [2], contaminated water [3], and fly ash [4]. We have adopted X-ray fluorescence XAFS to heavy metals in sewage sludge in order to determine their chemical states directly [5, 6]. In this paper, K-edge XAFS spectra of Cu, Zn, and As in condensed sewage sludge measured under anaerobic and aerobic conditions are presented. The chemical states of these elements in the sewage sludge are discussed in terms of the stability of these elements. The results for Cu and Zn are compared with published data obtained by a sequential extraction technique.

2. Experimental

Secondary sludge (excess sludge or waste activated sludge) was collected after the anaerobic treatment from a typical sewage treatment plant in a city area of Japan. The sludge was condensed up to solid concentration of about 5%. The concentrations of Cu, Zn, and As are about 160 ppm, 200 ppm, and <250 ppb, respectively, in the condensed sludge.

XAFS measurements were carried out on the station BL01B1 with a two-crystal Si(111) monochromator at SPring-8 (Hyogo, Japan). The K-edge XAFS spectra were measured for Cu, Zn, and As in the X-ray fluorescence mode using a Ge 19-elements solid-state detector. Spectra for reference compounds and dilute solutions (about 100 ppm) of Cu and Zn were measured in the transmission mode and the X-ray fluorescence mode, respectively.

For the XAFS measurements under anaerobic conditions, the sludge was put into bags made of Mylar film and shielded from air. In order to put the sludge under aerobic state, the sludge was being aerated in a home-maid cell during XAFS measurements. The cell was made of acrylic plates and has Mylar windows for incident and reflected X-rays. The redox potential (E) of the sludge was measured using an ORP meter (Central Chemical Co.) just before and after each measurement. Typical redox potentials were about −100 mV and 400 mV for the sludge under anaerobic and aerobic conditions, respectively.

3. Results and discussion

Figure 1 ∼ Figure 4 show Cu-K, Zn-K, and As-K edge X-ray fluorescence XAFS spectra for sewage sludge measured under anaerobic conditions (spectrum (a)) and aerobic conditions (spectrum (b)). Spectra for several reference specimens are also shown in each figure. The Cu-K edge X-ray absorption near edge structure (XANES) spectra for the sludge under anaerobic and aerobic conditions are indistinguishable and similar to that for

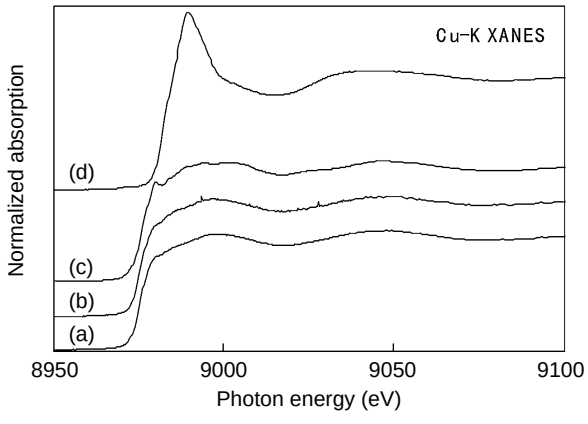

Fig. 1. Cu-K XANES spectra for excess sludge under (a) anaerobic and (b) aerobic conditions. The spectra for (c) CuS and (d) dissolved Cu (2+) in water are also presented.

*e-mail: m-nagoshi@jfe-steel.co.jp

CuS as shown in Fig. 1. The extended X-ray absorption fine structure (EXAFS) spectra for the sludge in both conditions were almost identical to that for CuS. These results show that almost all Cu atoms in the sludge form sulfide with the Cu valence of 2+ and the sulfide is stable against aerobic treatment.

The Zn-K edge XANES spectrum for the sludge in anaerobic state is close to that for ZnS (Fig. 2), which shows that Zn in the sludge mainly forms sulfide. However the amplitude of the EXAFS oscillation for the sludge is weaker than that for ZnS as shown in Fig. 3. Fine structures which are seen at about 3.5, 5, 6.5, and 8.5 $Å^{-1}$ in the spectrum for ZnS are smeared out in the spectrum for the sludge. These characteristics suggest that Zn sulfide forms small clusters and / or is structurally deformed in the sludge under anaerobic conditions. The Zn-K XAFS spectra for the sludge under aerobic conditions (spectra (b) in Fig. 2 and Fig. 3) were well reproduced by synthesizing the spectra for the sludge under anaerobic conditions and Zn (II) ions in water (spectra (d) in Fig. 2 and Fig. 3). This result shows that Zn sulfide in the sludge is partially dissolved by the aerobic treatment. It was estimated by the curve fitting method for the XANES spectrum that about 70% of Zn atoms in sulfide are dissolved under aerobic conditions in this study.

The As-K edge XANES spectra which are applicable to the identification of the chemical state of As are successfully recorded for As of less than 250 ppb in the sewage sludge as shown in Fig. 4.

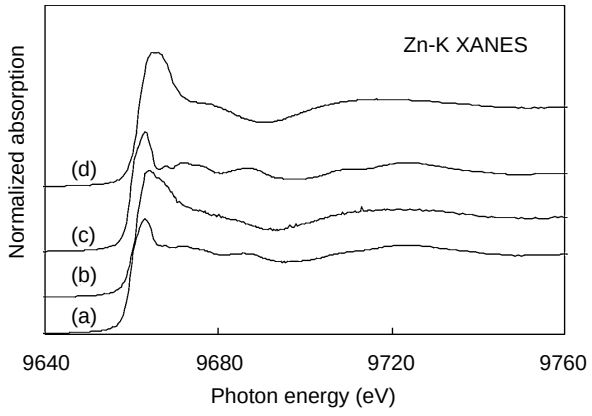

Fig. 2. Zn-K XANES spectra for excess sludge under (a) anaerobic and (b) aerobic conditions. The spectra for (c) ZnS and (d) dissolved Zn (2+) in water are also presented.

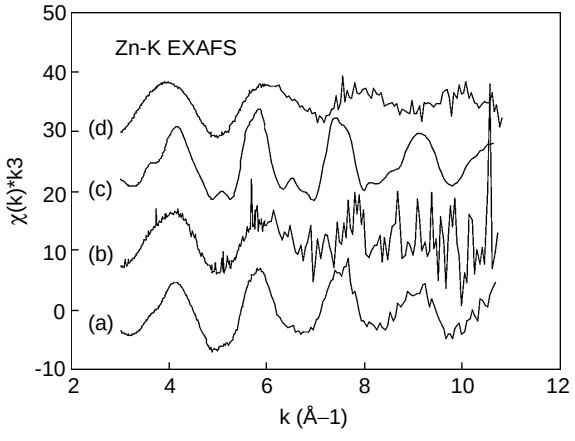

Fig. 3. k^3-weighted Zn-K EXAFS spectra for excess sludge under (a) anaerobic and (b) aerobic conditions. The spectra for (a) ZnS and (d) dissolved Zn (2+) in water are compared.

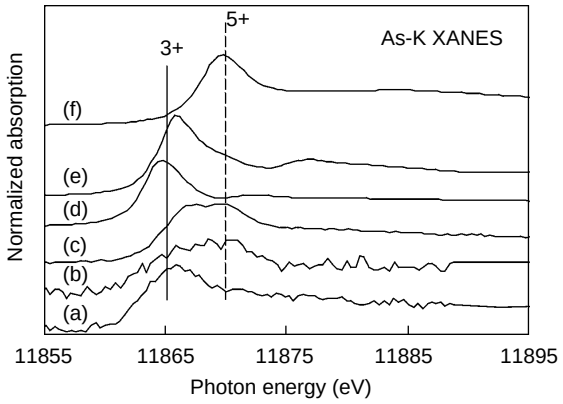

Fig. 4. As-K XANES spectra for excess sludge under (a) anaerobic and (b) aerobic conditions. The spectrum for (c) dried sludge is also shown as well as those for (d) As_2S_3, (e) As_2O_3 and (f) As_2O_5.

The main peak in the spectrum for the sludge under anaerobic state is located at a photon-energy corresponding to As of 3+. The spectral intensity at about 11870 eV where a peak of As of 5+ appears to increase under aerobic condition. This demonstrates that As of 3+ is partially oxidized to 5+ by the aerobic treatment.

In Fig. 4, the spectrum for a sludge dehydrated at 105 °C for 24 hr is also shown (spectrum (c)). A peak corresponding to As of 5+ appears in the spectrum for the dried sludge, which means that As of 3+ in the wet sludge is oxidized by the dehydration treatment. This result demonstrates that accurate information on the chemical state of sludge can be obtained from non-destructive analysis for wet sludge.

The stability of metal sulfides is well known. An E – pH (Pourbaix) diagram for the metal-sulfide system shows that the sulfides are dissolved when pH decreases or the redox potential (E) increases. The diagram also shows that copper (II) sulfide is more stable than zinc (II) sulfide. The pH value of the sludge was hardly changed by aerobic treatment. The dissolution of Zn sulfide, when the sludge is aerated, is explained by the transition from reduction to oxidation atmosphere.

The chemical forms of Cu and Zn in sewage sludge collected from several plants in Japan were estimated by a sequential extraction method [7]. The results averaged for excess sludge showed that about 50% of Cu and about 10% of Zn were classified as "sulfide precipitates". More than 70% of Zn was classified as "carbonate precipitates" and "organically bound" materials. These are significantly different from our XAFS results, although comparison of the results between different plants should be carefully done. As mentioned above, Zn sulfide is less stable than Cu sulfide in the same condition. The sequential extraction method classifies the chemical form of elements by searching whether substances are soluble in specific solvents or not [1]. The results of the method would be useful in controlling the stability of chemical substances. In the present case for Zn, the method would have estimated the fraction of sulfide to be only 10% due to the poor stability of Zn sulfide. The relatively high stability of Cu sulfide certainly provided higher fraction of sulfide. The sequential extraction technique will become more useful when complemented with chemical states obtained by XAFS analysis.

4. Conclusions

The chemical states of trace heavy metals, Cu, Zn, and As in the actual sewage sludge under anaerobic condition are clarified by X-ray fluorescence XAFS. *In-situ* measurements reveal the changes

of chemical states of Zn and As and the relatively high stability of Cu sulfide under aerobic condition. These results can be obtained only by non-destructive XAFS analysis. The differences between the identified chemical states of Cu and Zn in this study and those estimated by the sequential extraction method are explained by the stability of their sulfides.

Abstract

Uranium is a toxic and radioactive contaminant in many settings, such as groundwaters and sediments. In oxidizing environments, uranyl (U(VI)) is thermodynamically the most stable oxidation state. Sorption or incorporation of U(VI) into reactive mineral phases are processes of major importance because they retard its transport. Biogenic manganese oxides are an important source of reactive mineral surfaces in the environment and may be potentially enhanced in bioremediation cases to improve natural attenuation. Experiments were performed in which U(VI) at various concentrations was present during manganese oxide biogenesis. At all concentrations there was strong uptake of U onto the oxides. Synchrotron based x-ray studies were carried out to determine the manner in which uranyl is incorporated into the oxide and how this incorporation affects the resulting manganese oxide structure and mineralogy. The EXAFS experiments show that uranyl does not appear to substitute into the lattice of the oxides, and is rather present as a strong surface complex. However, the presence of U(VI) on the Mn-oxide layers modifies the lattice constants and coherence lengths of the oxides. These results suggest a complex mechanism in which U transport is retarded by sorption and the surface area of the sorbent is increased.

1. Introduction

Uranium ore mining, processing, and manufacturing have contributed to groundwater contamination in numerous locations in the United States [1]. Uranium contamination is transported in groundwater primarily as the dissolved uranyl ion (U(VI)) which can intercept water supplies. Manganese oxide surfaces have been shown to have large capacities for heavy metal ion uptake [2–4]. In some groundwater environments, it has been shown that transuranic elements associate with manganese oxides preferentially over other mineral surfaces, including iron oxides [5]. Much of the manganese oxides found in the natural environment is considered to be of biologic origin [6–8]. Many diverse bacteria have been shown to rapidly catalyze the oxidation of the Mn(II) to Mn(III,IV) [9]. Biogenic rates of oxidation have been shown to be up to five orders of magnitude greater than abiotic rates under the same conditions [6, 8]. Thus, understanding the molecular mechanisms that are involved in the binding of uranyl to biogenic manganese oxide surfaces is critically important. This work uses x-ray techniques such as x-ray absorption spectroscopy and x-ray diffraction to examine how uranyl attaches to biogenic manganese oxides that form in the presence of the uranyl contamination and how this incorporation affects the structure of the biogenic manganese oxide.

2. Methods

Manganese oxide samples were prepared using spores of the marine bacterium *Bacillus sp.* g strain SG-1 to catalyze the oxidation of Mn(II) to Mn(IV) [10]. Spores were added to flasks containing 400 mL of incubation solutions to a final spore concentration of 10^8 spores per mL. The incubation solution contained 10 mM HEPES to maintain the pH at 7.5 and 10 mM Mn(II)-triflate. Additions of Mn-triflate and U(VI)-triflate were added daily to maintain metal concentrations as the oxidation progressed. Triflate was used as the counter-ion for all metal additions in order to minimize ternary complexation of uranyl by ions such as nitrate or chloride [11]. Carbonate was not excluded from the solutions to so as to simulate natural conditions. Uranyl concentrations in the flasks ranged in concentrations from 50 nM to 100 μM to span a large range of adsorption conditions (Table I). Incubations progressed for two weeks on a shaker platform after which the supernatants were drawn off and the manganese suspensions concentrated into a pellet by centrifugation.

All EXAFS and XRD measurements were performed on wet bioxides to prevent oxidation state and structural changes that can be driven by sample dehydration. Mn-K and U-L_{III}-edge XAS spectra were collected at SSRL beamline 4-3 with a Si(220) monochromator and, in the case of Mn, a harmonic rejection mirror with a cut-off energy set at 9 keV. Samples were collected in transmission geometry if possible, or in fluorescence mode for dilute samples. Fluorescence data were collected using either a 13-element Ge array detector or a Kr-gas-filled Lytle-type ionization chamber detector equipped with Sr x-ray filters. All spectra were background subtracted and splined using the SIXPack software [12]. Linear combination fitting and EXAFS fitting were also performed with SIXPack. O_{ax} and O_{eq} shells for U were fit initially and then subtracted from the raw data to create second-shell residual spectra. This allows a more sensitive fit of the second-shell contributions in the sample spectra without the interference of the O shells. Phase and amplitude files for the EXAFS fitting were created with FEFF7 [13, 14]. Since the Debye-Waller factors (σ) correlated highly with coordination numbers (CN), σs for some shells were each fixed at their average values. The U=O_{ax}=U=O_{ax} transdioxo multiple scattering path [15] was included in all fits. Mn EXAFS were fit using a model based on a layered phyllomanganate structure, loosely based on that of Ressler, *et al.* [16]. This model also accounts for splitting of the Mn-O and Mn-Mn distances in the structure due to Jahn-Teller distortions, angular deviations from planar sheets (particularly important with Mn-Mn multiple scattering), aqueous Mn(II), surface bound Mn species, and vacancies present in the Mn-layer lattice. Full details of the model are provided elsewhere [17]. This model has been tested on relevant model spectra (birnessite, δ-MnO_2) and found to fit the EXAFS up to $R \sim 5.5$ Å for samples with good data up to k of 15 $Å^{-1}$.

*e-mail: samwebb@slac.stanford.edu

X-ray diffraction intensity data were collected on wet solids in transmission geometry using the two-circle diffractometer on SSRL beamline 2-1 using a Bicron NaI detector equipped with Soller slits to examine the crystallinity and phases present in the biogenic Mn-oxide samples. The incident x-ray beam was tuned to 10 keV ($\lambda = 1.24$ Å) to improve beam penetration in to the wet samples and to provide Q-space access up to about 12 $Å^{-1}$. Wet sample slurries were placed in a custom sample cell between two lexan windows. The diffractometer was calibrated with LaB_6 and has a 0.04° 2θ fwhm resolution. Data were collected in Q-space in 0.004 $Å^{-1}$ intervals in dose mode of 10,000 counts per point. Several scans were added together to improve signal to noise ratios for interesting regions.

3. Results and Discussion

Incubation samples with large concentrations of U(VI) in the solution (>4 μM) visually appeared to inhibit manganese oxide formation. This was apparent by the decrease in amount of biogenic product in the centrifuged slurry at the end of the incubation experiment. The extreme case occurred in the highest U(VI) sample (100 μM) in which no manganese oxidation occurred.

Mn K edge EXAFS spectra change substantially as the amount of U(VI) in the sample increase, indicating that the local structure around Mn changes significantly as shown in Figure 1. At the highest U(VI) concentration, the spectra are similar to those for todorokite, a 3 × 3 tunnel structure tecktomangantate. Tunnel structures can be fit using the phyllomanganate EXAFS layer model (Figure 1). Doing so produces apparently high dihedral angles in the manganese octahedral plane and an abnormally high percentage of vacancies, which can be used to distinguish todorokite from true phyllomanganates. Table I shows the summary of major fitted EXAFS parameters for the sample series, including a metal-free biogenic manganese oxide and todorokite. The fit derived parameters for the samples progresses from those typical of well-defined layer structures at low metal concentrations, to value indicating a highly bent or pseudo-tunnel structure at high U(VI) concentrations. The transition from a layer to tunnel-like structure begins to occur at U(VI) concentrations around 4 μM and appears to be complete at 20 μM.

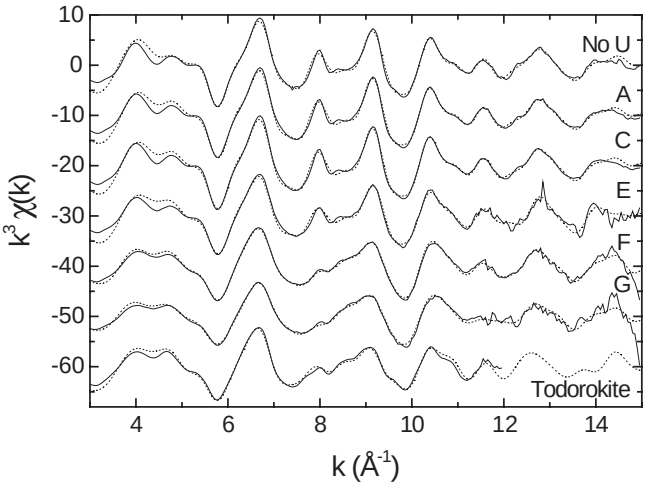

Fig. 1. Mn K-edge EXAFS for selected incubation samples and todorokite standard. Data are represented by solid lines, EXAFS fits by dotted lines. Note the change in diagnostic features around $k \sim 8$ $Å^{-1}$.

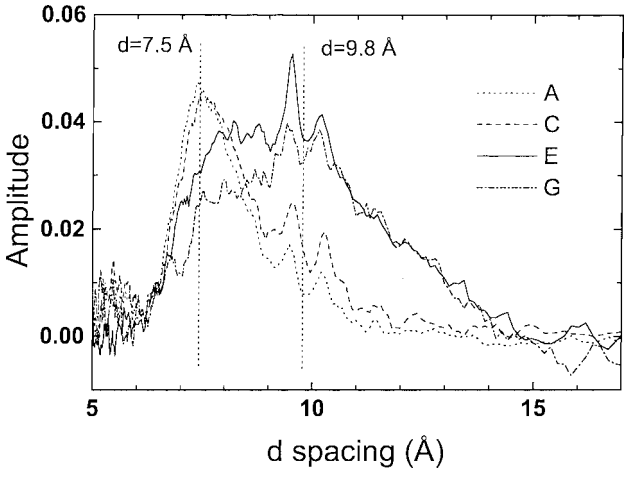

Fig. 2. X-ray diffraction data for the 001 basal plane reflections for the uranyl incubation samples.

XRD (Figure 2) shows that at low U(VI) concentrations, the XRD structure of the metal incubated oxides is dominated by a 7.5 Å phyllomanganate basal plan relection typical of birnessite-like phases and very similar to that of biooxides formed in the absence of U(VI). The breadth and low intensity of the peaks indicates very small particle size as well as structural disorder. The two sharp peaks at 9.4 and 10.1 Å are due to diffraction from the spores. As the concentration of U(VI) in the incubation increases, the intensity of the phyllomanganate basal plan reflection decreases. At the same time, a new broad peak at 9.8 Å is observed, indicating a phase with differing long-range structure, possible similar to todorokite. The change from 7.5 to 9.8 Å phases occurs at sample E, which is the same region in which EXAFS indicated significant changes in the Mn local structure were occurring.

U-L_{III}-edge EXAFS (Figure 3) of the incubation samples is dominated by the strong presence of equatorial and axial oxygens. Sample C and G were used as components for linear combination fits to spectra from samples D–F. Samples A and B have the same structure as C, but are significantly noisier due to the trace concentration of U in the sample. EXAFS fitting analysis of the residuals from the second shell of sample C shows contributions

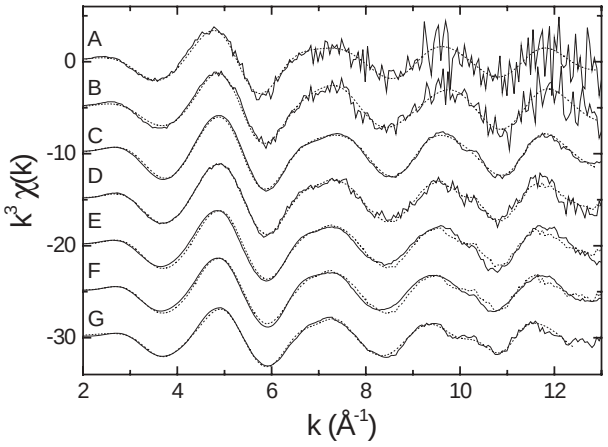

Fig. 3. U L-edge EXAFS for incubation samples. Data are represented by the solid lines, fits by the dotted lines. Samples A, B, C and G were fit in a shell-by-shell EXAFS fit, whereas samples D, E, and F were fitted as linear combinations of C and G.

Table II. *Fitting results of major parameters in shell-by-shell fitting of U L-edge EXAFS.*

Sample	Shell	N	R	σ^2
C	U-C	0.81	2.84	0.0041
	U-Mn	0.73	3.30	0.0130
G	U-C	1.43	2.88	0.0041
	U-Mn	0.31	3.81	0.0050
	U-Mn	0.28	4.29	0.0050
	U-O	1.31	4.01	0.0050

from C and Mn shells, suggesting a uranyl-carbonate ternary surface complex to the manganese oxide surface. The U-Mn distance of 3.30 Å is suggestive of a bidentate surface complex. Analysis of sample G is far more complex. The residual EXAFS shows strong oscillations past k of 12 $Å^{-1}$, suggesting the presence of more than just surface complexation, with the presence of strongly scattering metal shells. This sample is best fit with U-Mn shells at 3.81 and 4.29 Å and a U-O shell at 4.01 Å. These results are summarized in Table II.

The measurements all show that at increasing U(VI) concentrations, not only does the mechanism of U(VI) uptake on the biogenic oxide change, but the structure of the oxide itself changes as well. All three of these techniques show that the onset of the transitions occurring in the manganese oxide structure and U(VI) complexation take place at the same uranyl concentrations. At low uranyl concentrations, the results show that the dominant form of manganese oxide is poorly ordered, turbostratic layer manganate structure. Uranyl is adsorbed onto the oxide surfaces as a ternary carbonate complex, coordinated to the oxide surfaces in a bidentate fashion.

At high concentrations, the presence of U(VI) affects the manganese structure. The EXAFS model applied gives rise to larger apparent vacancies and increases in the dihedral angles along the a-b plane. This increase in angle has the effect of reducing the importance of Mn-Mn multiple scattering paths. The results are also strikingly like that of the 3 × 3 tunnel structure of todorokite. Additionally, the oxides 001 basal plane reflections of the XRD data move from 7.5 toward 9.8 Å. These items suggest a transformation of the manganese oxide to a pseudo-tunnel structure similar to todorokite. Since the XRD suggests that the altered biogenic oxides are still very poorly ordered, it is unlikely that the uranyl incorporated oxide is a typical 3 × 3 tunnel structure. These results suggest that the structure is more likely a 3 × n, where the distance between layers is consistent at 3 octahedra (9.8 Å), and the horizontal spacing is considered nearly random. The U(VI)-carbonate complex may stabilize the formation of these structures. The lack of bidentate U-Mn binding suggests that the mechanism of U incorporation into the structure is different at these high loadings as well. Further work is still required to develop a definitive model. However, the presence of a pseudo-todorokite manganese phase and the presence of strongly scattering Mn neighbors in the U EXAFS suggests that U is located in the tunnels of the manganese oxide.

4. Conclusions

At low U(VI) : Mn rations, uranyl is associated with biogenic manganese oxide surfaces as a ternary carbonate complex. At higher uranyl concentrations, the manganese oxides become strongly distorted and exhibit spectral characteristics suggesting the existence of tunnel structures. Uranyl appears to be structurally incorporated in the tunnels of these biooxides. This bonding mechanism, were it to occur in the environment, implies that manganese oxides may be suitable materials for long-term *in situ* stabilization of U(VI). Other work has shown that elevated concentrations of other metals, such as Co and Cu can also lead to todorokite-like tunnel structures [18]. Thus the concentrations of dissolved Ca and Mg may be major controls on the existence and reactivity of tunnel-structure biooxides in the environment.

Abstract

Chemical speciation of toxic elements in the environment is an active area of research. In a physical (i.e. chemically inert) mixture of compounds, the X-ray absorption spectra in transmission mode or fluorescence mode at low concentration and high dispersion are linear combinations of the spectra of the constituents. As long as the linearity conditions are met, and the relevant constituents are known, linear fitting procedures can then be used directly to determine the composition. However, physical effects such as large particle sizes and aggregation can cause the breakdown of the linearity condition, resulting in systematic errors and incorrect conclusions. Here we present a simple and robust procedure for determination of molecular speciation by XAFS using a Linear Programming (LP) algorithm with constraints (positively and normalization), and errors introduced by particle size effects and other problems on the speciation results are discussed.

1. Introduction

Many samples studied by XAFS comprise a mixture of chemical forms, particularly environmental samples [1–3]. The interpretation of such spectra using conventional XAFS data analysis methods is not straightforward, and having an appropriate model which directly determines the speciation of the sample is very desirable. To our knowledge, all direct speciation methods used to date are based on the linearity assumption, i.e. the spectra consist of a weighted linear combination of the spectra of the sample's constituents. The validity of the linearity assumption depends on experimental conditions that may or may not be satisfied. Successful deconvolution of the spectra depends on how distinct (orthogonal) are the spectra of the various species, and one needs to have a sufficiently large and appropriate set of basis functions (standard spectra) to describe the data.

The validity of the linearity criterion depends on whether the particle sizes of the various species in the sample are much less than about one "absorption length" – otherwise the spectra will be distorted to some extent, in a nonlinear manner. In environmental samples measured *in situ* the particle size distribution is not controlled (being an intrinsic property of the sample), and the X-ray absorption lengths are strongly energy dependent, so that the particle size often may be comparable to or greater than natural particle sizes. Often one successfully apply linear methods to the speciation problem, but one also may readily encounter the limits of such approaches.

This paper presents a robust approach to applying the linear programming (LP) method to decompose the XAFS data into its constituent spectra within the linear approximation. This method has been applied to the soil core samples, environmental samples, and also calibrated with synthetic mixtures of specific materials. Experiments were performed on undulator beamlines ID–10 (MR-CAT) and ID-18 (BioCAT) at Advanced Photon Source. Initial measurements were made at Zn K-edge because Zn was the highest concentration element of interest. In an effort to obtain a sufficiently complete set of the basis functions, we tested several compounds, and also for calibration of the methods we tested synthetic mixtures of these compounds both in fluorescence and transmission modes.

The outline of this paper is as follows: Section 2 is devoted to a brief description of Linear Programming Method. Section 3 presents the results of the LP fitting and discussion about them. Section 4 addresses the particular and important problem of the Particle Size Effects and finally, conclusions are given in section 5.

2. Linear Programming Method

LP [4, 5] is a constrained minimization technique that in general allows one to find the global maximum or minimum of any linear function of multiple variables subject to a set of constraints that are defined by linear inequalities. One of the advantages of the LP that makes it especially useful for our task is the fact that "nonnegativity" is the usual constraint on any variable x_i, that represents the tangible amount of the some physical quantity. For example, in our case the physical quantity that can not be negative is the fraction of the ith compound α_i.

In the linear approximation the XAFS $\mu(E)$ data can be expressed as:

$$\mu_{\text{Sample}}(E) = \sum_i \alpha_i * \mu_{\text{i, Standard}}(E) \tag{1}$$

with two constraints:

$$\sum_{\text{i}} \alpha_i = 1 \quad \text{and} \quad \alpha_i \geq 0 \tag{2}$$

where the index i identifies the particular standard, and α_i is the fraction of the metal atoms in the sample that are found within species i. The first constraint implies that these coefficients are actually the fractions of the constituent species in the sample and their sum should be equal to one. Evidently the weights α_i cannot be negative (second constraint).

The starting point for any direct method is the fact that any spectrum consisting of N data points can be presented as a N-dimensional vector. In this work the term spectrum will be used to refer to the experimental data and vector to denote the mathematical representation of the spectrum. The term basis functions will refer to the set of all spectra of the standards. Also all of the XAFS spectra that are presented in this work are normalized to unit edge step and interpolated onto a uniform energy grid.

The mathematical representation of the linearity assumption for the $\chi(k)$ data which are multiplied by k^W is:

$$K^W * \chi_{\text{Sample}}(K) = \sum_i \alpha_i * K^W * \chi_{i,\text{Standard}}(K) \tag{3}$$

with the same constraints as eq (2). W is a weighting factor and in this example the data were un weighted ($W = 0$). We found that the result of the LP fitting for $\chi(k)$ data is much more accurate than

*email: bunker@iit.edu

the $\mu(E)$ data, presumably because the orthogonality conditions are met better for the $\chi(k)$ data compared to the $\mu(E)$ data. This is not necessarily always the case however.

The basic goal of LP is very simple: for n independent variables $x_1, \ldots x_n$, we want to minimize the *objective function* f:

$$f = c_1x_1 + c_2x_2 + \cdots + c_nx_n \tag{4}$$

subject to the m linear inequality constraints;

$$\begin{aligned} m_{11}x_1 \quad &+m_{12}x_2 + \cdots + m_{1n}x_n \geq b_1, \\ m_{21}x_1 \quad &+m_{22}x_2 + \cdots + m_{2n}x_n \geq b_2, \\ &\vdots \\ m_{m1}x_1 \quad &+m_{m2}x_2 + \cdots + m_{mn}x_n \geq b_m. \end{aligned} \tag{5}$$

It is more convenient to handle LP problems simply by setting up the vectors and matrix that represent the appropriate coefficient of the linear function that appears. The model problem then will be:

$$\text{Min}\{\boldsymbol{C} \cdot X | \mathbf{M} \cdot \boldsymbol{X} \geq \boldsymbol{B}\} \tag{6}$$

where $\boldsymbol{C}$ is an n-dimensional vector, $\mathbf{M}$ is an $m \times n$ matrix and $\boldsymbol{B}$ is an m-dimensional vector.

In the speciation problem, our goal, according to eq (1), is to minimize the following expression:

$$\left| \mu_{\text{sample}}(E) - \sum_i \alpha_i * \mu_{i,\,\text{standard}}(E) \right|. \tag{7}$$

We use the vector $\boldsymbol{S}$ to represent the spectrum μ_{sample} sampled on a specific grid, and the basis functions $\boldsymbol{b}$, or vectors $\boldsymbol{b}$, refer to the spectrum $\mu_{i,\,\text{standard}}$. Then the minimization of the expression (7) will be:

$$\text{Min}\left\{ \left| S - \sum_i \alpha_i * b_i \right| \right\} \tag{8}$$

subject to the constraint $\sum_i \alpha_i = 1$. Since the absolute value of the deviation between the data and the fit is minimized, rather than its square, this approach is less sensitive to outliers (and more robust) than least squares minimization. In the LP problem all of the coefficients are non-negative so additional positivity constraints on the coefficients are unnecessary. At this stage, if we have interpolated the $\mu(E)$ onto m energy points, then instead of having one objective function in the conventional LP model, we have $2m$ objective functions with one constraint, so a change in perspective is needed. It appears at first glance that the LP problem is of the wrong structure, but the approach we have taken is to reframe the problem.

The vector that is sought consists of the unknown weight coefficients, and also new variables that describe upper and lower bounds on the difference between the data and the linear combination at each point. Solving the problem in this form, consists of adding the auxiliary variables in the problem (i.e. the residuals) and taking the $2m$ objective functions as constraints. If we define an m-dimensional vector Y as:

$$\left| S - \sum_i \alpha_i * b_i \right| = \boldsymbol{Y}. \tag{9}$$

That implies:

$$-y_j \leq s_j - \sum_i \alpha_i * b_i \leq y_j, \qquad j = 1, \ldots, m \text{ and } i = 1, \ldots, n \tag{10}$$

where m is the number of energy points and n is the number of standards, and if we write them in the LP inequality model, the right hand inequalities can be written in this form:

$$y_j + \sum_i \alpha_i * b_i \geq s_j \tag{11}$$

and the left hand inequalities will be:

$$y_j - \sum_i \alpha_i * b_i \geq -s_j. \tag{12}$$

Writing the constraint: $\sum_i \alpha_i = 1$ in the LP form, we will have the conditions:

$$\sum_i \alpha_i \geq 1 \quad \text{and} \quad -\sum_i \alpha_i \geq -1. \tag{13}$$

Then we can show the constraints equations; eq (11), eq (12) and eq (13) in a matrix representation in the form of: $\mathbf{M} \cdot \boldsymbol{X} \geq \boldsymbol{B}$, eq (6):

$$\begin{bmatrix} 1 & 0 & 0 & 0 & \ldots & 0 & b_{11} & b_{21} & \ldots & b_{n1} \\ 0 & 1 & 0 & 0 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 1 & 0 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & 1 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & 0 & \ldots & 1 & b_{1m} & b_{2m} & \ldots & b_{nm} \\ 1 & 0 & 0 & 0 & \ldots & 0 & -b_{11} & -b_{21} & \ldots & -b_{n1} \\ 0 & 1 & 0 & 0 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 1 & 0 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & 1 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & 0 & \ldots & 1 & -b_{1m} & -b_{2m} & \ldots & -b_{nm} \\ 0 & \ldots & \ldots & \ldots & \ldots & 0 & 1 & 1 & \ldots & 1 \\ 0 & \ldots & \ldots & \ldots & \ldots & 0 & -1 & -1 & \ldots & -1 \end{bmatrix} \times \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ \ldots \\ y_m \\ \alpha_1 \\ \alpha_2 \\ \ldots \\ \alpha_n \end{bmatrix} \geq \begin{bmatrix} s_1 \\ s_2 \\ s_3 \\ s_4 \\ \ldots \\ s_m \\ -s_1 \\ -s_2 \\ -s_3 \\ -s_4 \\ \ldots \\ -s_m \\ 1 \\ -1 \end{bmatrix} \tag{14}$$

where $\mathbf{M}$ is a $(2m + 2) \times (m + n)$ matrix, and as mentioned before, m is the number of the energy points, n is the number of basis functions. The data matrix $\boldsymbol{X}$ is an $(m + n)$ column matrix and evidently the matrix $\boldsymbol{B}$ is a $(2m + 2)$ column matrix. Our interests are primarily in the last n components of the matrix $\boldsymbol{X}$, which are the unknown coefficients α_i that we are seeking. The other (y) values are the residual errors, which are useful for quantifying errors through comparison with the measured or estimated noise distribution in the data. Error estimates can alternatively be obtained through a Monte Carlo type approach by generating an ensemble of spectra with random noise that corresponds to the error distribution, and then statistically describing the distribution of parameter values returned by repeated runs of the LP procedure.

The matrix representation of the objective function, $\boldsymbol{C} \cdot \boldsymbol{X}$, which is minimized in this program is:

$$\begin{bmatrix} 1 & 1 & 1 & 1 & \ldots & 1 & 0 & 0 & \ldots & 0 \end{bmatrix} \times \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ \cdots \\ y_m \\ \alpha_1 \\ \alpha_2 \\ \cdots \\ \alpha_n \end{bmatrix}. \tag{15}$$

$\boldsymbol{C}$ is an $m + n$ row matrix whose first m components are equal to one and whose last n components are zero. That means the function that will be minimized in this program is the sum of the auxiliary variables or residuals, $\text{Min}\{y_1 + y_2 + \cdots + y_m\}$, which is in agreement with our first attempt to minimize expression (7).

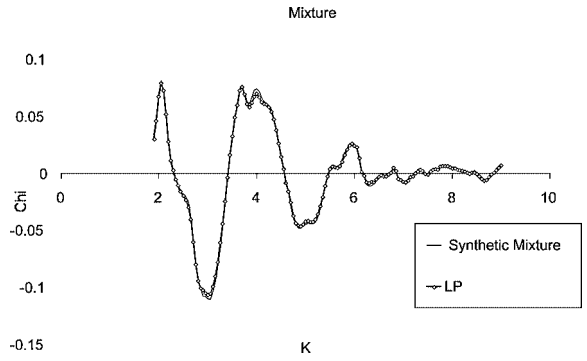

Fig. 1. LP fit to Synthetic mixture of four Zn compounds (see text). Experimental Data (solid line) and LP fit (symbols).

We have implemented this LP method in the *Mathematica* language. The result of fitting using this program for analytical mixtures was excellent. For experimental mixtures, although the accuracy of fitting results was very good, small discrepancies were observed which are mostly due to the quality of the samples and noise. Example of LP fitting for EXAFS and XAFS spectra are shown in the next section.

3. Results and Discussion

The LP method has been applied to several synthetic mixtures of Zn compounds. The standards which have been used to make these mixture samples are: ZnS, $ZnSO_4$, ZnO, $Zn(OH)_2$ and $ZnFe_2O_4$. Fig. 1 shows the result of LP fitting with the $\chi(k)$ spectra of a mixture of just four compounds; $ZnSO_4$, ZnS, ZnO and $ZnFe_2O_4$. The program was run with five basis functions one of which was an unnecessary basis function corresponding to the standard $Zn(OH)_2$ that was not present in the mixture. The results correctly indicated that the fraction was zero. The result of the decomposition of the unknown mixture was:

$$9\%ZnSO_4 + 40\%ZnS + 31\%ZnO + 20\%ZnFe_2O_4.$$

Our original goal of developing LP was to solve the speciation problem as applied to soil core samples from the Depue Wild Life Management Area in Illinois. The results of LP fitting for XAFS/XANES and EXAFS spectra are presented in Fig. 2 and Fig. 3. The LP program is very flexible in choosing which parts of the spectra we are trying to fit. For XAFS, choosing the first 30% of the m energy points is enough and for the EXAFS part 70% of the last m energy points is proper. The orthogonality of the basis functions differs in XANES and EXAFS regimes. LP fits for core samples included basis spectra of Zn sulfide, Zn oxide, Zn sulfate, Zn carbonate, Zn nitrate, Zn adsorbed to Montmorillonite (aged 6 months), and Zn adsorbed to HFO (aged 6 months) indicate predominantly Zn carbonate and Zn sulfate coordination.

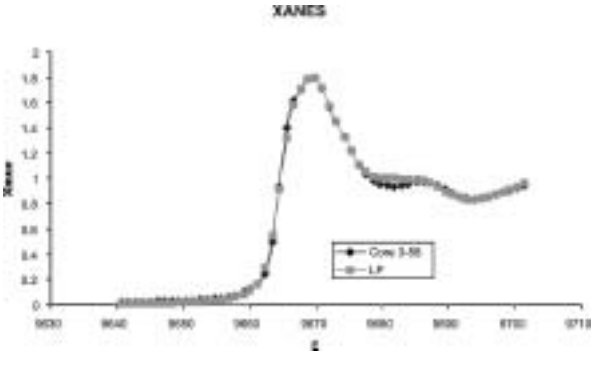

Fig. 2. XANES LP fit to experimental soil sample 3-58.

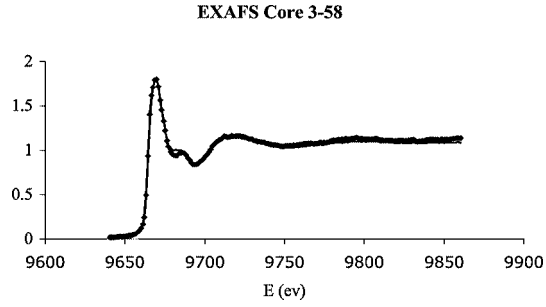

Fig. 3. XAFS LP fit to experimental soil sample 3-58.

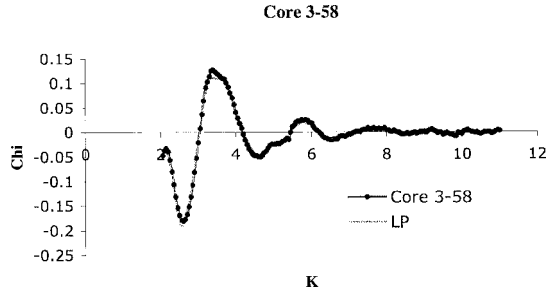

Fig. 4. EXAFS LP fit to experimental soil sample 3-58 chi data.

Fig. 4 shows the result of the LP fitting for the same soil core sample but for $\chi(k)$ data. As it was mentioned before, results of fitting to $\chi(k)$ data are much more reliable than fits to the $\mu(E)$ data, presumably because the $\chi(k)$ basis spectra are much more orthogonal than the $\mu(E)$ spectra. However, in some special cases the differences between spectra could be more distinct in the near-edge region, and in those cases, fitting to $\mu(E)$ would be preferred.

The imperfections in LP fitting for the soil core samples can be the result of any of the following reasons: insufficient basis set, similarity (nonorthogonality) between the XAFS spectra of the different standards, differences between the XAFS spectra of the synthetic standards which have been made in the laboratories and what is present in the natural sample, and particle size effects.

Speciation using linear approximation works well when the sample consists of a small number of known discrete components that are accurately represented in the library of basis functions. There are a number of complicating factors that must be considered, however, some obvious, and others less so:

1) The basis set must be sufficient to completely represent all the constituents of the samples. A large basis set is good, but only if it includes the correct basis functions for the sample. Omission of a needed basis function will cause systematic errors in the parameter values. A larger basis set is not necessarily better if it does not include the right functions.
2) Instrumental energy shifts between spectra of the standards must be carefully corrected, especially when fitting $\mu(E)$ data. EXAFS data are less sensitive to small energy shifts. Similarly, the energy resolution must be the same when near edge data are included in the fits.
3) The spectra that make up the basis set must reflect the material as it is found within the sample. For example, the standard spectra must be measured at the same temperature as the

sample. To some extent temperature effects can be addressed by including into the basis set spectra measured at different temperatures, but the strong similarity (and therefore non orthogonality) between basis functions can cause numerical instabilities, depending on the algorithm used.

Performing measurements of sample and standards at multiple temperatures could significantly improve the speciation results, because although the basis functions would change with temperature, their proportions generally would not.

4) Basis functions must correspond to well defined compounds. In some amorphous materials, the spectra may depend on time as the sample ages. Ignoring this effect can introduce significant errors.
5) Nonlinear relationships between the measured spectra and the compositions of the sample naturally occur in fluorescence, as described in the next section, and can cause serious systematic errors by effectively distorting the basis functions. We are exploring methods to correct for these effects.

4. Particle Size Effects

The physical characteristics of complex media can have a strong effect on the detected fluorescence spectra, which can undermine the reliability of speciation studies by XAFS.

Particle size effects [6, 7] can influence the apparent concentrations and therefore the speciation results.

In the simplest case of a slab of material with thickness x, it is easily shown that the fluorescence that is emitted from the sample is proportional to:

$$\left(\frac{\mu_s(E)}{\sin\theta}\right)\left(\frac{1-\exp(-\alpha x)}{\alpha}\right); \qquad \alpha = \left[\frac{\mu_t(E)}{\sin\theta} + \frac{\mu_t(E_f)}{\sin\varphi}\right] \quad (16)$$

where $\mu_s(E)$ and $\mu_t(E)$ are respectively the absorption coefficients of the element of interest and the total sample matrix, E and E_f are the energies of the incident and fluorescence X-ray photons, and θ and φ are the angles of incidence and exit radiations relative to the sample surface. The measured spectra are linear if $\alpha x \ll 1$, or if $\mu_s(E) \ll \mu_t(E)$, but in general the measured spectrum depends nonlinearly on $\mu_s(E)$.

Nonlinearity problems arise when the sample consists of concentrated species with particle sizes that are not small compared to one absorption length. In this case the penetration depth into the particles has an energy dependence that derives from the absorption coefficient of the element of interest, making the interpretation of the results much more complicated. Figure 5 simulates how the measured XAFS spectrum of MnO would vary as the size of the particles increases. The absorption length above the edge in MnO is only about 5 micrometers. Each spectrum is divided by the thickness to more clearly show the nonlinearity.

The detected fluorescence can be easily calculated from the equation above for various film thicknesses (here the incident and exit angles are taken as 45 degrees to the surface). The results are shown in figure 5 for thicknesses 0.125, .25, 0.5, 1.0, 2.0, 4.0 and 8.0 μm. It is evident that the spectra are reduced in magnitude and the spectra are also distorted in a nonlinear manner. These distortions are certain to cause systematic errors in the derived speciation results unless the particle sizes are much smaller than one absorption length.

In the environmental XAFS literature these potential problems appear to have been often ignored. In such samples the investigator has very little control over particle size, and when making *in situ* measurements one wishes to study the samples as they are, without further grinding.

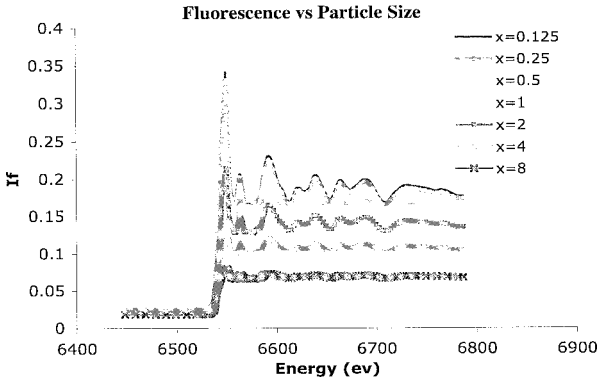

Fig. 5. Fluorescence spectrum vs particle size for MnO. Data simulated using equation 16. Each spectra is scaled by the thickness x, which its unit is micron.

The difficulties associated with particle size effects in *in situ* studies have a potential solution through use of resonant X-ray inelastic scattering. This technique in effect provides EXAFS spectra of a low energy edge while measuring at high energies. Experimentally one allows an intense high energy beam to penetrate the sample, while energy-analyzing with appropriate crystal optics the elastically scattered X-rays. Since the incident and scattered X-rays are both at high energies, particle size effects are irrelevant. The disadvantage of this technique is that it is relatively insensitive, but it should be suitable on appropriate undulator beamlines at third generation sources.

5. Conclusions

We have implemented a simple and robust approach to fitting compositions of experimental XAFS data in the linear superposition approximation by using Linear Programming methods. This approach has the benefits of directly locating the global minimum subject to positivity and normalization constraints. It also allows the experimenters to easily impose additional arbitrary linear constraints or bounds on the parameters. Some of the pitfalls and possible solutions associated with speciation by XAFS are discussed.

Abstract

A large number (67) of silicate glasses containing variable amounts of iron oxide were studied by high-resolution XANES spectroscopy at the Fe K-edge to determine an accurate method to derive redox information from pre-edge features. The glass compositions studied mimic geological magmas, ranging from basaltic to rhyolitic, dry and hydrous, with variable quench rates. The studied glasses also include more chemically simple calco-sodic silicate glass compositions. The Fe contents range from 30 wt.% to less than 2000 ppm. For most of the series of composition studied, the pre-edge information varies linearly with redox, even under high-resolution conditions. The average coordination of Fe(II) is often similar to its Fe(III) counterpart except in highly polymerized glasses because of the strong influence exerted by the tetrahedral framework on iron's sites. Natural volcanic glasses (from various volcanoes around the world) show similar variations. The average coordination of Fe(II) is often comprised between 4.5 and 5. Fe(III) shows larger variations in coordination (4 to 6, depending on composition). Bond valence models are proposed to predict the average coordination of Fe based on composition. Molecular dynamics simulations (Born-Mayer-Huggins potentials) were carried out on some compositions to estimate the magnitude of disorder effects (both static and thermal) in the XAFS analysis. XANES calculations (based on the MD simulations and FEFF 8.2) show large variations in the local structures around Fe. Also, 5-coordinated Fe(III) is found to be an important moiety in ferrisilicate glasses. For Fe(II), discrepancies between glass and melt are larger and are related to its greater structural relaxation at T_g. Also, a strong destructive interference between network formers and modifiers explain the relatively weak intensity of the next-nearest neighbors contributions in the experimental spectra.

1. Introduction

Iron affects significantly silicate melt and glass properties such as viscosity [1]. High resolution pre-edge and XANES features can help to further understand the origins of these dependences, provided systematic studies of glasses are undertaken at a given composition but variable oxygen fugacity conditions. If past studies demonstrated the presence of 5-coordinated sites around Fe(II) [2, 3] and the presence of a continuum of sites around Fe(II) [4], the exact effect of oxygen fugacity on the speciation of iron remain poorly understood, mostly because of the need to investigate a large experimental set of samples, which requires a significant amount of high-quality beamtime (i.e., under high resolution). In this study, we present a pre-edge, XANES and EXAFS study of iron in silicate glasses, in which the speciation if iron and the effects of disorder on XAFS spectra are understood in the light of molecular dynamics simulations.

2. Experimental

We studied a set of 67 silicate glasses containing variable amounts of network formers (such as Si and Al), network modifiers (Na, Ca, K), thus providing a large range of composition and polymerization degree encountered in silicate glasses of geochemical and industrial interest. For each composition, 3 to 7 glasses were equilibrated under variable oxygen fugacity to stabilize a specific Fe(II)/Fe(III) ratio. Fe K-edge XANES spectra were collected using the 11-2 beamline at SSRL (Stanford, USA) using Si(220) monochromators and reduced slit heights (0.3 mm) to achieve 0.6 eV experimental resolution. The monochromator energy calibration stability was ±0.05 eV. XAFS spectra were collected in the fluorescence mode, using a Stern-Heald type detector, a 3 μm Mn filter, Ag Soller slits and Xe absorbing gas. In the pre-edge region, energies were scanned with 0.1 eV steps, whereas 0.3 eV steps were used for the main edge crest region. Molecular dynamics calculations were undertaken following a similar procedure to the one described in [5]. *Ab-initio* XANES/EXAFS calculations were undertaken using the FEFF8.28 package [6] using default conditions, which included HL potentials, dipolar/quadrupolar transitions, self-consistency and full-multiple scattering formalism.

3. Pre-edge results

Fig. 1 shows typical XANES and their pre-edges collected for a series of sodo-calcic silicate glasses ("CNF1") containing 1 wt.% Fe and equilibrated at 7 different oxygen fugacities. The Fe(II)/Fe(III) ratio (as determined from wet chemical analyses) varies from 0.95 to 0.11 in this series of samples. When plotted in a diagram previously established for Fe(II)-, and Fe(III)-bearing model compounds (see [7] for details), the pre-edge information for these glasses (i.e., the centroid of the pre-edge doublet versus its integrated area) plots linearly as a function of the Fe(II)/Fe(III) ratio of the glasses (Fig. 1c). A Principal Component Analysis (see [8] for details) for each series of glasses suggested that two spectral end-members contribute to the XANES spectra (see also Fig. 1b). By inversion of the experimental XANES data set, we can estimate the XANES spectra for these end members as it was difficult to obtain experimentally CNF glasses containing only Fe(II) (respectively Fe(III)). The pre-edge information for these calculated end-members suggests that the average symmetry/coordination for the theoretical Fe(II) end member is similar (within errors) to that for its Fe(III) counterpart (CN ∼ 5.1 and 4.6 ± 0.3, respectively). This

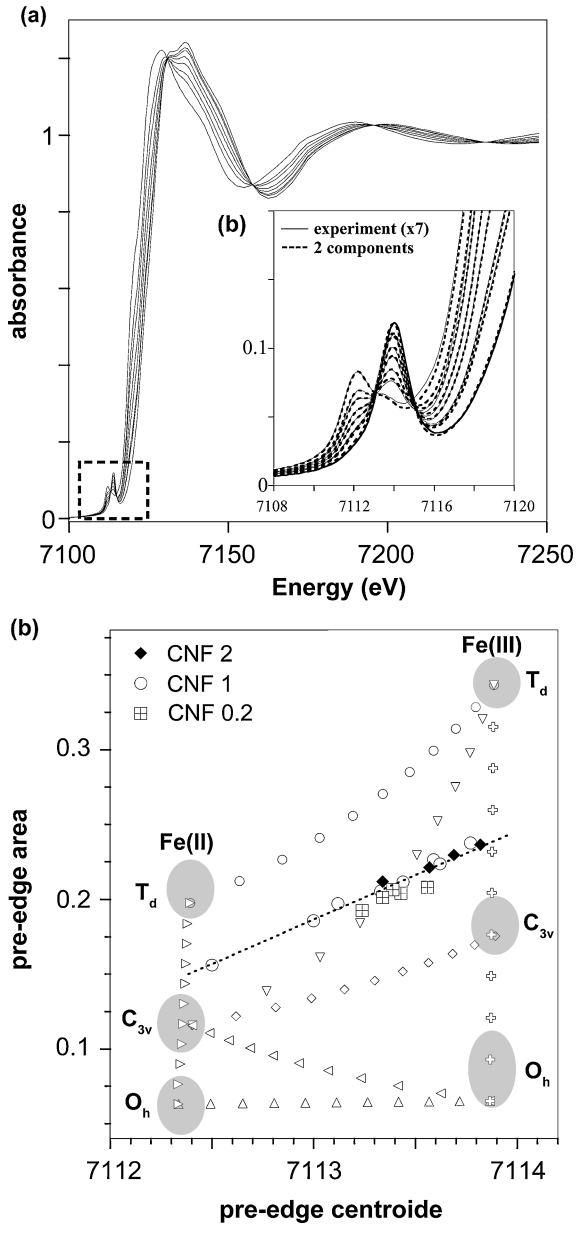

Fig. 1. Left: (a) Example of high-resolution Fe-K edge XANES spectra collected in the CNF1 series of sodo-calcic silicate glasses (1 wt.% Fe) and equilirated at 7 oxygen fugacities. (b) Zoom of the pre-edge feature, reconstructed using 2 components in the principle component analysis. Right: pre-edge information for 3 CNF glass series, which differ by their Fe content (2, 1 and 0.2 wt.%).

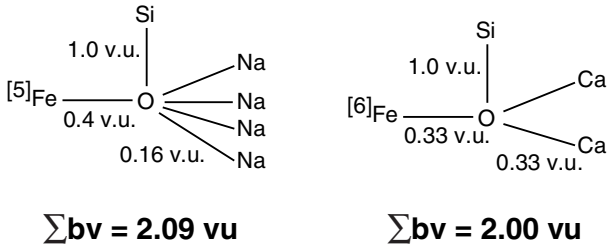
is consistent with the linear variation of the pre-edge information with redox (Fig. 1c). Most of the other series of glasses studied in this work show the same trends: under high resolution, Fe(II) and Fe(III) have similar symmetry in the end-member components (hence, a number of neighbor $= 5 \pm 0.5$).

4. MD simulations

Molecular dynamics (MD) simulations were performed for the two end-members of the CNF1 series (labelled CNFe2+ and CNFe3+) (see [4] and [5] for details). In each simulation, 10 atoms among 3800 are iron (either ferrous or ferric depending on the simulation considered). In each MD model, one site around Fe converged to a 3-coordinated site that was disgarded (as this coordination has never been observed experimentally around Fe(II) or Fe(III)). A bond valence analysis (see [9] and [5] for details) was conducted around each of the validated Fe atoms (i.e., in the 4-, and 5-coordination) to understand their connectivity to the main "glass/melt" structure. We could rationale most of the medium range environment around each iron atoms using a bond valence sums ($\sum$bv) around connecting oxygens:

Na-bearing glass : **Ca-bearing glass :**



$\sum$bv = 2.09 vu **$\sum$bv = 2.00 vu**

"Half-way" configurations are possible in Na- and Ca-bearing compositions, with 1 Ca and 2 Na around the connecting oxygen. Around each oxygen connecting Fe to the tetrahedral framework (mostly Si atoms), the bond valence sums are close to 2, the value required for Pauling's second rule to be verified. These models suggest that Na and Ca are occupying the same structural position in Fe-bearing silicate glasses/melts (i.e., network modifiers). A systematic analysis of bond valence sums was conducted for each atom in the simulations (O but also Si, Na, Ca and Fe). On the average, most atoms are well bonded in terms of Pauling's second rule, suggesting that the simulations are structurally plausible. The MD-derived average Fe(III) coordination (4.3) is in excellent agreement with the experiment (4.6(3)). In contrast, Fe(II) shows a significant discrepancy (4.2 in the MD-"melt" vs. 5.1(3) in the glass) that is related to the much larger structural relaxation that occur at the glass transition temperature (Tg $\sim$ 950 K) around Fe(II) (a network modifier) than around Fe(III) (a network former; see [2]). Also, significant amounts of 5-coordinated Fe(III) can be observed (instead of 6-coordinated Fe(III) as often reported in previous studies). If confirmed experimentally, this is the first report of 5-coordinated moieties around Fe(III) in silicate glasses. As a result, we extracted the local structure to 10 Å around each Fe atom in the CNFe2+ and CNFe3+ simulations. We, then, conducted XANES and EXAFS *ab initio* calculations for each of these clusters.

5. FEFF models

Ab-initio XANES and EXAFS spectra were calculated using FEFF8.28 [6] for each iron site in each simulation. The calculated Fe K-edge XANES for CNFe2+ and CNFe3+ (Fig. 2a,b) show large variation of the spectrum profile from one cluster to another due to various local structure around Fe(II) and Fe(III). The agreement between the average XANES around Fe(III) and the experiment is better than for Fe(II), which is related to the coordination change around Fe(II) at Tg (see [2]). The EXAFS for the CNFe2+ simulation (Fig. 2c) shows large contributions arising from network formers (mostly Si) in the FT near 3 Å (see top curve). But these contributions suffer large phase cancellation (see curve "6 Å" on Fig. 2b) from network modifiers (Ca and Na). This suggests that important disorder effects occur in the medium range environment of Fe(II) in that model. Such analysis helps to better understand how disorder effects contribute to the XAFS spectra in disordered materials. In contrast, phase cancellation are less important around Fe(III) (Fig. 2d). Finally, the average

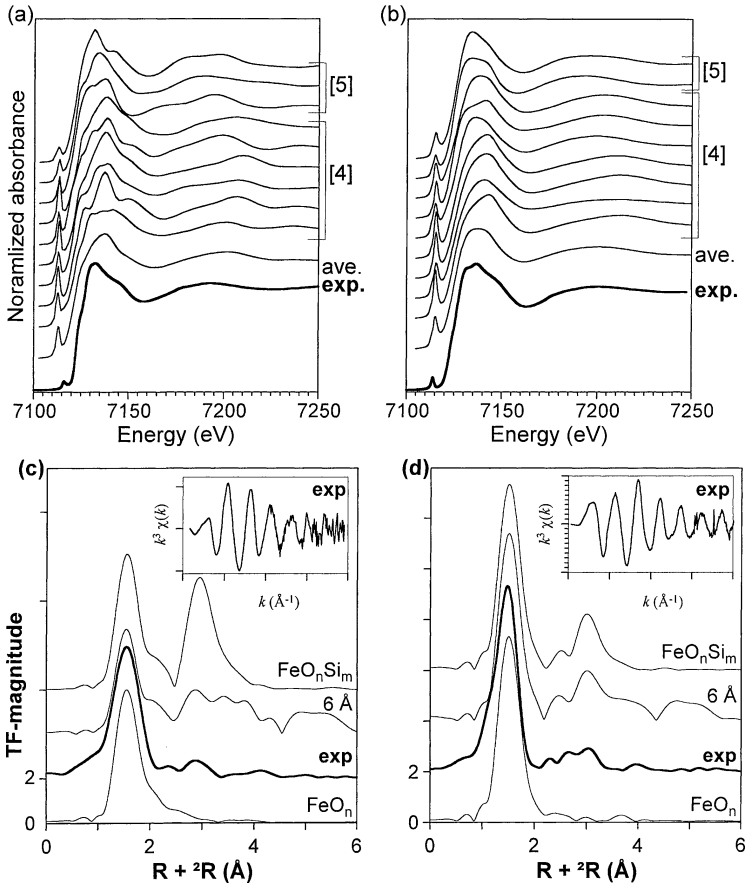


Fig. 2. FEFF 8.28 XANES (a,b) and EXAFS (c,d) calculated spectra based on the molecular dynamics models of the end-members of the CNF 1 composition: CNFe2+ (a,c) and CNFe2+ (b,d) respectively. Note the large variations in the XANES for CNFe2+ and CNFe3+ (for both model, the 10th cluster was omitted because of its unusal 3-coordination). On Figs. 2c/d, the cluster for "FeO_n" ($n = 4$ or 5) was calculated using a radial cut-off distance of 2.2 Å around the central Fe's. For the "FeO_nSi_m" cluster ($n = 4$, 5 and $m = 1$–4), a radial cut-off distance of 3.5 Å was used and, in addition, all network modifiers were excluded from the list of next-nearest neighbors. For the "6 Å" cluster, all next-rearest atoms up to 6 Å around the central atom were taken into account. Note also strong destructive interference for CNFe2+ due to network modifiers in the 3–4 Å range around Fe(II).

spectra calculated using FEFF for CNFe2+ and CNFe3+ MD models are comparable to the experiment (also obtained by inversion, see above) in the short-range environment (below 3 Å on the FT) but differs more in the medium-range environment (>3 Å). This is related to the poor modelling of thermal disorder by FEFF, which enhance artificially distant Fe-Si/Ca/Na pairs.

6. Conclusions

The Fe K pre-edge information for silicate glasses shows that the average coordination environment for Fe(II) and Fe(III) are close to each other and centred around a CN of 4.7 (±0.5). Molecular dynamics simulations confirm these findings and suggest that Fe(III) may occupy a significant amount of 5-coordinated sites in ferrisilicate glasses/melts. Bond valence analysis suggests that all atoms are usually well bonded, which means that they occupy plausible positions in the simulations. Then, *ab initio* XANES and calculations were undertaken (using FEFF8.28) and compared to the experiment (calculated by inversion of the data set). As the agreement is fair with experiment (it cannot be accurate because it compares a glassy to a melt state), the MD model provides interesting information of the effect of disorder in the next-nearest environment of Fe. According to MD simulations, the relatively weak Fe(II)-Si interactions observed in the EXAFS region is due mostly to a strong phase cancellation between constructive contributions arising from network forming Si and destructive contributions arising from network modifiers. This explains why the contribution arising from next-nearest neighbors are always relatively weak in the Fe K-edge EXAFS for silicate glasses (even around a network former like Fe(III)).

Abstract

We report about XAS (X-ray absorption spectroscopy) and ESXD (energy scanning X-ray diffraction) experiments on molten Cu_xSn_{1-x} and Ag_xPd_{1-x} and Cu_xPd_{1-x} alloys under high-pressure/high-temperature conditions for selected concentration. Recent advances in the analysis of XAS spectra of molten or disordered binary systems in the framework of the GNXAS method are discussed and their application to determine partial pair distribution functions in Cu6Sn5 is shown. The resulting distributions are compared with published X-ray diffraction data. Results about the disorder-order transition in $Ag_{0.5}Pd_{0.5}$ and $Cu_{0.6}Pd_{0.4}$ fcc random alloys are briefly discussed.

1. Introduction

Binary noble-metal alloys form an heterogeneous class of materials with different structural and electronic properties and a great variety in their phase diagrams corresponding to differences in the solubility of individual components. The Cu_xSn_{1-x} melts are known to crystallize in many distinct solid phases for different temperatures and concentrations [1]. On the other hand, several fcc binary alloys crystallize into various kind of ordered phases around the equiatomic composition upon decreasing temperature [2]. In particular the $Cu_{0.6}Pd_{0.4}$ alloy undergoes a peculiar transition ($T_c = 866$ K) toward an ordered β-phase having the B2(CsCl)-type structure [1] with a complete change in the lattice type instead of a simple atomic rearrangement in the original fcc lattice (as for $L1_0$(CuAu)-type, $L1_1$(CuPt)-type, and $L1_2$(Cu_3Au)-type structures). On the other hand, Ag_xPd_{1-x} alloys are known to form solid solutions for any concentration [1]. Very recently first-principles predictions of yet-unobserved structures in the Ag-Pd phase diagram have been reported [3]. According to these calculations, equiatomic $Ag_{0.5}Pd_{0.5}$ has a stable $L1_1$(CuPt)-type structure, below a critical transition temperature $T_c = 320$ K. The occurrence of such a structure has never been observed experimentally in binary materials other than Cu-Pt.

Despite the large interest of silver and copper alloys both for basic physics and for applications (ranging from medicine to electronics and electrical engineering), the structure of these systems has been poorly investigated, especially in the molten state and as far as the local order is concerned. In addition, the phase diagram of these alloys under high pressure conditions remains an almost unexplored domain (with some notable exceptions [4, 5]). Since pioneering studies by X-ray and neutron diffraction [6, 7], very few investigations have been performed to determine the short range arrangement around each atomic component.

In this context, the application of X-ray absorption spectroscopy (XAS) can play a fundamental role. The fine structure modulations (XAFS) of the X-ray absorption cross-section above the atomic absorption edges in condensed matter, are known to provide accurate information about the short range order around selected elements. Advances in data analysis scheme allowed us to obtain a reliable analysis of X-ray absorption spectra of molten and disordered systems [8, 9]. These methods have been recently extended, in order to make feasible the analysis of binary mixtures as binary alloys [10].

In this work we report about some recent experiments on copper and silver alloys studied in different regions of the (P,T) phase diagram, for selected concentrations. Cu_xSn_{1-x} alloys have been measured at 1073 K in their liquid phase for different concentrations. Solid $Ag_{0.5}Pd_{0.5}$ and $Cu_{0.6}Pd_{0.4}$ alloys have been investigated in a wide pressure and temperature region. Recent advances in the treatment of XAFS data of binary disordered system, are briefly discussed and the results of their application to the analysis of the Cu6Sn5 alloy are shown. The paper is organized as follows. Section 2 contains some experimental details about sample preparation, X-ray absorption and diffraction measurements. In sections 3 and 4 we report and discuss some results on different alloys. Section 5 contains concluding remarks.

2. Experimental

The experiments were performed mainly at the BM29 X-ray absorption spectroscopy beamline of the ESRF (European Synchrotron Radiation Facility). XAFS data on Cu-Sn alloys at Cu K-edge were collected at the LURE-D42 beamline. At the BM29 beamline, the conventional X-ray absorption transmission setup was complemented by a recently developed multi-channel detector collimator for the collection of high resolution energy-scanning X-ray powder diffraction patterns [11]. This setup supports different scanning and detection modes and allows us to switch between X-ray absorption spectroscopy, X-ray absorption temperature scans and energy scanning X-ray diffraction measurements [12]. High temperature measurements were performed using an high vacuum special furnace (L'Aquila-Camerino oven) designed to collect XAS and XRD spectra at high temperatures [13]. High pressure-high temperature conditions were obtained placing the samples in boron/epoxy bi-conical gaskets loaded inside a "Paris-Edinburgh" type large-volume press [14].

Cu_xSn_{1-x} alloys were produced mixing high purity CuO and SnO oxides powders, in the appropriate weight ratios, to obtain $x = 0.2$, 0.4, 0.55, 0.6, and 0.8 concentrations. These mixtures were finely ground, mixed with inert graphite powder (1 : 10 weight ratio) and then pressed into pellets (thickness $\simeq$1 mm). The alloys were produced *in-situ* by heating the pellets in

*Corresponding author. E-mail: angela.trapananti@unicam.it

high vacuum up to 1400 K. Copper and tin oxides decompose around 900 K forming metallic particles which alloy completely in the phase diagram region above the liquidus curve. X-ray diffraction measurements showed that the final samples were a dispersion of alloy particles, with a narrow spreading around the average concentration. Samples for high-pressure/high-temperature measurements were prepared mixing high purity Ag/Pd and CuO/Pd powders in suitable weight ratio for each concentration. The mixture was dispersed in an inert composite α-Al_2O_3/MgO (1 : 3) matrix in the appropriate ratio (1 : 12), then pelleted and melted in a graphite crucible under high vacuum conditions. After an accurate structural characterization by a laboratory angle-dispersive X-ray powder diffractometer, the final pellets were crushed into a fine powder and then pressed again into a 1.6 mm^3 cylinder. Each cylinder was directly placed into a graphite cylindrical oven and eventually loaded in a 7 mm boron/epoxy gasket, completed with the electrical feedthroughs for the sample heating. Temperature was monitored by inserting a Pt 10% Rh/Pt thermocouple through the gasket, while pressure was measured using the energy-scanning X-ray diffraction patterns and the MgO [15] and $MgAl_2O_4$ [16] equations of state.

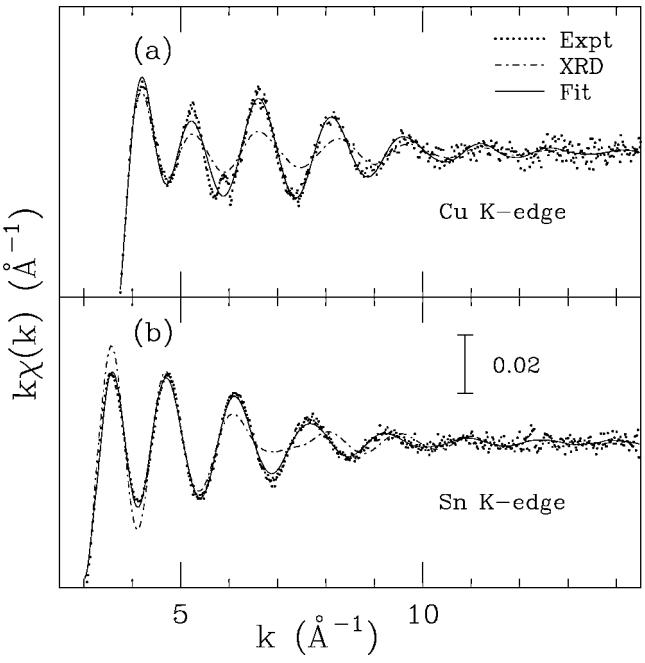

Fig. 1. Best-fit Cu (a) and Sn (b) K-edge XAFS signals compared with experimental data on molten Cu6Sn5 at 1073 K. Signals calculated from XRD partial distribution functions are also reported (dotdashed lines).

3. Local structure of molten alloys: Cu-Sn

Thermodynamical and structural properties of liquid Cu-Sn alloys have been extensively studied [17, 18]. The partial structure factors of molten Cu6Sn5 alloys have been determined by isotopic substitution neutron diffraction [6] and by X-ray scattering methods [7] assuming that the $S_{\alpha\beta}(k)$ were concentration independent. For this reason, we have chosen the Cu6Sn5 alloy to put to a test a new procedure for the refinement of the short-range structure of liquid binary mixtures from XAFS measurements. A valid method to combine XAFS data with the information provided by complementary techniques, like scattering experiments or molecular simulations, has been proposed by [19] and applied to the study of many different single component systems (see [9] for a review). In this framework the short-range peak of the partial distribution function is refined constraining the $g(r)$ and the corresponding $S(k)$ to keep their long-distance behavior, namely:

$$\lim_{r\to\infty} g(r) = 1, \tag{1}$$

$$\lim_{k\to 0}\left[1 + 4\pi\rho\int_0^\infty r^2[g(r)-1]\frac{\sin(kr)}{kr}\,\mathrm{d}r\right] = \frac{\rho K_T}{\beta} \tag{2}$$

where K_T is the isothermal compressibility and $\beta = (k_B T)^{-1}$. The same procedure has been successfully applied to two components charged liquids (e.g. molten salts [20]). In fact, requiring the charge screening in the Coulomb fluid, equation (2) still holds for each $S_{\alpha\beta}(k)$ separately (apart from a constant) [21]. It follows that each partial $g_{\alpha\beta}(r)$ can be refined independently from the others extending the constraints originally derived for mono-atomic systems.

In the general case, the isothermal compressibility is related to the $k \to 0$ limit by a more complicated equation [21], involving non-linear combinations of the $S_{\alpha\beta}(k)$. The derivation of physical constraints on the $g_{\alpha\beta}(r)$ is not straightforward. We have developed a new procedure which exploits the three long-wavelength limits of the Bhatia-Thornton $S_{NN}(k)$, $S_{Nc}(k)$ and $S_{cc}(k)$ structure factors [17], also related to isothermal compressibility. Full details on this method and its implementation in the framework of the GNXAS data analysis scheme are described elsewhere [10]. Here we report a simultaneous refinement of both Cu and Sn K-edges XAFS measurements on liquid Cu6Sn5 assuming the set of partial $g(r)$'s derived from X-ray scattering [7] as a starting model.

In Fig. 1, best-fit Cu and Sn K-edge calculated signals are compared with experimental data collected at 1073 K and signals calculated from the XRD partial distribution functions. The main frequency and amplitude of the signal, roughly associated with the first shell distance and coordination number are well reproduced. Reconstructed partial pair distribution functions are compared in Fig. 2 with XRD models.

The $g_{\mathrm{CuSn}}(r)$ first peak is slightly higher but qualitatively similar to that found by XRD. On the other hand, $g_{\mathrm{CuCu}}(r)$ and $g_{\mathrm{SnSn}}(r)$ distributions differ from the original model, especially on the short-distances side, to which XAFS is exceptionally sensitive. The rise of the $g_{\mathrm{CuCu}}(r)$ peak is steeper and the most probable Cu-Cu bondlength slightly shorter than from XRD. Similarly the first maximum and the foot of the $g_{\mathrm{SnSn}}(r)$ distribution are shifted of about 0.1 Å toward the low r side, indicating that the Sn-Sn bondlength and also the corresponding closest approach distance are shorter than from XRD. In order to follow the changes of the partial distributions functions with composition we are currently applying the same refinement to data collected for each concentration.

4. Metal alloys under high-pressure and high-temperature

The Ag_xPd_{1-x} alloy, with $x = 0.5$ nominal concentration, has been investigated in the 298-1650 K temperature range for pressures up to 5.6 GPa. High quality XAFS spectra at Ag and Pd K-edges and X-ray diffraction patterns have been collected. The subtle changes associated with an order-disorder transition, like variation of the bond variances affecting XAFS signals and intensity of Bragg peaks have not been observed upon increasing temperature. Therefore the occurrence of an ordered L_1 structure

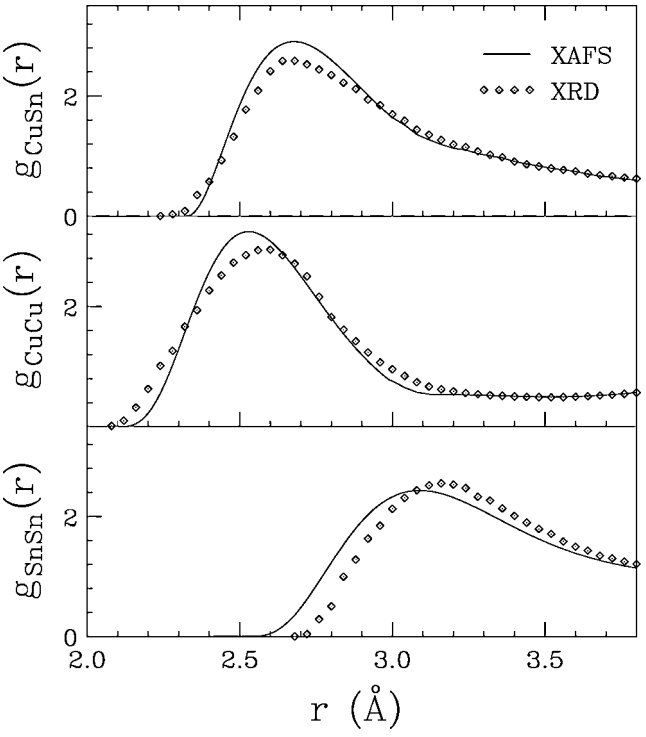

Fig. 2. Partial pair distribution functions reconstructed by XAFS compared with published XRD results [7] for liquid Cu6Sn5.

below $T_c = 320\,\mathrm{K}$, predicted by first-principles calculations, is not confirmed by the present work.

Since regular arrangements of atoms on lattice sites usually give higher packing densities than random arrangements, the application of pressure should make the ordered state favorable and then shift T_c toward higher temperatures, making easier its experimental detection. In Fig. 3 we report a series of XAFS spectra collected at room temperature for different pressures. Besides the slight frequency decrease (indicated by dashed lines), related to an obvious contraction of the first-neighbor bondlength as a function of pressure, we do not observe any evidence of changes in the short-range structure induced by pressurization. Similarly, no evidence of phase transitions has been found for increasing temperature in the whole range of pressures.

A similar investigation has been performed for the $Cu_{0.6}Pd_{0.4}$ alloy for which the presence of an order-disorder transition is well known. In this case a clear transition between the ordered B2(CsCl)-type structure and a disordered fcc structure has been observed by fixed energy X-ray absorption temperature scans, even under high pressure conditions.

5. Conclusions

In conclusion, we have developed new experimental and theoretical tools for a complete structural characterization of solid and molten binary alloys under extreme thermodynamical conditions. Cu- and Ag-based alloys have been investigated through a combination of complementary techniques like X-ray absorption spectroscopy, X-ray diffraction and fixed-energy X-ray absorption temperature scans. New procedures to prepare

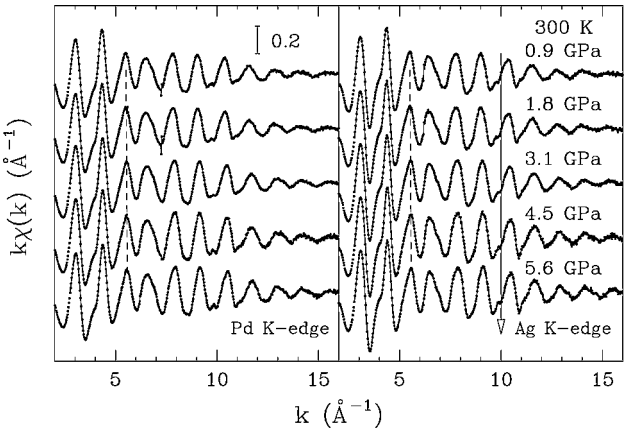

Fig. 3. Experimental XAFS signals at Pd (left panel) and Ag (right panel) K-edge of $Ag_{0.5}Pd_{0.5}$ alloy collected at RT for different pressures.

alloy samples for experiments under high-pressure and high-temperature conditions have been developed. A new methodology for the analysis of the X-ray absorption spectra of molten and disordered binary mixtures has been shown to give reliable results in a prototypical system like Cu6Sn5. Some short-distance details of the liquid Cu6Sn5 partial pair distribution functions, as the rise of the $g_{CuCu}(r)$ peak and the position of the foot and the first maximum of the $g_{SnSn}(r)$ have been refined respect to the XRD results, exploiting the unique sensitivity of the XAFS signal to short-range correlations. Temperature and pressure induced order-disorder transitions have been investigated. Evidence of the existence of an ordered phase in the $Ag_{0.5}Pd_{0.5}$ fcc random alloy has not been obtained in the present work.

Abstract

Surface sensitive, grazing incidence reflection mode X-ray absorption spectra were conducted in order to study the reactive sputtering processes in situ. The spectra were measured in the Quick-scanning EXAFS (QEXAFS) mode, so that, beginning from the initial stages of thin film formation, all the growth processes can be followed with a time resolution of about 30 s. The experiments were performed in a small sputter chamber with a magnetron source. In the present study, the growth of amorphous Ta-oxide films is studied.

1. Introduction

Thin film growth by magnetron sputtering usually involves the bombardment of the target material with accelerated ions, the evaporation of the target material into the gas phase and its deposition on the substrate. If a reactive gas species such as oxygen is present in the gas phase, a chemical reaction with the evaporated material can occur, leading to the deposition of a chemical compound, the surface and volume microstructure of which depends strongly on the details of the preparation procedures, like the working pressure and the gas composition, the nature of the substrate and its temperature etc (see, e.g. [1–4]). In the present study, we investigated the structure of reactively sputtered Ta_2O_5-films on float glass substrates in situ. Surface sensitive, grazing incidence reflection mode X-ray absorption spectra were measured using the Quick-scanning EXAFS (QEXAFS)-technique with a time resolution of about 25 s. Previous ex situ reflection mode EXAFS studies have shown that stochiometric amorphous thin films with very smooth surfaces can be prepared by reactive sputtering from a tantalum metal target in a pure O_2-atmosphere [5]. The sputter chambers for in situ investigations with X-rays that have been previously published in the literature usually consist of large vacuum chambers which require complex diffractometers for the experiments [6–8]. In this paper we will report on the first grazing incidence EXAFS experiments of reactively sputtered Ta_2O_5 thin films which were prepared and investigated in situ in a miniaturized high vacuum chamber with a magnetron source which can be mounted on a rather small reflectometer stage. Ta-oxide has potential applications in microelectronic devices, e.g. for the use as capacitor material in dynamic random access memories [9] or as gate insulator in metal-oxide-semiconductor field effect transistors [10].

2. Experimental

The experiments presented here were performed at the bending magnet station RÖMO II [11] at the DORIS III storage ring at HASYLAB (Hamburg, Germany). A double-crystal monochromator with two flat Si(111) crystals was used. Time resolved reflectivity data were collected at room temperature in the vicinity of the Ta L_3-edge (9.881 keV) for various glancing angles in the vicinity of the critical angle of total reflection ($\Theta_C \approx 0.25^\circ$). The incident, monochromatic X-ray beam was collimated to a size of about 255 µm × 10 mm (vertical × horizontal) by a slit system. Incident and reflected intensities were measured by means of nitrogen and argon filled ionization chambers, respectively. A second slit system in front of the second ionization chamber suppresses the intensity of non specularly reflected X-rays and shields this detector from the direct beam. All components of the reflectometer, i.e. the sample position, the angle of the detector arm and the slit system can be adjusted by stepper motors. Simultaneously with each EXAFS scan, a Ta-metal foil was measured in transmission between the second and third ionization chamber in order to calibrate the energy scale of the monochromator. Time resolved spectra were recorded in the quick-scanning EXAFS mode, in which the monochromator is moved continuously from smaller to higher energies and the spectrum is measured on the fly [11]. Typical reflection mode scans with a scan range of about 0.4 keV took about 25 s and consist of ca. 800 data points each of which was measured in about 0.016 s.

3. In situ cell design

Fig. 1 shows the sputter chamber on the reflectometer. It mainly consists of a glass cylinder with a diameter of ca. 10 cm with two large area Kapton windows for the incoming and the reflected beam. The used glass substrate (approx. 10 mm width and 20 mm length) is placed on a resistive heater in which a tungsten filament is embedded. The heater is remote controlled by a computer and enables temperatures up to 300 °C. The glass cylinder is placed on a stainless steel vessel with flanges for the sputter gas inlet, electrical feedthroughs for the measurement of the substrate temperature and the electrical resistivity of the sample and a pumping connection to a turbo-molecular pump. The top flange of the vacuum chamber accommodates the magnetron source with a tantalum metal target of approx. 60 mm diameter. The base pressure of the chamber is below $1 * 10^{-5}$ mbar. We used Argon with a small amount of O_2 as sputter gas. The films were sputtered at a pressure of about $3.44 * 10^{-3}$ mbar and a current of about 20 mA.

4. Results and Discussion

In Fig. 2, raw reflection mode EXAFS data are presented for a glancing angle $\Theta = 0.22^\circ$. It should be noted that no data processing or reduction such as smoothing or averaging was applied to the experimental data points. Every second spectrum is displayed, i.e. subsequent spectra in the graph correspond to a time interval of ca. one minute. The decrease in reflectivity at about

*e-mail: dirklh@uni-wuppertal.de

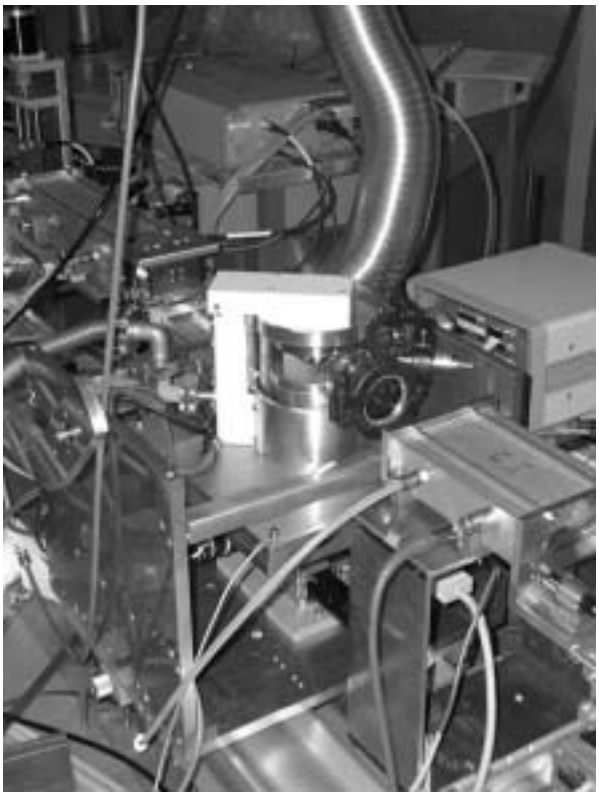

Fig. 1. Photo of the in situ sputter chamber on the reflectometer at the RÖMO II beamline at HASYLAB.

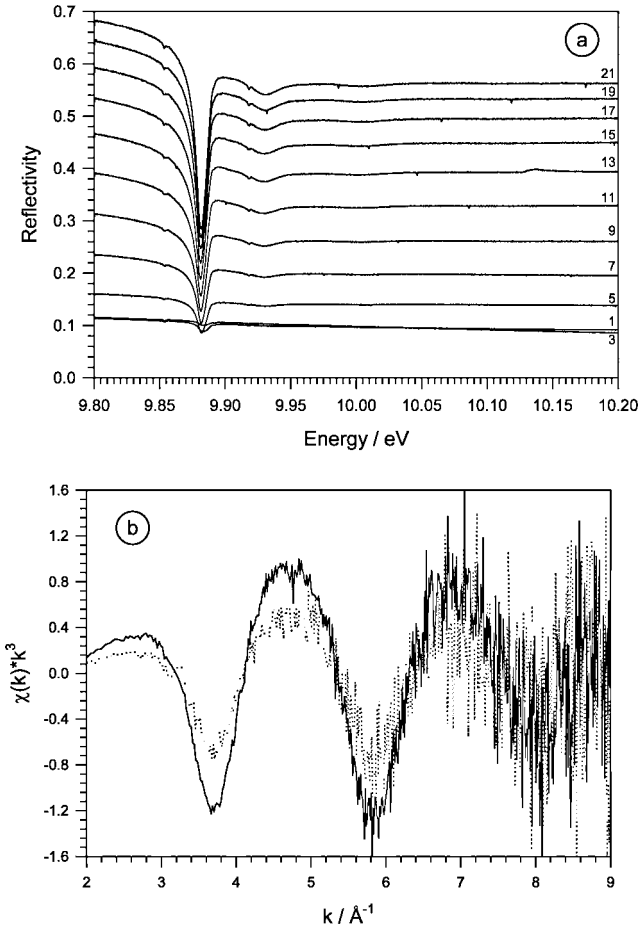

Fig. 2. (a) In situ reflection mode ($\theta = 0.22^\circ$) Ta L_3-edge spectra of the amorphous Ta-oxide layers during reactive sputter deposition at room temperature. Each spectrum was measured in about 25 s, every second spectrum is displayed. (b) k^3-weighted reflection mode fine structure of a single spectrum. The full and the dotted line correspond to sputtering times of about 700 s and 100 s, respectively.

9.89 keV belongs to the Ta L_3-edge. Obviously, the reflectivity of the sample increases with the sputtering time and thus with the oxide film thickness. This effect can easily be understood because the critical angle of total reflection for the bare glass substrate is about $\Theta_C \approx 0.18^\circ$ only, while that of Ta-oxide is about $\approx 0.25^\circ$. Working slightly below the critical angle of total reflection of Ta-oxide results in a high reflectivity of the deposited Ta-oxide layer and an increase of the X-ray reflectivity during the sputtering process accordingly. As can be seen in Fig. 2(a), the experimental data quality is high enough to resolve the weak EXAFS oscillations belonging to the amorphous sample even for films of some few nanometers thickness only.

For the further data processing, a smooth background $R_0(E)$ was subtracted from the reflectivity above the edge and the normalized reflectivity fine structure $\chi(E)$ was calculated according to:

$$\chi(E) = \frac{R(E) - R_0(E)}{R_0(E)}.$$

Subsequently, the energy scale was converted into a photoelectron wave number scale. Examples for the obtained reflectivity fine structures are presented in Fig. 2(b) for two different sputtering times. Obviously, even for only 100 s of sputtering, a pronounced fine structure belonging to the grown Ta-oxide film could be measured.

These fine structures were subjected to a Fourier-transform. As can be seen in Fig. 3, the intensity of the first peak at about 1.5 Å radial distance – which belongs to the first Ta-O-coordination of the oxide film – increases as a function of the sputter time, while its radial distance remains constant. This can be seen in more

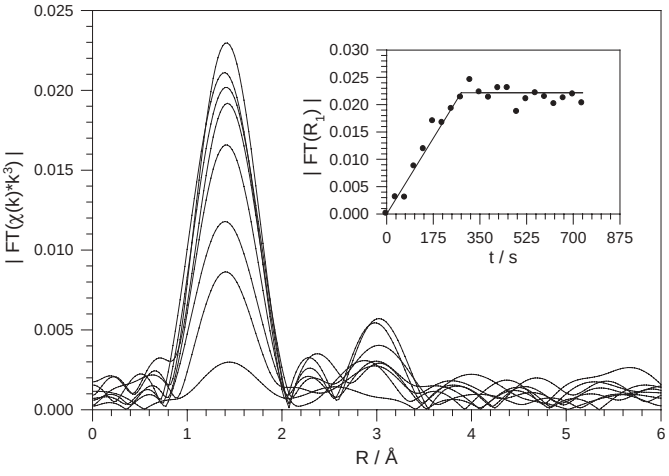

Fig. 3. Magnitude of the Fourier-transforms of the fine structure oscillations extracted from the reflection mode spectra presented in Fig. 2. In the insert, the increase of the peak at about 1.5 Å radial distance (R_1) belonging to the first Ta-O coordination of the growing oxide film is shown as a function of time. 60 s sputter time correspond to about 1.23 nm film thickness. (The data are not phase shift corrected. The k-range for the Fourier transformation is $2\,\text{Å}^{-1} \leq k \leq 9\,\text{Å}^{-1}$).

detail in the insert of Fig. 3, where the intensity of this peak is plotted as a function of sputtering time. According to the detailed analysis of specular reflectivity measurements (Θ-2Θ-scans) with

fixed photon energy, the film thickness was about 15 nm ± 0.2 nm, i.e. the deposition rate is about 1.23 nm/minute. Up to about 300 s sputtering time corresponding to a film thickness of about 6.2 nm, a linear increase of the peak intensity was found, while it is approximately constant for larger sputtering times. Therefore the evolution of the structure of the Ta-oxide film can be followed in situ as a function of time. From the presented data we can conclude that the near range order structure of the amorphous Ta_2O_5 thin films is already developed at very low coverages of the glass substrate. Since the penetration depth of the X-rays into the Ta-oxide film is about 10 nm for the used grazing angle, the constant value observed for the magnitude of the first coordination in the Fourier-transform can not simply be related to the situation that the film thickness equals the penetration depth. A similar behaviour has been observed for sputtered copper films in the past [12]. These experiments were interpreted by the presence of small clusters with a high degree of static disorder [12], which is also given for the amorphous Ta_2O_5-films under investigation in the present study. Therefore it is very likely that such effects are also responsible for the observed thickness dependence of the reflectivity fine structure.

Acknowledgements

We like to thank U. Haake for his help at the beamline during the experiments. We gratefully acknowledge the financial support by HASYLAB and the MWF Nordrhein-Westfalen.

Abstract

The electronic structures of crystalline and aqueous solutions of NaBr and $NaBrO_3$ were studied using *in-situ* Na K and Br L edge X-ray absorption spectra measured under ambient conditions. Analyses of Na K-edge X-ray absorption spectra show that NaBr and $NaBrO_3$ strongly dissociate in aqueous solution and form Na^+ hydration structures, $[Na(H_2O)_n]^+$ ($n = 0$–6). However, the size of the anions significantly affects the formation of the Na^+ hydration structures in aqueous solutions. The ligand field potential (10 Dq) observed in the Br L-edge X-ray absorption spectra allows in determining their dependence not only on the coordination structure between the Br and the first near neighbor but also the second near neighbor in crystalline state, and, the hydration structure and the counter cations in aqueous solutions. DV-Xα molecular-orbital calculations predict that the transitions in the Br L-edge NEXAFS occur from Br 2p to the unoccupied states containing mainly 4d orbitals of Br for both crystalline and aqueous solution. However, 5s and 5p of Br and 3p of Na in addition to the 4d orbitals of neighbor Br for crystalline NaBr and 5s and 5p of Br, 2p of O and 1s of H for aqueous NaBr also contribute to the unoccupied states.

1. Introduction

Many bromine containing compounds have been widely used in a variety of applications such as water purification, agriculture, cars, healthcare, photography, and most importantly as flame-retardants, and recent investigations have shown they persist in the environment [1–3]. Most of these bromine compounds are carcinogenic and toxic [2]. Recent *in-situ* X-ray absorption spectroscopic studies show that the inorganic chlorine compounds rapidly transform to less volatile organic compounds with chlorinated phenolic and aliphatic groups as the principal Cl forms during the humidification of plant material and, thus play a critical role in the cycling of Cl and of several major and trace elements in the environment and may influence human health [4]. Accordingly, the bromine compounds also have opportunities flowing out in the environment, and have possibilities to subsequently change to harmful substances in part of them since these compounds used for commercial applications. Thus, understanding the local electronic structures and the chemical states of the basic bromine compounds in aqueous solution in comparison with corresponding crystalline compounds is extremely important not only in environmental science but for solution chemistry as well.

The availability of synchrotron-radiation sources for X-ray-absorption spectroscopy has made near-edge X-ray-absorption fine structure (NEXAFS) and extended X-ray-absorption fine structure (EXAFS) powerful tools for detailed understanding of electronic and structural properties of materials lacking long-range order, such as catalysts, inorganic materials, minerals, glasses, organometallic complexes, and biological samples like enzymes [5–8]. A new experimental setup for materials requiring *in-situ* X-ray absorption spectral measurements under ambient conditions in the 400–2000 eV photon-energy region using both transmission and total-fluorescence-yield detection techniques has been developed. It's utility has been demonstrated by studying the optically switchable amorphous metal thin films (Mg-*TM*, where *TM* = Ti, Mn, Co, and Ni) under reaction conditions by the exposure of hydrogen, Na, Mg, Al, Br, Sr and Si compounds in crystalline state and in aqueous solutions etc. [9–11].

As a representative example, we present the structural and electronic properties of crystalline and aqueous solutions of NaBr and $NaBrO_3$ obtained from the analyses of the Na K-edge EXAFS and theoretical simulations of Br L-edge NEXAFS using DV-Xα molecular-orbital calculations in comparison with measured *in-situ* X-ray absorption spectra under ambient conditions.

2. Experimental section

Crystalline compounds (NaBr and $NaBrO_3$) were purchased from Aldrich Chemical Co. (Milwaukee, WI) and used for the measurements. The 0.1 M aqueous solutions were freshly made with de-ionized water. The X-ray absorption measurements were conducted at Beamline 6.3.1 at the Advanced Light Source (ALS), Lawrence Berkeley National Laboratory [12]. During the measurements, the ALS operated at 1.9 GeV between 200 mA and 400 mA. The total-fluorescence-yield was detected using a Hamamatsu GaAsP photodiode (G1127-02). The aqueous solutions were placed in a 6 mm diameter tube containing a 1.5–2 mm wide slit. The surface of the solution at the slit in the tube was exposed to the X-ray beam and fluorescent photons were collected from the solution by the detector (90° to the X-ray beam). For crystalline compounds, very thin layer of the sample was prepared on a conducting carbon tape and the measurements were performed at gracing incidence to minimize the self-absorption effects in the measured absorption spectra. Details of the experimental setup are given elsewhere [10]. The photon energy was calibrated using the first inflection points of the Na K and Al K edge X-ray absorption spectra of crystalline NaBr and Al metal, respectively. All the spectra were normalized to the absorption-edge jumps [6].

The Na K-edge EXAFS were analyzed using WinXAS (2.1) [13]. The theoretical phase shifts and scattering amplitudes for the crystalline NaBr and $NaBrO_3$ were derived from the crystallographic data using the FEFF (6.01) codes [14]. The structure of $[Na(H_2O)_6]^+$ reported previously based on the solution X-ray diffraction studies was used for the aqueous solutions [15]. The curve fittings were performed in k space between $\sim 2.8\,Å^{-1}$ and $7.1\,Å^{-1}$ using multi-shells for crystalline and single-shell (Na-OH_2) for aqueous solutions.

The DV-Xα molecular-orbital calculations [16] were performed for Br L_3-edge NEXAFS for the crystalline and aqueous solution of NaBr as a representative example using a half-occupied core-level (Slater's transition state [17]) and an expanded basis set. For crystalline NaBr, a model consisting of 14 Na and 13 Br atoms with Br atom at the center based on the crystallographic data was used for the calculations [18]. For 0.1 M aqueous NaBr, the calculations performed previously based on a model with one Br atom surrounded by six water molecules were used for comparison [11]. In the DV-Xα calculations, Na and Br atoms were given the charges of $+1$ and -1, respectively. The resulting model was embedded into a Madelung potential field consisting of 702-point charges for the influence of electrostatic energy of the clusters. The unoccupied orbitals included in the calculations are 3p, 3d, 4s, and 4p of Na, and, 4d, 5s, 5p and 5d of Br. The outermost orbitals, 4p of Na and 5d of Br, were included in the calculations to suppress the numerical error for the rest of the orbitals, but they were excluded when evaluating the partial density-of-states (PDOS). The electron transition probabilities (ETP) were evaluated from the dipole matrix element between a core state and unoccupied molecular states [19, 20]. The ETP were convoluted using Gaussians with FWHM of 1.5 eV and 2.5 eV for NaBr clusters and hydrated Br^- ion models, respectively. An appropriate arctangent function was included in the simulated spectra to describe the absorption continuum.

3. Results and discussion

The Na K-edge EXAFS spectra for crystalline and aqueous solutions of NaBr and $NaBrO_3$ are shown in Fig. 1. The features

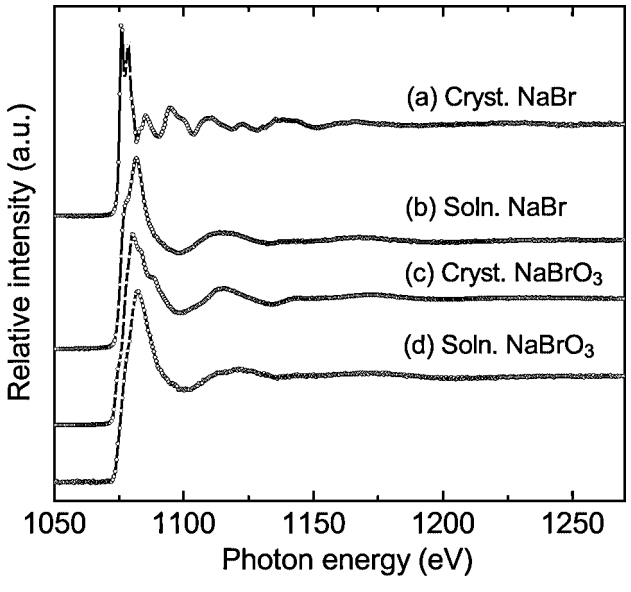

Fig. 1. The Na K-edge EXAFS for (a) crystalline NaBr, (b) 0.1 M aqueous NaBr, (c) crystalline $NaBrO_3$ and (d) 0.1 M aqueous $NaBrO_3$.

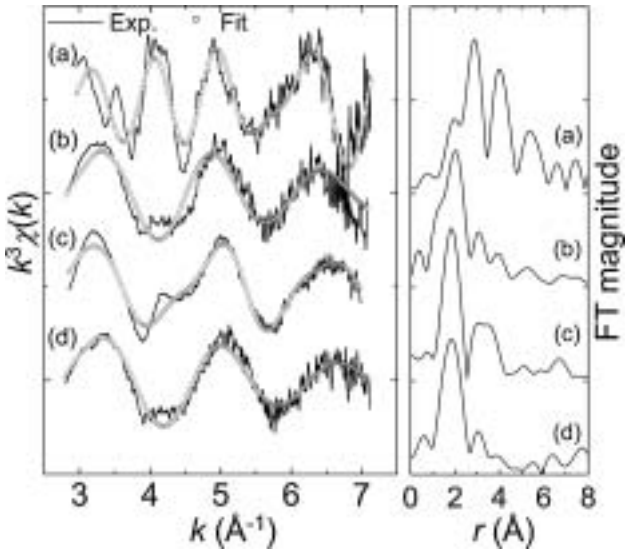

Fig. 2. The Na K-edge k^3-weighted EXAFS (left panel) and the corresponding Fourier-transformed radial distribution functions (right panel) for (a) crystalline NaBr, (b) 0.1 M aqueous NaBr, (c) crystalline $NaBrO_3$ and (d) 0.1 M aqueous $NaBrO_3$.

in the NEXAFS region for the crystalline NaBr are in good agreement with those reported previously by Murata *et al.* [21]. Further, the fine structures in the post-edge region are prominent in the spectrum for the crystalline NaBr unlike for the aqueous solution, where these features became broad suggesting the lack of long-range order in solution. The k^3-weighted Na K-edge EXAFS spectra and the corresponding Fourier-transformed radial distribution functions (RDFs) for crystalline and aqueous solutions of NaBr and $NaBrO_3$ are shown in Fig. 2. The changes in the profiles in both k^3-weigthed EXAFS and RDFs between crystalline and the corresponding aqueous solution reflect the effect of dissolution of NaBr and $NaBrO_3$ in water resulting from the disassociation of Na-Br/Na-BrO_3 bonds and the formation of Na^+ hydration structures, $[Na(H_2O)_n]^+$ ($n =$ 0–6). The coordination number (N), inter-atomic distance (r) and the disorder parameter (σ^2) derived from the analyses of Na K-edge EXAFS are given in Table I. For crystalline NaBr and $NaBrO_3$, the inter-atomic distances derived from the EXAFS fits with fixed coordination number of Na^+ to 6 are comparable to

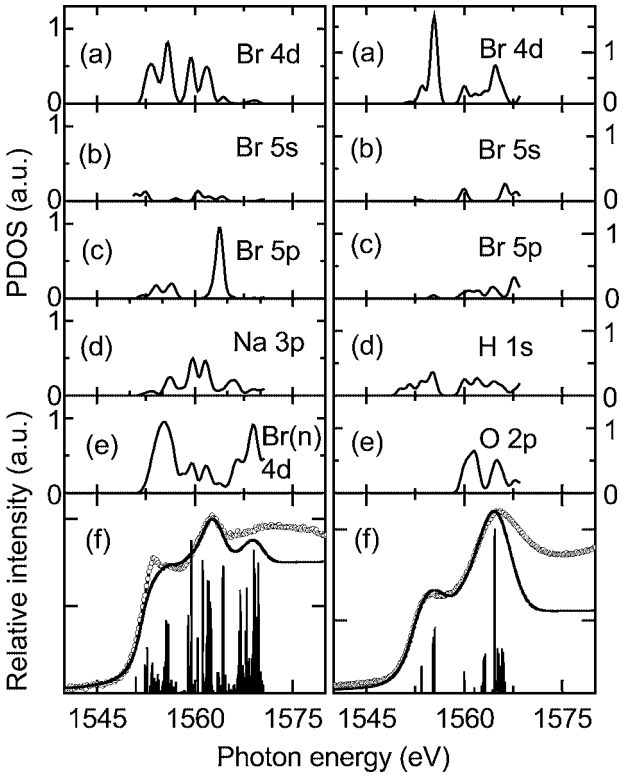

Fig. 4. Partial density of states (PDOS) (a–e), and the electron transition probabilities (ETP) (f) obtained from the DV-Xα molecular-orbital calculation using NaBr clusters and hydrated Br models in the energy range, 1540 eV to 1580 eV, for the crystalline (left panel) and aqueous solution (right panel) of NaBr, respectively. The convoluted ETP using Gaussians (FWHM of 1.5 eV and 2.5 eV for NaBr clusters and hydrated Br^- ion models, respectively) and appropriate arctangent functions (solid line) are compared with the experimental spectra (circle) for crystalline (left panel) and aqueous solution (right panel) of NaBr. Br(n) indicates neighbor Br.

those reported previously [18, 22]. The coordination numbers of Na^+ and the inter-atomic distances of Na-O are ∼5.1 and 2.38 Å for aqueous NaBr, and, ∼4.4 and 2.29 Å for aqueous $NaBrO_3$, respectively. The uncertainty of the hydration structures of Na^+ ions causes a decrease in the coordination numbers of Na^+ in the aqueous solutions of NaBr and $NaBrO_3$ compared to the corresponding crystalline compounds as suggested by the first-principles molecular dynamics simulations and solution X-ray diffraction studies [15, 23, 24]. However, the difference in the coordination numbers of Na^+ and the inter-atomic distances of Na-O between the aqueous solutions of NaBr and $NaBrO_3$ suggests the size of the anions, Br^- and $[BrO_3]^-$, plays an important role in the formation of the Na^+ hydration structures.

Bromine L_3-edge NEXAFS for the crystalline and aqueous solutions of NaBr and $NaBrO_3$ are shown in Fig. 3. The spectra show relatively two broad bands. In NaBr and $NaBrO_3$, Br is situated in cubic symmetry. Hence the unoccupied 4d orbitals of Br split into lower energy t_{2g} and higher energy e_g states by the ligand-field potential. Thus, the two bands observed in the Br L_3-edge NEXAFS are assigned to the excitation of $2p_{3/2}$ core electrons into the t_{2g} and e_g states of the unoccupied 4d orbitals. Consequently, the energy separation between t_{2g} and e_g states [$10\,Dq = E(e_g) - E(t_{2g})$] is directly related to the ligand-field potential which in turn depends on the inter-atomic distances between Br and the first near neighbor in crystalline compounds and the hydration in aqueous solutions as shown previously [11, 25]. The values of 10 Dq for the crystalline and aqueous solution of NaBr are ∼9.0 eV and ∼ 10.5 eV, respectively. Unlike NaBr, the 10 Dq value of ∼14 eV is found for both crystalline and aqueous solution of $NaBrO_3$. This is in turn ∼2 eV larger than the value reported for $KBrO_3$ (∼12 eV) [11]. These results suggest the dissociation of NaBr and $NaBrO_3$ into Na^+, Br^- and $[BrO_3]^-$ in aqueous solutions. However, $[BrO_3]^-$ ions are stable in aqueous solution and do not dissociate further. The change in the 10 Dq values between $NaBrO_3$ and $KBrO_3$ gives evidence that the ligand field potential depends not only on the coordination structure between the Br and the first near neighbor but also the second near neighbor in crystalline state, and, the hydration structure and the counter cations in aqueous solutions. This is also in accordance with the Na K-edge EXAFS results that suggest the size of the anions significantly affects the formation of the cation hydration structures in aqueous solutions.

The PDOS (a–e) and the electron transition probabilities (ETP) (f, bars) obtained from the DV-Xα molecular-orbital calculation using NaBr clusters and hydrated Br models in the energy range, 1540 eV to 1580 eV, are given in Fig. 4 for the crystalline (left panel) and aqueous solution (right panel) of NaBr, respectively. The simulated curves (f, solid line) along with the experimental (f, circle) spectra are also included in Fig. 4. It can be seen that the simulated spectra are in good agreement with the experimental spectra for both crystalline and aqueous solution of NaBr. Further, the ETP suggest that the transitions occur from Br 2p to the unoccupied states containing mainly 4d orbitals of Br for both crystalline and aqueous solution. However, 5s and 5p of Br and 3p of Na in addition to the 4d orbitals of neighbor Br for crystalline NaBr and 5s and 5p of Br, 2p of O and 1s of H for aqueous solution of NaBr also contribute to the unoccupied states as shown in PDOS.

4. Conclusions

Analyses of the Na K-edge EXAFS show the disassociation of Na-Br/Na-BrO_3 bonds in aqueous solution and the formation of Na^+ hydration structures, $[Na(H_2O)_n]^+$ ($n = 0$–6). However, the size of the anions significantly affects the formation of the Na^+ hydration structures in aqueous solutions. The Br L-edge NEXAFS also shows that NaBr and $NaBrO_3$ dissociate in aqueous solutions, however, $[BrO_3]^-$ ions do not dissociate

further. The ligand field potential obtained from Br L_3-edge NEXAFS indicates that it depends not only on the coordination structure between the Br and the first near neighbor but also the second near neighbor in crystalline state, and, the hydration structure and the counter cations in aqueous solutions. DV-Xα molecular-orbital calculations predict that the transitions in the Br L-edge NEXAFS occur from Br 2p to the unoccupied states containing mainly 4d orbitals of Br for both crystalline and aqueous solution. However, 5s and 5p of Br and 3p of Na in addition to the 4d orbitals of neighbor Br for crystalline NaBr and 5s and 5p of Br, 2p of O and 1s of H for aqueous NaBr also contribute to the unoccupied states.

Abstract

FAME is the French Absorption spectroscopy beamline in Material and Environmental sciences at the ESRF (France), operational since September 2002. Technically speaking, the source is a 0.85 T bending magnet and the main optical element is a two-crystals monochromator using either Si(111) or Si(220) monocrystals so that the available energy ranges from 4 to 40 keV. The first crystal is liquid nitrogen cooled in order to avoid a thermal bump and thus preserve the energy resolution. The second crystal is dynamically bent during the energy scan in order to focus the beam in the horizontal plane. Two bendable mirrors are located before and after the monochromator, for beam-collimation (to optimize the energy resolution) and vertical focalization, respectively. During scans, the beam on the sample is kept constant in position and size (around $150 \times 200\,\mu m^2$, V × H). The high flux on the sample combined with the sensitivity of our 30-elements fluorescence detector allow to decrease the detection limit down to 10 ppm or around less than a monolayer. Moreover, quick-EXAFS acquisition is operational: the acquisition time may be reduced down to 30 s.

1. Introduction

FAME is the French Absorption spectroscopy beamline in Material and Environmental sciences at the ESRF (France), in operation since September 2002. This beamline is one of the four french Collaborating Research Group (CRG) beamlines.

The possibility of determining the local structure of elements at very low concentration is one of the most important and appealing features of X-ray Absorption Spectroscopy. This technique gathers a large and growing community of users comprising environmentalists, electrochemists, biologists, material and catalysis scientists. That is why it was decided to provide this community with a dedicated beamline, thus extending available beamtime for absorption experiments. The XAS-station of CRG-IF was then transferred to the CRG-FAME beamline and a new optical line was designed and built. The project was supported by a number of laboratories from the Centre National de la Recherche Scientifique (CNRS), the Commissariat à l'Energie Atomique (CEA) and the Universities of Grenoble and Lyon. Given the high implication of regional laboratories, a partial financing from "Région Rhone-Alpes" has been moreover obtained. 50 to 60% of the beam time will be dedicated to environmental and earth science studies, the remainder will be used for material, chemical and biological applications. We give herein a brief description of the beamline, the various optical elements and the experimental apparatus. More technical details and pictures can be found on the FAME website [1].

2. General features

The FAME beamline is located on a 0.85 T bending magnet (BM) of the ESRF storage ring working at 6 GeV. The beamline design has been optimized in order to accept the 2 mrad horizontal and 0.3 mrad vertical divergences delivered by the BM, *i.e.* its full fan. The magnification ratio (source to monochromator distance *vs* monochromator to sample distance) has been chosen to be 3 to maximize the monochromator transmission. The flux on the sample is maximized when the beam is horizontally focused bending the 2nd crystal of the monochromator [2].

The basic optical design of FAME is shown in Fig. 1. The main optical element is the monochromator, located between two grazing-incidence mirrors. Due to the Rhodium coating of the mirrors, such a configuration is suitable for studies at energies lower than 22 keV. The beamline can also operate in a mirror-free configuration, extending the energy limit close to the BM cutoff. The photon energies available on FAME range then from 4 to 40 keV: all the elements with atomic number higher than 20 (Calcium) can be studied either at the K or L or both edges.

In order to define the size and the optic axis of the beam, two pairs of vertical and horizontal micrometric slits are located at 23.5 m (slits 1) and 30.5 m (slits 2) from the source. To decorrelate the beamline from possible variations in direction or position of the X-ray source, water-cooled tungsten carbide slits are located before our optical elements. The distance between these slits was taken as large as possible in order to precisely define the beam. Other slits are located after the first mirror (slits 3) and after the monochromator (slits 4), to remove the scattered beams induced by the optical elements.

FAME was designed in order to have the maximum flux on the sample, especially at low energies. Only two Be windows are on the beam path, a first 500 μm Be window between the storage ring and the beamline and a second one at the end of the beamline, just before the sample. The vacuum device was conceived using differential pumping between the different elements, in order to have a smooth transition between the $1 \sim 2 \cdot 10^{-9}$ mbar range

*Corresponding author: proux@grenoble.cnrs.fr

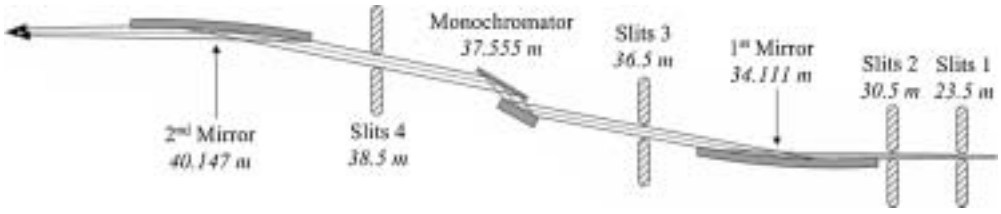

Fig. 1. Schematic diagram of the CRG-FAME beamline optic elements (side view). The distances from the BM source of the various elements are indicated (the sample is located at 50.065 m).

achieved in the mirrors chambers (ionic pumps) and the $2 \sim 5 \cdot 10^{-8}$ mbar range achieved in the monochromator (turbo pump linked to a cryo-pumping effect).

3. Optical elements

3.1. *First mirror*

The first optic component installed on FAME is a horizontal bendable mirror that deflects the beam vertically, manufactured by IRELEC (France). The mirror is a monocrystalline Silicium ingot with a 50 nm Rhodium coating (manufactured by SAGEM – REOSC S.A., France). Transverse and longitudinal inclinations of the mirror use goniometric cradles. They are completely separated from height and bender adjustment: all the movements are then uncorrelated. The mirror can be bended using a single jack bender (symmetric bending) and its position (height, incidence and tilt angles) can be adjusted independently from the vacuum vessel. The white beam incidence angle on the mirror can vary in the 3–7 mrad range. The cutoff energy ranges then from 9 to 22 keV.

The main functions of the 1st mirror are the following:

- collimation of the incident beam to adapt its vertical divergence to the 1st crystal of the monochromator, in order to optimize the energy resolution of the monochromator,
- reduction of the high energy harmonics' intensity,
- reduction of the heat load on the monochromator.

Optical tests were performed in the ESRF metrology laboratory with a Long Trace Profiler [3] and a PROMAP 512 apparatus, in order to check the radius of curvature, the slope error, profiles and shape errors and the rugosity. The obtained values are gathered in table I. With respect to the large size of the polished surface, the measured slope errors and roughness are really good.

The cooling device of the mirror has been designed in order to limit as much as possible the transmission of vibrations coming from the beamline to the reflecting surface. For this, the cooling apparatus is linked to the cooled part of the mirror *via* a liquid metallic alloy. The vibrations induced by the cold water circulation are then damped by the liquid alloy. Moreover, the cooling water temperature is continuously adjusted in order to obtain a 2 °C gradient of temperature for the water between the entrance and the exit of the mirror chamber. The slope error of the mirror is then as low as possible.

Table I. *Mirrors main characteristics.*

Mirrors characteristics	1st mirror	2nd mirror
optical and geometrical Lengths (mm)	*1150*–1350	*1250*–1450
optical and geometrical Widths (mm)	*80*–110	*80*–110
Thickness (mm)	54	35
minimum Bending Radius (km)	38	10
maximum Bending Radius (km)	3.4	1.0
mean and central rms slope error (μrad)	*2.4*–1.8	*3.0*–2.5
mean rms roughness (Å)	1.4 ± 0.3	2.6 ± 1.0

Table II. *Monochromator main characteristics.*

Monochromator characteristics	wanted	obtained
axis angular resolution	1/10000°	1/40000°
maximum angular deviation of the axis during rotation	5 μrad on 5° range	5 μrad on 40° range
2nd crystal translation precision	0.1 μm	0.1 μm
monochromator translation	65 ± 0.05 mm	100 ± 0.001 mm
maximum angular deviation of the monochromator during translation	5 μrad on 65 mm translation	5 μrad on 100 mm translation

3.2. *Monochromator*

A two-crystals monochromator is located after the first collimating mirror. Its design and construction were performed by our team. The main numerical characteristics are gathered in table II. The obtained characteristics, as checked by metrology at the ESRF [4], are always better than expected. Two kinds of monocrystals are available, Si(111) and Si(220), well adapted in the energy ranges 4–25 keV and 5–40 keV, respectively. Moreover, the monochromator can be used in two configurations: variable exit (pseudo-channelcut mode) and fixed exit (constant vertical position of the beam after the monochromator).

The first crystal is liquid nitrogen cooled at around 110 K to avoid thermal bump. At this temperature, the thermal conductivity of silicon is maximum and its thermal expansion is almost zero. The high heat load of the incoming beam (300 W at the maximum, in the mirror-free configuration) is removed using flexible copper wires, avoiding vibrations. The second crystal is dynamically curved (from 1 m to ∞) during XAFS energy scans in order to keep the beam focused on the sample in the horizontal plane [5]. The horizontal FWHM size of the spot is always below 300 μm, even at low energies (small radius of curvature of the 2nd crystal). Figure 2 shows an example of a focused beam shape obtained at 7 keV.

The axis of the monochromator is equipped with a RON905 encoder (resolution: 1/1000°), linked to an interpolator box (1/800). The theoretical resolution is then 1/80000° while the measured resolution is 1/40000° (Tab. II). The axis brushless motor is equipped with a McLennan PM600 motor controller.

The monochromator can work in two configurations: in the step-by-step mode (classical EXAFS) and in the continuous one (quick EXAFS). In both cases, the angle movement during the energy scan operates simultaneously with the adjustments

1) of the 2nd crystal curvature,
2) of the parallelism between the two crystals, allowing to remain at the maximum of the 2nd crystal's rocking curve,
3) of the EXAFS table height (see § 4).

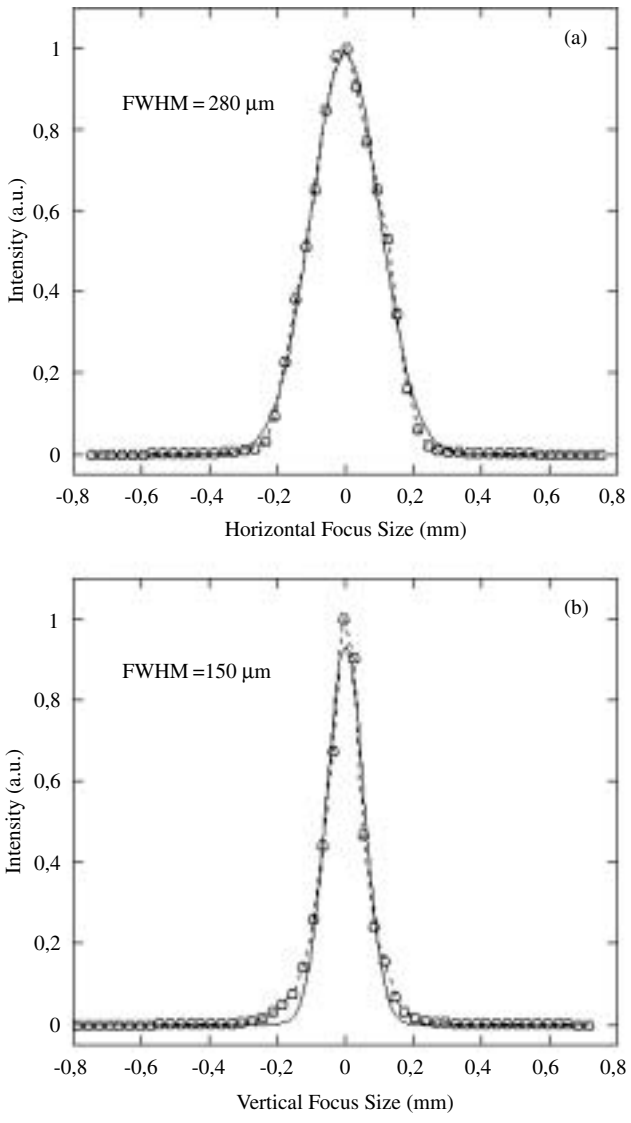

Fig. 2. Focused beam shapes in the horizontal (a) and vertical (b) planes, measured (open circles and dashed line) and superimposed Gaussian fit (solid line). The measurements have been performed at 7 keV using Si(111) monochromator crystals, with a 7 mrad incidence angles for the mirrors and using the entire vertical and horizontal divergences.

3.3. *Second mirror*

The 2nd mirror is located in the monochromatic part of the beamline. Its objectives are to eliminate the remaining harmonics and mainly to focus the beam in the vertical plane on the sample. The reflective angle is always equal to the one of the 1st mirror, in order to obtain a perfect horizontal beam after it. Compared to the 1st mirror, the 2nd one is longer and thinner (Tab. I), in order to reach smaller radius of curvature. Moreover, this high length allows us to keep its height fixed during an energy scan even if the output height of the monochromator varies (variable exit mode). The position of the beam on the mirror can then slightly change without being close to the edges.

The vertical size of the beam on the sample can then be adjusted between 100 to 500 µm (example Fig. 2.b), with respect to the kind of studied samples (mainly with respect to their homogeneity).

4. Experiment apparatus

The X-ray Absorption Spectroscopy (XAS) apparatus on FAME is composed of the previously existing elements on the IF beamline XAS station. The position of the experimental table (height, transversal translation and rotation) can be controlled so that the beam position on the sample remains constant. The height position (precision about 1 µm) is dynamically adjusted during an EXAFS scan, allowing the beam position on the sample to remain constant.

The sample is located on a "goniometric head" sample holder. Different movements are motorized: transverse and vertical translations, rotation (360°) and goniometric cradles (±7°). Different classical environment can be mounted on the goniometric head: 1) basic vacuum chamber (for low energy experiment), 2) liquid nitrogen and 3) liquid helium cryostats.

Moreover, the experimental environment can be easily adapted to the users' need and can accept several apparatus elaborated in other laboratories. This is especially suitable for *in situ* studies, electrochemistry cells [6], catalysis ovens in gaseous atmosphere [7], high temperature and high pressure cells [8, 9]...

Three kinds of detectors are used on FAME. The transmitted signals are measured with Si diodes collecting the beam scattered by kapton foils. The fluorescence measurements are performed using a 30-elements solid germanium Canberra energy-resolved detector. This detector is very well adapted for studies on highly diluted samples or thin films. For a 125 and 500 ns shaping time, its energy resolution is about 300 and 250 eV and the maximum allowed count rate by element is about 100 000 and 30 000 counts/s, respectively. Finally, an electron detector (analysis temperature from 77 to 300 K) working with helium atmosphere (Conversion Electron mode) is also well suitable for thin films studies.

5. Perspectives and conclusion

We have described the new CRG-FAME XAS beamline in operation at the ESRF (France) since september 2002. The main optic element is a two-crystals monochromator equipped with two kinds of monocrystals, Si(111) and Si(220). The available energy ranges from 4 to 40 keV. The first crystal is liquid nitrogen cooled in order to avoid thermal bump and thus to preserve the energy resolution. The second crystal is dynamically bended during the energy scan in order to focus the beam in the horizontal plane. Two bendable mirrors are located before and after the monochromator, for beam-collimation (optimisation of the energy resolution) and to obtain a vertical focus. The size (around $250 \times 150\,\mu m^2$) and the position of the beam on the sample is then kept constant during scans. The high flux on the sample combined with the sensitivity of the fluorescence detector allow to decrease the detection limit down to 10 ppm and the acquisition time of a spectrum to around 30 s (QEXAFS mode). A micro-focalisation apparatus (Kirkpatrick-Baez) will allow to decrease the size of the beam, $20 \times 20\,\mu m^2$ with full flux, $1 \times 1\,\mu m^2$ with slits. Preliminary micro-XAS experiments have been performed: construction of the optic elements will be achieved this year.

Abstract

The time-resolved X-ray absorption spectroscopy (QEXAFS) yields structural information about e.g. fast chemical decomposition reactions, thin film deposition, solid-state reactions, and phase transformations. Here we describe a new experimental set-up for QEXAFS experiments enabling the acquisition of full EXAFS spectra with a scan range of up to about 3 keV and a repetition rate of typically 10 Hz. Depending on photon flux and sample quality, repetition rates of up to 40 Hz can be used. The new monochromator design employs a fixed-exit channel cut crystal and a cam driven tilt table for rapid angular oscillations. The detection of fluorescence radiation or surface sensitive techniques can be applied. The new monochromator in combination with refractive X-ray lenses for beam focusing also allows XANES-microtomography in a reasonable time frame.

1. Introduction

Approximately 15 min are necessary to measure both the X-ray absorption near edge structure (XANES) and the extended X-ray absorption fine structure (EXAFS) in bulk materials with high accuracy using standard scanning monochromators. The continuous Quick scanning EXAFS (QEXAFS) technique [1, 2], however, allows measurements in seconds and can be applied especially for *in situ* experiments in condensed matter physics, chemistry and materials science. Processes studied cover e.g. catalytic reactions [3], thin film deposition [4], surfaces [5] and metal dissolution [6, 7]. However, the speed range of the normally used stepper motors limit the data collection times for one spectrum to about 1 s [8], however, even several edges can be accessed subsequently. Many QEXAFS beamlines are in standard operation worldwide at bending magnet and insertion device sources. An optimized crystal bender was developed to cope with the high heat loads from high power synchrotron radiation sources [9]. Using a synchronously moving undulator, even dilute biological samples can be investigated [10]. Faster measurements are feasible by combining fast data acquisition [11] with the Piezo-QEXAFS method [12], where tilt tables actuated by piezo-stages mounted below the monochromator crystals are used to change the Bragg angle in an oscillatory manner. This allows XANES scans at the Cu K-edge with a time resolution of down to 4.5 ms [11]. This technique allows investigating e.g. solid-state transformations in the millisecond range [13]. Even dilute samples can be investigated by detection of the fluorescence radiation [14] or total electron yield. Also wide scan ranges of typically 500 eV at 10 keV photon energy are accessible with a time resolution of down to 50 ms [15]. Such monochromators can make excellent use of third generation synchrotron sources as the attainable time resolution directly depends on the available photon flux.

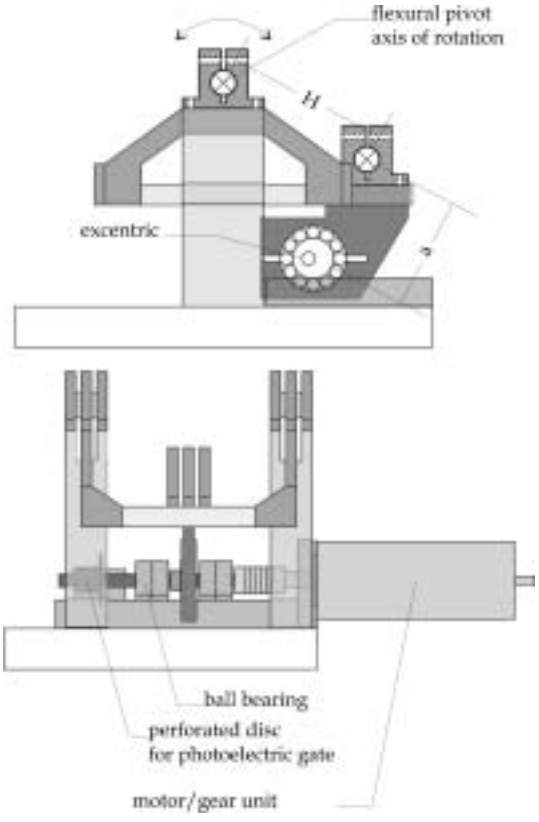

Fig. 1. Construction of the driving system of the monochromator: View from the front (top) and in the beam direction (bottom). See text for details.

2. New setup for wide energy ranges

In this paper we present a new experimental setup for QEXAFS experiments. The monochromator design employs a channel cut crystal mounted on a cam driven tilt table for rapid angular oscillations [16]. The general setup is shown in Fig. 1.

The excentricity of the disk mounted on the rotating shaft and the lengths H and a of the lever arms determine the accessible angular range. For the experiments $H = 79.4$ mm and $a = 55.5$ mm were used. Different disks can be mounted to change the angular range; in our case an excentricity of e.g. 1.4 mm relates to 1.01° amplitude in Bragg angle. The oscillating movement is approximately sinusoidal around the selected central Bragg angle.

3. Experimental results

Fig. 2 shows QEXAFS spectra of a Cu metal foil at different rotation frequencies of the drive shaft. Each rotation corresponds to two spectra, one up and one down in energy. Thus the scan times range from 50 ms at 10 Hz oscillation frequency to 12.5 ms

*e-mail: frahm@uni-wuppertal.de

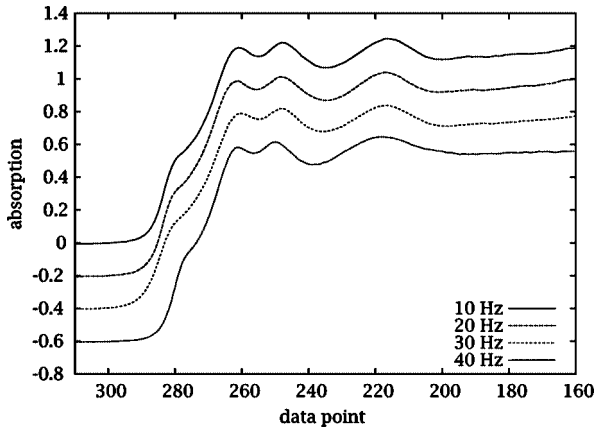

Fig. 2. QEXAFS spectra of a Cu metal foil at different oscillation frequencies. Scan times range from 50 ms (10 Hz) to 12.5 ms (40 Hz). Data were collected at the undulator beamline 1-ID at the APS (spectra vertically shifted).

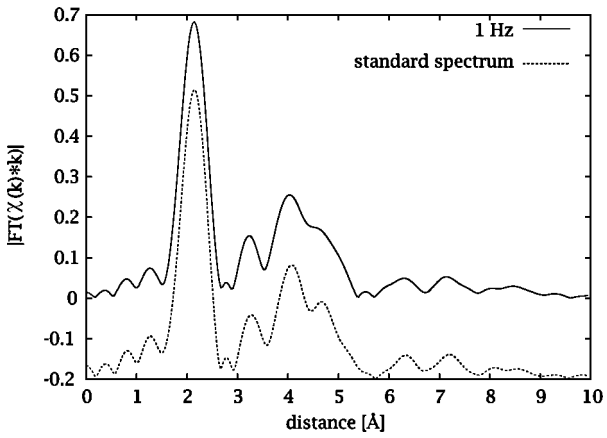

Fig. 4. Magnitude of the Fourier-transform of a fast Ni spectrum in comparison to the result of a standard measurement (vertically shifted).

at 40 Hz. A Si(111) crystal and a small excentricity resulting in a small angular range were selected to cover the Cu XANES range. The maximum frequency for stable operation of the whole setup amounted to about 40 Hz. Data were collected at the undulator beamline 1-ID at the APS. To avoid thermal effects in the first monochromator crystal due to the high heat load of the insertion device the first monochromator crystal was cryogenically cooled using liquid nitrogen.

An extended energy range of 700 eV at the K-edge of a Ni-foil measured with a larger excentricity is shown in Fig. 3, its Fourier transform in Fig. 4. The results agree with the standard data collection mode.

An EXAFS spectrum of a typical catalyst material composed from a mixture of CuO and ZnO is shown in Fig. 5. The scan range amounts to 1800 eV covering both Cu and Zn K-edges; the operation frequency was 10 Hz. The single scan shown was collected in 50 ms. Also displayed is a Cu reference foil measured *simultaneously* using the transmitted beam after the sample. This is an important possibility of the QEXAFS method which allows determining even small edge shifts during chemical reactions unambiguously.

In the case of large energy ranges, however, the beam offset changes significantly by the rotation of a simple channel cut crystal. Such beam movement is not acceptable for certain experiments. Thus for improved performance of the monochromator system, a fixed-exit channel cut crystal is available. In this case the two reflecting planes have a special shape [17, 18] to maintain a fixed exit height. A Si(311) crystal based on this principle is shown in Fig. 6. First tests demonstrated the basic operation of the principle; however, this crystal is optimized for work at high energies.

Especially in the fields of materials and environmental sciences much interest is in imaging the two or three dimensional

Fig. 6. Channel cut Si(311) crystal for a fixed exit beam. Total length 100 mm, reflecting surfaces 45 mm.

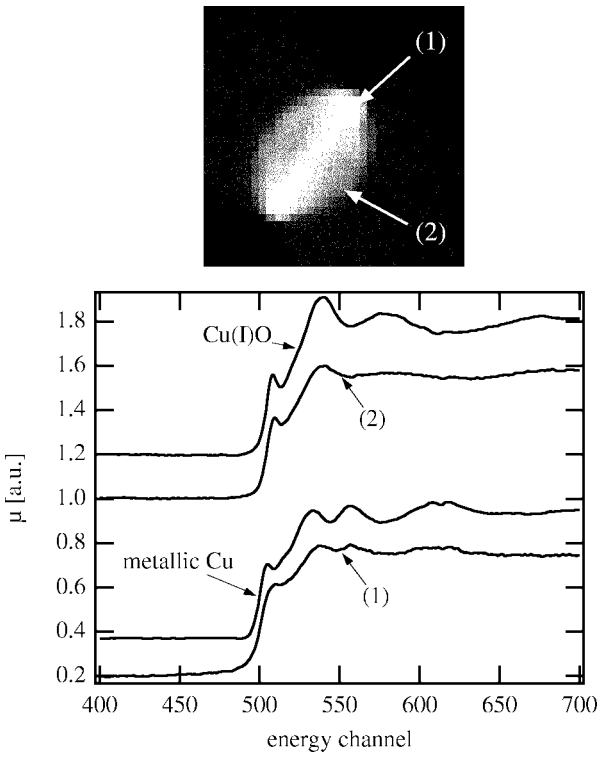

Fig. 7. Top: Absorption of the Cu(I)O/Cu sample described in the text. The size of the cross section shown is $170 \times 170\,\mu m^2$, the pixel size $5 \times 5\,\mu m^2$. Bottom: Reconstructed Cu K-edge spectra of the sample at the two positions labelled (1) and (2) in comparison to reference materials (spectra vertically shifted).

distribution of elements and their valance states with μm resolution. For a detailed analysis the knowledge of the XANES spectra or even EXAFS spectra at each position in three dimensions is necessary. Such investigations involve a multiplicity of scans, and conventional scanning is impractical. To cover 0.25 mm^2 with 5 μm resolution in just two dimensions requires 10.000 spectra, which results in several days of necessary beam time using conventional XAFS beamlines. If one uses an oscillating monochromator at reasonable 10 Hz operation frequency, the scan time reduces to about 8 min. Thus fast monochromators make such data collection feasible – even for the more demanding XAFS 3D-tomography. Such experiments were performed at the ESRF (bending magnet beamline) and the APS, exploiting here the highly intense beam from an X-ray undulator. Focusing was performed by X-ray lenses [19] yielding a micro beam size of about $6 \times 2\,\mu m^2$. The sample was translated and rotated to obtain a sufficiently large number of projections for the 3D reconstruction of the sample. At each position several fast XANES scans were collected, which makes it possible to determine the spatial distribution of valence and atomic short range order on the μm-scale, as shown in Fig. 7. Here a small tip made from a Cu foil covered with Cu(I)O was reconstructed. The Cu K-edge spectra shown in Fig. 7 were reconstructed for the two locations pointed out in the cross section of the sample. Further results of a real catalyst are given in [20].

4. Conclusions

The new cam driven monochromator system shows an excellent performance, long time stability and allows scanning large energy ranges up to several keV. Thus several edges can be covered in one spectrum. The accessible time resolution of currently 12.5 ms is sufficient for a wide range of scientific applications. Using cryogenic cooling, the silicon crystal optics is capable of receiving the full heat load from third generation undulator sources. The monochromator is a portable device that can easily be installed on almost any white beam experimental station. The new possibility to perform XAFS-microtomography investigations is very promising especially for materials science. By operating beamlines at special insertion devices generating circularly polarized light (see e.g. [21]) one can use QEXAFS even for investigations of magnetic processes in technologically important materials [22, 23].

Acknowledgment

The authors thank the staff members of the ESRF (BM5) and the APS (1-ID) for the excellent support. Use of the Advanced Photon Source was supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Science, under Contract No. W-31-109-ENG-38. This project was funded by the MWF Nordrhein-Westfalen. The preparation of figures by B. Griesebock and C. G. Schroer is highly appreciated.

Abstract

The present paper describes the concept of the Dispersive X-ray Absorption Spectroscopy beamline at the Brazilian Synchrotron Light Laboratory. The present performance and some of the very first experiments are reported. Emphasis is put on experiments related to electrochemical reactions and resonant reflectivity on magnetic thin films and multilayers.

1. Introduction

We describe here the concept and present performance of the Dispersive X-ray Absorption Spectroscopy (DXAS) beamline at LNLS (Brazilian Synchrotron Light Laboratory). The specificity of this beamline is that it allows collecting absorption data simultaneously over an extended range of photon energies without any mechanical motion [1, 2]. This characteristic is specially suited for measurements requiring good accuracy and high stability, for instance in XANES and XMCD experiments [3, 4]. We present in this paper some very first commissioning results and preliminary experiments related to electrochemical insertion of metals into polymers and resonant reflectivity on magnetic thin films and multilayers.

2. The conceptual design and optics

The concept of a dispersive XAS beamline is based on a curved crystal monochromator that selects a bandwidth of a few hundred eV from the white synchrotron light source and focuses it at the sample position. The incident angle varies continuously along the crystal, providing a continuous change of the energy of the Bragg-reflected photons. The bending mechanism of the curved crystal monochromator has been developed at LNLS and its technical details will be published elsewhere. All rotations (Bragg, tilt and yaw angles) are accomplished by high precision Huber goniometers. The radius of curvature is imposed by two independent momenta on crystal extremities without changing the position of the central part. There is also a mechanism for twist correction and for cooling the crystal. Everything works inside a high vacuum chamber. The two independent momenta allow reducing significantly the spherical aberrations. The whole bandwidth is focused in the horizontal plane down to 150 μm. The vertical focusing is provided by an 800 mm-long Rh coated mirror, working at a grazing angle of 4 mrad. Its bending mechanism allows vertical beam collimation or focusing to about 500 μm at the sample position. This leads to the possibility of working with very small samples, like small single crystals or samples inside a high pressure cell.

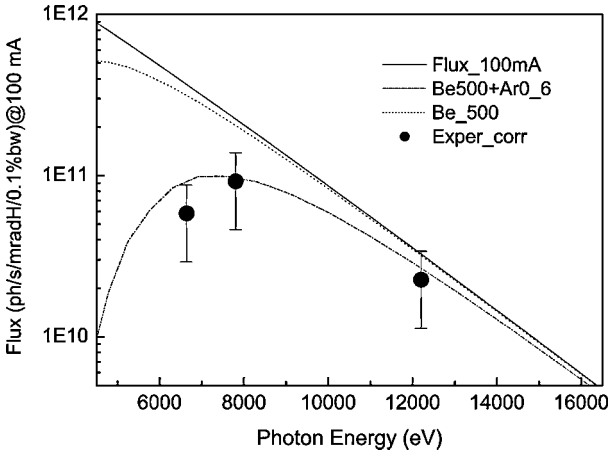

Fig. 1. Calculated photon flux at the DXAS/LNLS beamline. The continuous line represents the emitted flux from the bending magnet; the dotted line the flux attenuated by four 125 μm Be-windows, and the dashed-dot line the flux attenuated by the Be-windows and the 0.6 m-beam path in the air. Experimental points were measured with a photodiode at the focus point.

A curved Si(111) crystal monochromator selects radiation from a bending magnet source in the X-ray range from 4 keV up to 14 keV. The calculated flux throughput from LNLS storage ring working at 1.37 GeV and 100 mA is shown in figure 1. The measurements, after a total of 500 μm (4 × 125 μm) Be-windows and 0.6 m beam path in the air, have been performed with a photodiode at the focus point and are in good agreement with calculations. The beam path in the air can be reduced to a very small value and, for the range of interest, one can recover practically all emitted photons from the source, as shown by the curve that takes into account just the Be-windows. Taking advantage of this flux, time resolved experiments can be performed with a typical resolution of 100 ms. The acquisition of a spectrum that, in sequential mode, normally takes 20 to 40 minutes can be accomplished in less than one second in dispersive mode.

The detection handles the high flux conditions with a modified CCD camera. The cryogenically cooled CCD camera system has a front-illuminated, scientific grade 1, MPP CCD of 1340 × 1300 pixels, each pixel has $20 \times 20\,\mu m^2$ for a total image area of $26.8 \times 26.0\,mm^2$. A GdOS phosphor screen, optimized for 8 keV X-rays, receives the incoming beam at an angle of 20° and converts the X-ray to visible light. A set of lenses guides the light to the CCD detector with a demagnification factor of 1.75, so that the real pixel at the phosphor screen is $35 \times 35\,\mu m^2$. In fact, the resolution measured in the dispersion direction has been about 2.5 to 3 times that pixel, i.e. 100 μm, limited by the phosphor screen. To improve this resolution, which turns out to be the limiting factor, we have to work out the phosphor screen with a thinner deposited film.

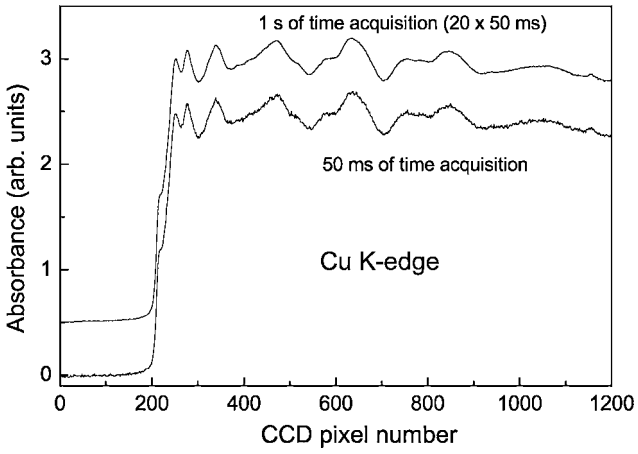

Fig. 2. Cu K edge spectrum at the DXAS beamline.

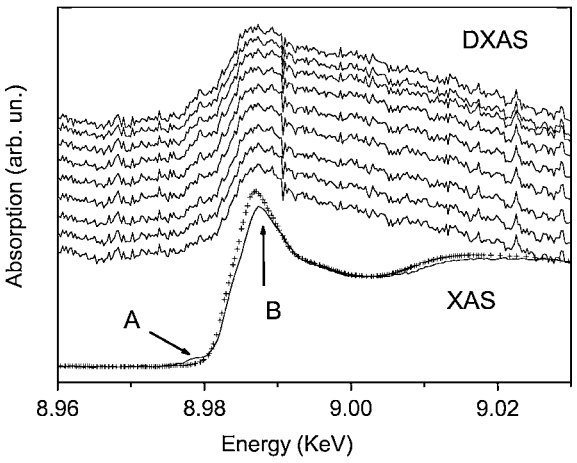

Fig. 3. In situ reaction at the Cu K edge spectrum followed at the DXAS beamline (bottom) and initial and final state measured using a step-by-step XAS scheme.

The energy-direction correlation coming out from the monochromator is transformed into an energy-position correlation along one direction of the two-dimensional CCD detector. The pixels of the CCD detector are integrated along the other direction to produce the XAS spectrum. There is no mechanical motion during the acquisition of a full spectrum. Spectra with a good signal/noise ratio can be collected with a typical time resolution of 50 ms. To improve the signal/noise ratio, 20 frames compose a full spectrum with 1 s of total acquisition time (Fig. 2).

3. Preliminary results

3.1. *Electrochemical cell for in situ study of metal insertion into polymers*

One of the most appealing applications of the dispersive XAS set-up is to follow in detail the many steps in a chemical reaction. Special attention is dedicated to the development of electrochemical cells to study the metal insertion into polymers and to the growth of small nanometric particles [5]. The aim is to understand the very first steps in the nucleation mechanism and to study the different phases of the reaction [6, 7]. In the particular case of copper insertion into polypyrrole, very different results have been presented in the literature, concerning the first steps of metal-polymer interaction. Some authors propose that the copper insertion is conducted by means of a Cu+1-PPy complex [7], while others suggest that this step is described by the formation of the $[\text{-}\,[(C_4H_2N)_3CH_3(CH_2)_{11}OSO_3\text{-}]yCu + 2]n$ $(y = 4)$ complex [6]. The chemical interaction between the metal and the polymer as well as the metal crystalline structure and the chemical bond at the surface are crucial issues related to small particles of magnetic and catalyst materials. First test experiments have been performed at the Cu K edge using a transmission cell [8]. The inclusion of Cu atoms into polypyrrole films has been followed (Fig. 3). The results are promising: the A feature in the spectrum, which is related to an increase of the local distortion of Cu site, is clearly seen to evolve in the very first steps of the reaction.

3.2. *Resonant scattering on magnetic thin films*

Resonant scattering of polarized X-rays from magnetic materials represents a powerful tool to investigate interesting magnetic phenomena, because magnetic effects are strongly enhanced [9, 10] when the photon energy is swept across an absorption edge. Resonant scattering from films and multilayers have been largely used in the soft X-ray range [11, 12]. However, it is worth noting that, in the hard X-ray domain, very few experiments were attempted in the past [13], and none is implemented at present, in spite of the great advantage arising from the possibility of working under a variety of extreme conditions.

A prototype experiment was performed in a multilayer structure formed by the alternate deposition of 1 nm of Co and 0.2 nm of Gd, repeated 40 times. Both the Co 1s (7709 eV) and the Gd 2p (7243 eV) resonances are accessible. Co is present in large amounts (about 40 nm) and carries a high magnetic moment compared to the reduced amount of Gd (about 30 atomic layers) combined with its low magnetic moment, at room temperature. On the other hand, the dichroism effect on the Co K-edge is much smaller than for Gd L_3 edge. Around the Gd L_3 edge, we measured the scattered intensity as a function of angle and photon energy. The critical angle for total external reflection as well as the Kiessig fringes related to the multilayer structure could be clearly identified. Around the Co K edge, we selected the radiation emitted about 0.3 mrad above the orbit and we disposed of an elliptically polarized beam with about 50% circular polarization rate. By applying a magnetic field parallel or antiparallel to the beam propagation axis we obtained the asymmetry ratio (or dichroism spectrum). The superior stability of the dispersive set up allowed us to collect dichroism spectra at a given angle and over a given energy range with a noise of the order of 0.03%.

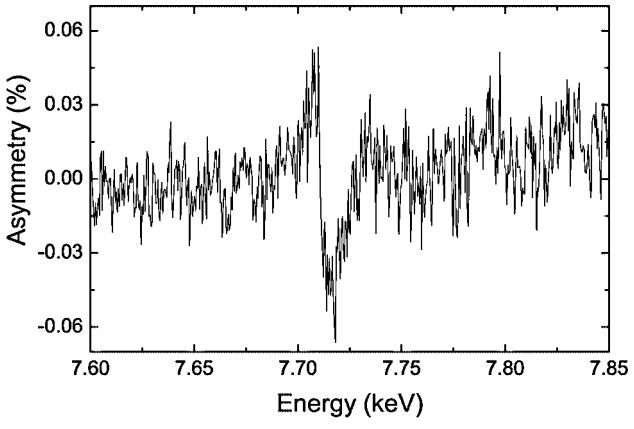

Fig. 4. The asymmetry ratio at the Co K edge for the Gd/Co multilayer system. The dichroic signal was obtained by collecting 128 spectra of about 30 s each. The applied magnetic field was 1 kOe at room temperature.

The measurement obtained at the Co K edge shows that a magnetic signal as low as 0.05% could be easily identified after one hour of acquisition time (Fig. 4).

Abstract

The design of a new beamline dedicated to X-ray Absorption Spectroscopy (XAS) at the french synchrotron radiation laboratory SOLEIL is under development. This beamline dedicated to large and varied scientific communities from physics to chemistry and biology will be characterised by a lot of techniques combined to XAS, such as X-ray Diffraction, Differential Scanning Calorimetry, Raman Spectroscopy and UV-Visible Spectroscopy. The design of the SAMBA optics will be optimised in order to be very versatile, to cover the 4–40 keV energy range with a high photon flux and a good energy resolution. Measurements of the absorption coefficients will be done either in the step by step mode or in a quick mode. The beamline should be in operation in 2006. This paper summarizes its technical characteristics and calculated performances. Typically the performance would be at 10 keV around 10^{12} ph/s in a $200 \times 200\,\mu m^2$ beam spot.

1. Introduction

SOLEIL is a third-generation synchrotron source which will deliver its first photons in 2006 for the users community. The energy of the beam in the storage ring is 2.75 GeV with a current of 0.5 A. On this source, the Scientific Advisory Comittee has recommended a beamline dedicated to X-Ray Absorption Spectroscopy (XAS) for a wide range of samples. The specificity of SAMBA (Spectroscopy Applied to Materials Based on Absorption) will be to offer the possibility to combine XAS with other techniques of characterisation such as X-ray Diffraction, Differential Scanning Calorimetry, Raman Spectroscopy and UV-Visible Spectroscopy. The spectral range 4–40 keV is covered. A wide range of applications will be concerned in chemistry, catalysis, environmental sciences, biology, solid state physics... The main X-ray optics are a first collimating mirror, a sagittal focusing double-crystal monochromator and a second focusing mirror in the vertical direction at the sample position. The horizontal angular acceptance of SAMBA is about 6.25 mrad. We give herein a first description of the beamline.

2. Source characteristics

The beamline is designed to be used from 4 to 40 keV and it will be located on the bending magnet D09-1, whose characteristics are given in Table I. The magnetic field is 1.7 T ($Ec = 8.65$ keV). These parameters are those used for the optical simulations.

3. Beamline optics

The principle of the optics of the beamline is given Figure 1. It is very similar to that of H10 (LURE) [1], FAME [2] or GILDA (ESRF) [3]. To reduce the divergence of the beam from a bending magnet, a mirror M1 is set between the source and the monochromator to provide vertical collimation of the beam. This parabolic bendable mirror allows to reject the harmonics according to the incident angle θ_M of the beam. It is made of silicon coated with a layer of about 50 nm of Pd. We have represented on Figure 2 the reflectivity of the mirror M1 versus the energy for different θ_M.

Table I. *Characteristics of the bending magnet exit where SAMBA is located.*

Bending magnet	σ_x(μm)	σ_z(μm)	σ_x'(μrad)	σ_z'(μrad)
exit 1°	60.1	24.9	134.8	2.1

To collect the maximum of photons this mirror is located near the source at 14 m. The characteristics of the different optics of SAMBA are listed in Table II. The dimensions of the M1 mirror are $120 \times 1300\,mm^2$ and it will be water-cooled.

The thermal charges on the different optical elements have been evaluated considering that the horizontal acceptance is 6.25 mrad. They are gathered in Table III and they will require a water cooling system.

The monochromatization system (DCM) is described in the next section.

A second parabolic mirror M2 at 19.5 m is then used to provide vertical focusing of the beam at the sample position. M1, DCM and M2 are sitting on a same girder of about 5 m long, to simplify the alignment of the beamline.

4. Monochromatization system

Several reasons led us to propose two monochromators to satisfy the permanent access to the 4-40 keV energy range, the sagittal focusing and the Quick-EXAFS acquisition mode.

First, in contrast to flat crystals monochromator, the energy range 4–40 keV can not be permanently covered by a commercial monochromator containing two pairs of sagittal focusing crystals (Si(111) and Si(220) or Si(311)). Second, although both acquisition modes (EXAFS step by step and Quick-EXAFS) pose no technical problem, it appears that the fast scanning mode is not straightforward for implementing if the beam is sagitally focused. Indeed this involves that dynamic sagittal focusing is operating during the fast acquisition (typically less than 1 min) of EXAFS data. Furthermore, even if the bender of the sagittal focusing crystal can be used in flat position, its mechanic is bulky and heavy leading to incompatibility with a frequent Quick-EXAFS working mode. So, we have chosen to dedicate DCM1 to sagittal focusing in the energy range 4–20 keV, and DCM2 to

Table III. *Thermal charges on the optics of SAMBA for 6.25 mrad horizontal acceptance.*

Element	transmitted P (W)	absorbed P (W)	∂P_{ABS} (W/mm^2)
Filter Be 200 µm	374.0	89.2	
Mirror M1 $\theta_M = 0.57°$	61.9	308.6	∼0.007
Crystal Si111 (23.29°) E = 5 keV	∼0.012	61.8	∼0.03
Filter Be 200 µm	373.5	93.6	
Mirror M1 $\theta_M = 0.1°$	130.8	16.0	∼0.001
Crystal Si220 (5.293°) E = 35 keV	∼0.005	118.1	∼0.23

The calculations are made considering perfect optical surfaces in the spectral range 0.1 to 100 keV.

Quick-EXAFS and step by step acquisition mode in the domain 5 to 40 keV without focusing. Both DCM will be installed in series on the girder of 5 m length. Note that the energy ranges correspond to standard incident Bragg angles between 5 and 40° for a monochromator equipped with Si(111) and Si(220) crystals. A first one, located 16 m from the source, DCM1, equipped with a first water-cooled Si(111) crystal permits horizontal focusing in the 4–20 keV energy range. A second monochromator, DCM2, located after DCM1 at 18 m from the source, will be dedicated to Quick-EXAFS and step by step acquisition mode in the domain 5 to 40 keV without focusing. It will be equipped with flat Si(220) crystals and the first one will also be water-cooled.

5. Choice of SAMBA geometry

The choice of SAMBA geometry arises from the study of the optical calculations realised by the optic group of SOLEIL. Four main requirements have been considered: the bending radii of the mirrors M1 and M2 versus the incident angle, the bending radius of the second crystal of DCM1 versus the Bragg angle, the beam size at the sample position versus the energy and the photon flux at the sample position versus energy. The results are plotted for the three considered geometries. The 3 : 1 notation means that the distance between the source and the monochromator is three times longer than the distance between the monochromator and the sample, this latter being fixed to 1.

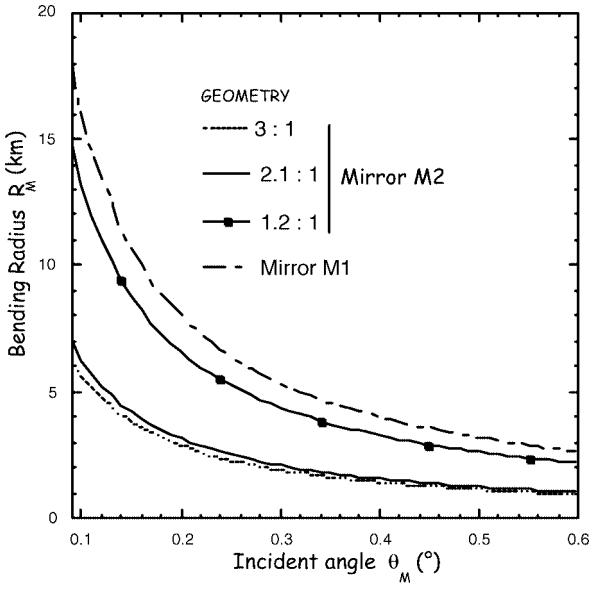

Fig. 3. Variation of the bending radius R_M of mirror M1 versus the incident angle θ_M.

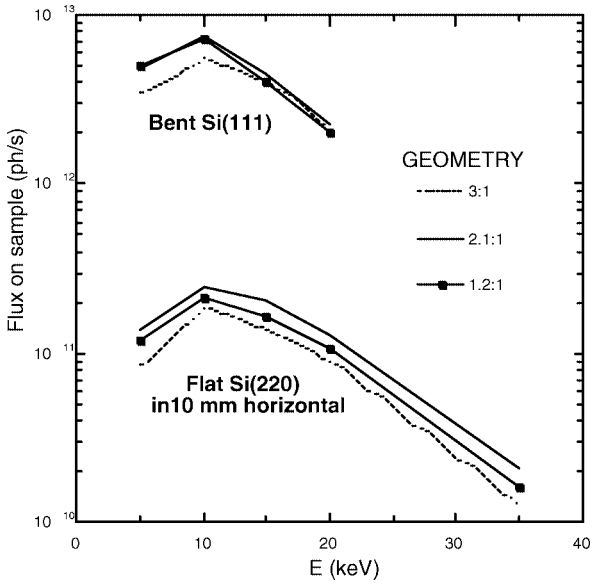

Fig. 5. Variation of the flux of photons at the sample position (30 m) as function of the incident energy.

5.1. *Bending radii*

The bending radii R_M of the mirrors M1 and M2 are presented in Figure 3 versus the incident angle. Note that 1 km is admitted as the smallest bending radius achieved with common bender without breakage or damage. Figure 3 shows that for M1 R_M is in all cases superior to 1 km whereas for M2, the 1.2 : 1 geometry is the only suitable one.

In the same way, we have reported in Figure 4 the variation of the bending radius R_S for the second crystal of the double crystal Si(111) monochromator DCM1 as function of the Bragg angle. As R_S must be larger than 1 m to avoid breakage, the 1.2 : 1 geometry is favourable if we want to reach a Bragg angle as small as 5°.

5.2. *Flux and size of the beam*

The calculated photon flux and beam size at the sample position are reported in Figures 5 and 6, respectively. The 1.2 : 1 geometry

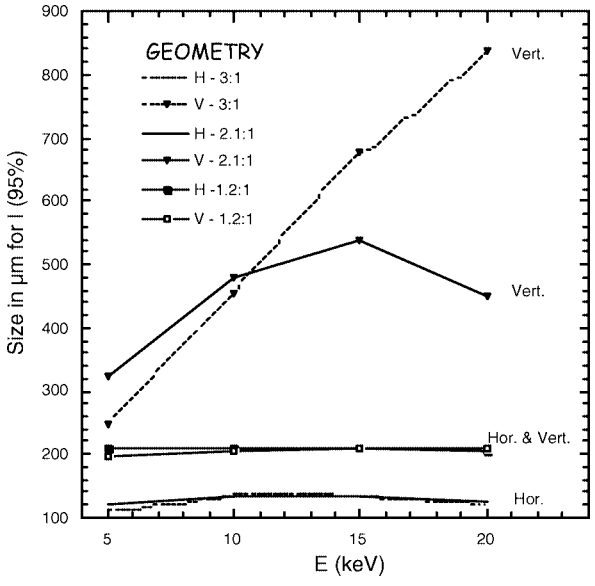

Fig. 6. Variation of the beam size at the sample position (30 m) versus the incident energy.

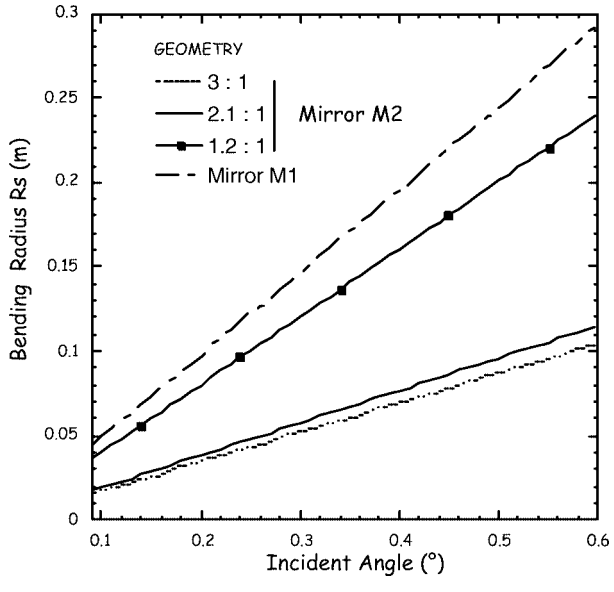

Fig. 4. Variation of the bending radius R_S of the second crystal of MDC1 equipped with Si(111) crystals versus the Bragg angle.

presents a higher photon flux than the 3 : 1 one. This geometry permits also to have a nearly symmetric and homogeneous size of the beam in the range 5 to 20 keV at the sample location (cf Figure 6). It is an interesting advantage in terms of distribution of the photon flux and also for combining complementary techniques with XAS.

6. Performances of SAMBA

The performances of SAMBA in terms of spot size, photon flux and energy resolution in the 1.2 : 1 geometry are summarized in Table IV. All these calculations were performed with slope error $\varepsilon_y = 0.3''(1.5\,\mu\text{rad})$ and $\varepsilon_x = 1''$ RMS (5 µrad) for the mirror M1 and M2 and with 3 Å roughness. Note that the spectral resolution is good. At 5 keV the spectral resolution is 0.6 eV, *i.e.* close to the Darwin resolution. At 35 keV the resolution close to 3.4 eV is better by a factor of 3.6 compared to the intrinsic spectral

Table IV. *Performances of SAMBA in the 1.2 : 1 geometry with 6.25 mrad of horizontal acceptance and with sagittal focusing for Si(111) and without focusing for Si(220).*

Energy (keV)		Flux (ph/s)	ΔE(eV)	Size	Bending Radius (mm)	θ Bragg (deg.)
5	Si 111	5×10^{12}	0.59	$210.5 \times 195.3\,\mu m^2$	5905.9	23.296
	Si 220	1.7×10^{12}	0.27	142 mm × 195 μm	—	40.225
10	Si 111	7.2×10^{12}	1.2	$208.3 \times 206.8\,\mu m^2$	2953	11.405
	Si 220	3×10^{12}	0.59	142 mm × 197.4 μm	—	18.838
15	Si 111	4.1×10^{12}	1.9	$207.4 \times 210.4\,\mu m^2$	1968.6	7.575
	Si 220	2.3×10^{12}	0.9	142 mm × 197 μm	—	12.431
20	Si 111	2×10^{12}	2.7	$206 \times 207.2\,\mu m^2$	1476.5	5.674
	Si 220	1.5×10^{12}	1.38	142 mm × 198.4 μm	—	9.291
35	Si 220	2.3×10^{12}	3.35	142 mm × 196.4 μm	—	5.293

broadening of K absorption edges of heavy elements (e.g. 12.3 eV at the Cs K edge (36 keV)) [4].

A comparison of SAMBA performances in focusing mode with other beamlines like FAME [2] or GILDA [3] (ESRF) shows that the implantation of the optics near the source is determinant to compete with these beamlines in terms of photons flux.

7. Beamline equipment

All the detection techniques will be available, transmission, total electron yield and emitted fluorescence.

Combined XAS experiments with other complementary techniques of characterisation of materials: X-ray Diffraction (XRD), Differential Scanning Calorimetry, Raman Spectroscopy and UV-Visible Spectroscopy will be proposed on SAMBA. Some of these combinations have already been implemented on the D44 station at LURE. They are fully described on a separate invited paper of the conference [5]. These combined techniques will be transferred to the new beamline SAMBA and they should take great benefit from the access to a third generation source, in particular for their use in time-resolved experiments.

Many ancillary devices like cryostats (He_{liq} and N_{2liq}), furnaces, goniometer, Paris-Edinburgh cells, thermostated liquid cells, many sample-holders . . . can also be used.

A second experimental hutch will be located at 35 m of the source in order to make surface EXAFS experiments.

Abstract

XAFS-PEPICO synchronous measurement has been applied to free neutral krypton clusters to study the X-ray absorption and de-excitation processes of clusters. The PEPICO measurements for krypton atom reveal that the highly charged daughter ions of Kr^{z+} ($z = 3$–11) are generated as a result of the de-excitation process. As the cluster size increases, the Kr^+, Kr_2^+ and Kr_3^+ daughter ion, which is hardly observed in the atomic spectra, shows remarkable increase. The PIY spectrum of Kr^+, which is distinct from those of highly charged ions, is similar to the XAFS spectrum of solid krypton.

1. Introduction

The X-ray absorption fine structure (XAFS) is a potentially useful method to study the structure of the cluster. However, it is difficult to measure the XAFS of free clusters in the hard X-ray region mainly for two major reasons. First, the atomic density in the cluster beam is extremely low to apply the usual XAFS measurement. Secondly the X-ray absorption cross section decreases with increasing photon energy. However, by utilizing the intense X-ray source of the third generation synchrotron, it would be possible to study the XAFS of rarefied systems, such as cluster, in the hard X-ray region.

Recently, we have developed a method for the XAFS-PEPICO synchronous measurements and applied it to Se cluster beam [1]. The XAFS spectra taken in the total ion yield (TIY) were measured simultaneously with the PEPICO measurement, from which the information on the de-excitation process can be derived. Our study has shown that the size-selective structural analysis of free clusters has been carried out by utilizing the information on the de-excitation process of clusters.

In the present study, the XAFS-PEPICO synchronous method is applied to krypton clusters to study their X-ray absorption and de-excitation process. Krypton may serve as a standard sample because de-excitation processes for atomic krypton have been well studied.

2. Experimental

Figure 1 is a photograph of the newly developed cluster beam apparatus for XAFS measurement. The apparatus is composed of an expansion chamber and an analyzing chamber, which were separated from each other by a conical skimmer with an aperture of 1 mm. Each of the chambers was evacuated by a turbo molecular pump. Typical operating pressure was 1.0–3.0×10^{-3} Torr in the expansion chamber, and 4.0×10^{-6}–1.0×10^{-5} Torr in the analyzing chamber.

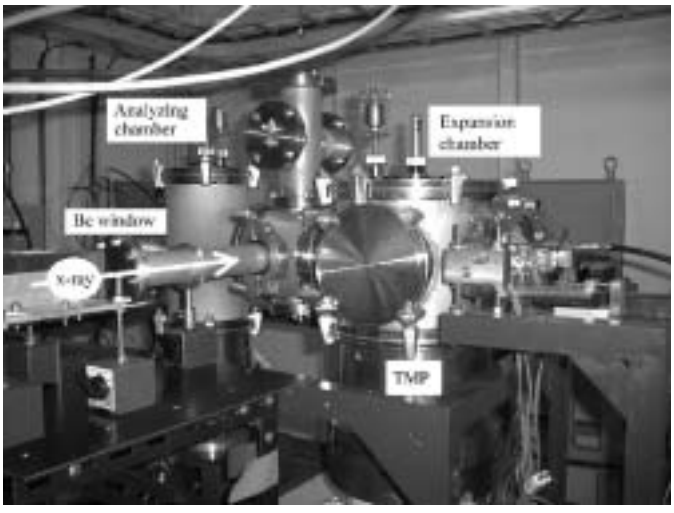

Fig. 1. Photograph of the cluster beam apparatus for XAFS measurement.

The cluster apparatus was placed in a high-brilliance XAFS station BL10XU at SPring8, where the X-ray emitted from the undulator was monochromized by a double crystal Si(111) monochromator [3]. Higher harmonics and back-ground radiation from the undulator were minimized by a double flat mirror with a variable critical energy. An ionization chamber filled with N_2 gas was used as a monitor of photon number. The photon flux of the X-ray was about 5.4×10^{12} photons/s during our measurement. After passage through an ionization chamber, the X-ray beam was led into the cluster beam apparatus through a beryllium window.

A neutral cluster beam was produced by a supersonic jet expansion method in the expansion chamber. In the cluster source, an alumina cylindrical nozzle of 0.08 mm in inner diameter was attached to the top of a cryostat, and cooled by liquid nitrogen. In the present study, both the temperature, T_0, and the stagnation pressure, p_0, of the krypton vapour were adjusted to control the cluster size distribution.

In the analyzing chamber, the cluster beam was intersected with the X-ray at right angles in the horizontal plane, then the ions and electrons were emitted. The photoions produced by absorbing an X-ray photon were extracted upward by a constant electric field to a modified Wiley-McLaren time-of-flight mass spectrometer [4] and detected by a channeltron, while the photoelectrons were extracted downward and immediately detected by another channeltron.

The XAFS spectrum for the mixed cluster beam was taken in the Total Ion Yield (TIY) mode. The TIY was obtained by counting

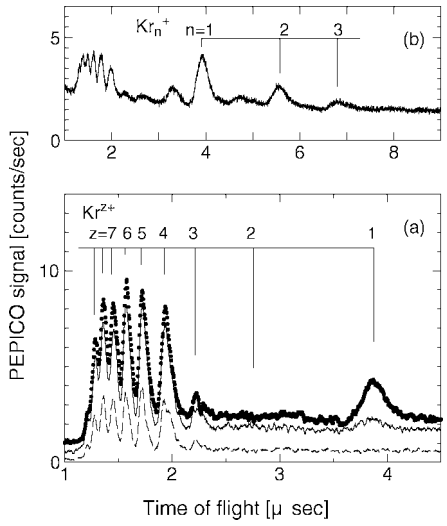

Fig. 2. PEPICO spectra for krypton clusters taken at photon energy of 14.5 keV. (a) PEPICO spectra with several p_0. The dashed line, solid line and dot correspond to $p_0 = 1, 3$, and 5 bar, respectively. T_0 was 302 K for all three spectra. (b) PEPICO spectrum for $T_0 = 150$ K and $p_0 = 4$ bar.

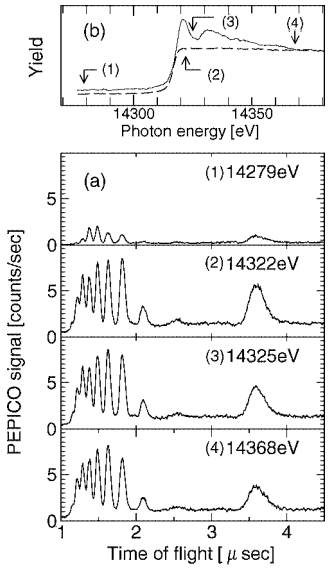

Fig. 3. (a) Typical PEPICO spectra measured at four energy points. (b) TIY spectrum of krypton atom (dashed line) and partial ion yield spectrum of Kr^{1+} (solid line).

the pulses due to the ion signals. For the PEPICO measurement, the photoelectron signal delivers the start pulse and the photoion signal delivers the stop pulse to a time-to-amplitude-converter, and the difference of the time-of-flight between the electron and ion was accumulated as a histogram in a multi-channel-analyzer. In the XAFS-PEPICO synchronous measurements, the PEPICO spectrum was recorded simultaneously at each photon energy where the TIY was measured [2].

3. Results

In fig. 2, the PEPICO spectra for krypton clusters taken at photon energy of 14.5 keV are shown as a function of the time of flight of the photoions. Fig. 2(a) shows the PEPICO spectra with the stagnation pressure p_0 of 1, 3, and 5 bar. The temperature T_0 was 302 K for all three spectra. The PEPICO spectrum taken under the condition of $T_0 = 302$ K and $p_0 = 1$ bar shows several prominent peaks in the time range between 1.0 and 2.5 μs which correspond to the highly charged daughter ions of Kr^{z+} with $z = 3$ to 12. Because no cluster has been observed for $T_0 = 302$ K and $p_0 = 1$ bar, these highly charged ions are produced by X-ray absorption of krypton atoms. The present distribution of the daughter ions stemming from atomic krypton agree well with the results of Krause [5], who measured the distribution of the daughter ions from krypton atom at a photon energy of 17.45 keV.

The krypton clusters have been generated by applying the pressure to the cluster source. As shown in fig. 2(a), Kr^{1+} ion appears with the increase of p_0. The peak width of Kr^{1+} is greater than that of higher charged daughter ions, suggesting that Kr^{1+} ions is produced by the coulomb explosion of multiply charged cluster ions. Cooling the nozzle promotes additional clustering. Fig. 2(b) shows a PEPICO spectrum for $T_0 = 150$ K and $p_0 = 4$ bar. The appearance of additional peaks at 5.7 μs (Kr_2^+) and 6.9 μs (Kr_3^+) indicates that the de-excitation process of clusters has been changed with the growth of cluster size.

In the present study, the PEPICO spectra have been measured simultaneously with the TIY spectrum at 140 energy points. Fig. 3(a) shows typical PEPICO spectra measured at four energy points. The energies are shown in the fig. 3(b) by arrows together with the TIY spectrum of krypton atom (dashed line) and partial ion yield spectrum of Kr^{1+} (solid line). As the photon energy increases, the intensity of the PEPICO increases abruptly at the absorption edge. For highly charged ions (Ke^{z+}: $z = 3$–10) the energy dependences of PEPICO peak intensity resemble the TIY spectrum of the atomic beam. However, the PIY of Kr^{1+} is distinct in energy dependence from those of highly charged ions. The PIY of Kr^{1+} looks like the XAFS spectrum of solid krypton [6]. These results are understood by the fact that the higher charged ions stem from krypton atoms and the Kr^{1+} stem from clusters. The likeness between the PIY of Kr^{1+} and the XAFS of solid krypton may be a result of the evolution of the electronic states in krypton clusters from the atom to the solid.

4. Summary

XAFS-PEPICO synchronous measurement has been applied to free neutral krypton clusters. The PEPICO spectra show a remarkable difference between krypton atom and krypton cluster. The energy dependence of PIY for Kr^{1+} is distinct from those of highly changed ions. The results suggest a difference of de-excitation processes between atomic krypton and krypton clusters.

Self-Absorption Correction Strategy for Fluorescence-Yield Soft X-ray Near Edge Spectra

R. Carboni[1], S. Giovannini, G. Antonioli[2] and F. Boscherini

INFM and Physics Department, University of Bologna viale C. Berti Pichat 6/2, 40127 Bologna, Italy

Abstract

It is well known that fluorescence-yield X-ray absorption measurements of thick concentrated samples can exhibit severe spectral distortions due to the "self-absorption" effect. While reliable corrections for this effect have been described for the EXAFS region an accepted procedure does not exist for the XANES region, in which the distortions are more severe. This problem is of particular relevance in the soft X-ray region in which transmission measurements are usually impossible. We describe a procedure for the correction of XANES spectra for self-absorption spectral distortions which is based on the scaling of the experimental spectrum to tabulated cross-sections. We apply the method to polarization-dependent O K-edge measurements in cubic NiO, in which no intrinsic polarization dependence is expected. The procedure is able to reduce by a factor of 3 the self-absorption distortions.

1. Introduction

The most common experimental set-up for X-ray absorption spectroscopy (XAS) is the transmission geometry. Fluorescence detection is principally used in experiments with hard X-rays since its use in the soft X-ray range is hampered by the extremely low values of the fluorescence yield (10^{-2}–10^{-3}). With the availability of high brilliance third generation synchrotron radiation sources new opportunities exist for the application of fluorescence yield XAS (FY-XAS). Areas of interest for the application of soft X-ray FY-XAS in this context are, among others, the study of dopants, impurities and defects, of insulating materials, of samples inserted in magnetic fields; compared to electron yield (EY) detection, FY is more bulk sensitive and therefore better suited when structural information from the bulk of the sample is sought.

The photon energy dependence of the fluorescence intensity from dilute samples and thin layers is directly proportional to the absorption coefficient of the excited element [1]. For thick, concentrated samples, however, FY-XAS measurements can exhibit severe spectral distortions due to the 'self-absorption' effect [2–7]. This problem is of particular relevance in the soft X-ray region in which transmission measurements are virtually impossible.

The expression for the fluorescence photons flux $I_f(E)$, in the limit of an infinitely thick sample and small detection solid angle is [1]:

$$I_f(E) = I_0(E)\frac{\Omega}{4\pi}\varepsilon_f \frac{\mu_A(E)}{[\mu_A(E)+\mu_M(E)]+\mu_{tot}(E_f)\frac{\sin\phi}{\sin\theta}} \qquad (1)$$

where ϕ and θ are the angles between the sample surface and the impinging and the fluorescence beams, respectively; $\mu_A(E)$, $\mu_M(E)$, $\mu_{tot}(E_f)$ are the absorption coefficients of the absorber atom (A) and of the matrix (M) at the incidence energy E and the total absorption coefficient at the fluorescence energy E_f; $I_0(E)$, $\Omega/4\pi$ and ε_f are the incidence flux intensity, the solid angle covered by the detector and the fluorescence yield of atom A, respectively.

As can be seen from Eq. (1), when the condition $\mu_M(E) \gg \mu_A(E)$ is not verified (i.e. for concentrated samples) the number of fluorescence photons is not proportional to the absorption coefficient of the absorber atom $\mu_A(E)$: the presence of $\mu_A(E)$ in the denominator induces a distortion of the XAS signal. These distortions depend on the angular configuration as expressed by the term $\sin\phi/\sin\theta$. When the incidence angle is near 90° the dominant term in the denominator of Eq. (1) is the last one and the spectral distortions are minimized and can often be neglected. On the contrary, near grazing incidence the first term in the denominator becomes dominant and the spectra can be severely distorted.

It is possible to obtain an estimate of the magnitude of the self-absorption effect by evaluating the ratio between $\mu_A(E)$ and the sum of the last two terms in the denominator of Eq. (1).

$$R = \frac{\mu_A(E)}{\mu_M(E)+\mu_{tot}(E_f)\frac{\sin\phi}{\sin\theta}}. \qquad (2)$$

When R is greater or equal to 1 distortions are significant while they are negligible when R is close to zero. It is possible to reduce spectral distortions by using a normal incidence geometry but this method cannot be a general solution, since it makes it impossible to exploit or to study the polarization dependence of the XAS signal.

The distortions of the EXAFS spectral region have been recently described, together with appropriate corrections, by Tröger *et al.* [5] and by Pfalzer *et al.* [6]. The latter paper extended the correction of the self-absorption effect to the case in which the solid angle subtended by the detector is not negligible. While reliable self-absorption corrections have been described for the EXAFS region a complete correction procedure has not been published for the XANES region, despite the fact that the effect is well-known and its physical origin understood [4]. In the XANES region modulations in the XAS signal are greater than in the EXAFS one and therefore self-absorption distortions are more severe. Obtaining distortion-free XANES spectra appears particularly important in view of recent advances in quantitative interpretation [8]. In this paper we describe a strategy for the correction of self-absorption distortions in the XANES regions which is based on the scaling of the spectra to tabulated cross sections and apply it to the O K-edge XANES of NiO. A related method applicable to EY-XAS measurements has been recently described [9, 10]; in this case, however, it was necessary to keep the electron mean free path as a free parameter, since its value can be uncertain up to a factor of 3.

2. Experimental Data

We carried out O K-edge XANES measurements of a NiO sample with its surface oriented parallel to the (100) lattice planes. The choice of NiO is motivated by its cubic structure: no intrinsic variation of the XANES signal is expected as a function of the angle between the impinging beam and the sample crystallographic orientation [11].

Measurements were made at the BEAR beamline [12] of the ELETTRA facility in Trieste, Italy. The resolution and flux were $\sim$200 meV and $5 \cdot 10^{10}$ ph/s, respectively, and the spot size was 20 by 200 μm. The NiO crystal was mounted in an ultrahigh vacuum chamber on a rotatable sample holder, biased +1000 V with respect to ground to avoid photoelectrons reaching the fluorescence detector. A signal proportional to the incident photon flux was obtained by measuring the photocurrent from a high transmission gold grid. A Si photodiode operated in the current mode was used for fluorescence detection; the photodiode area was 100 mm^2 and it was placed at a distance of 20 mm from the sample; typical photodiode currents were of the order of 10 pA.

We took FY-XANES spectra for two angles of the impinging beam ($\phi = 20^\circ, 70^\circ$) to observe the importance of self-absorption effect at the two extreme configurations, grazing incidence and normal incidence. The energy of the incidence X-rays was scanned between 520 eV and 570 eV. We normalized the FY raw spectra with $I_0(E)$ obtained from the gold grid, and from each spectrum we subtracted a linear pre-edge background.

The XANES data are reported in Fig. 1. While the two spectra are similar there are significant differences in the relative intensities of the peaks, the grazing incidence spectrum exhibiting an overall damping. The relative difference in the peak-to-valley ratio (taken respectively at 539 and 542 eV) between the two spectra is 39%. For the experimental conditions used the value of R defined in Eq. (2) is 0.72 for $\phi = 20^\circ$ while for $\phi = 70^\circ$ it is 0.25.

3. Correction Procedure

We now describe a procedure to correct the XANES spectra from self-absorption effects based on scaling the experimental spectrum to tabulated cross sections [13]. As a first step we describe a procedure which is applicable in the case of small solid angle of detection; subsequently this approximation is relaxed.

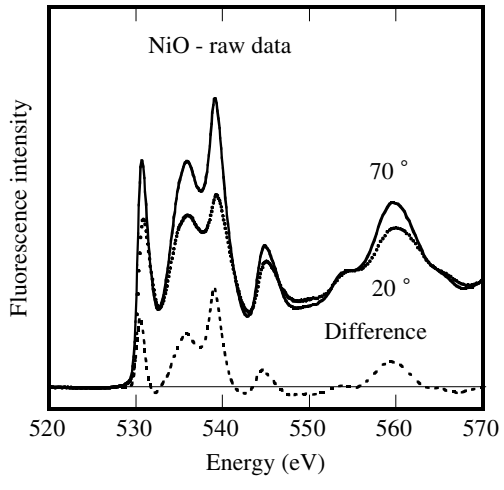

Fig. 1. Raw O K-edge XANES spectra of the NiO sample at 20°(dots) and 70°(continuous line) incidence angles and their difference (dashed line).

The method is valid provided: *i*) the composition and density of the sample are known, *ii*) the sample is much thicker than the photon absorption length and *iii*) the sample has a flat surface.

We define the normalized fluorescence intensity as $Y(E)$:

$$Y(E) = \frac{I_f(E)}{I_0(E)\varepsilon_f \Omega/4\pi}. \tag{3}$$

$Y(E)$ ranges from 0 to 1 and is equal to the fluorescence intensity per unit relative solid angle, fluorescence yield and incident flux. In terms of $Y(E)$ the absorption coefficient of the excited atom is:

$$\mu_A(E) = \frac{Y(E)}{1 - Y(E)} \left[\mu_M(E) + \mu_{tot}(E_f) \frac{\sin\phi}{\sin\theta} \right]. \tag{4}$$

If the quantities appearing in the denominator of Eq. (3) were reliably known it would be straightforward to calculate the corrected spectrum using Eq. (4). However, the precise determination of the solid angle is difficult and, especially in the soft X-ray range in which ionisation chambers are not commonly used, the quantitative measurement of the incident flux $I_0(E)$ is not available. The proposed method consists in bringing the experimental data $I_f(E)$ to the absolute scale of $Y(E)$ by multiplying by a factor β defined as:

$$\beta = \frac{1}{J} \frac{\mu_A^{At}(E)}{\mu_A^{At}(E) + \mu_M^{At}(E) + (\mu_A^{At}(E_f) + \mu_M^{At}(E_f))\sin\phi/\sin\theta}. \tag{5}$$

The symbols have their usual meaning and the superscript At indicates that tabulated atomic cross-sections at an energy just above the edge are used [13]; J is the experimental discontinuity in the fluorescence data which is estimated by extrapolating to the absorption edge energy the pre-edge and post-edge signals. The quantity $\beta \times I_f(E)$ is substituted for $Y(E)$ in Eq. (4) and the corrected spectrum is thus calculated.

When the solid angle covered by the detector is not small the geometrical factor in Eq. (1) and following cannot be simply defined as $\sin\phi/\sin\theta$; in this case the factor β, has a different value for each element of solid angle $d\Omega$ covered by the detector. In Fig. 2 the experimental geometry is illustrated. The incidence angle ϕ is constant in any particular measurement while the angle formed by the fluorescence beam with respect the sample surface varies across the detector. Defining the y axis as the normal to the sample surface and the plane xz as the sample surface, τ is the angle between the z axis and the exit beam, and θ is the angle between the x axis and the fluorescence beam. The solid angle element is $d\Omega = \sin\tau\, d\tau\, d\theta$. In this configuration the angle ξ of the fluorescence beam with respect the sample surface is not simply equal to θ except for $\tau = \pi/2$. ξ is important because it determines the length of the path the fluorescence X-rays must traverse through the sample and hence the magnitude of the self-absorption correction. For our experimental setup we obtained $\xi(\tau, \theta)$:

$$\xi(\tau, \theta) = \frac{\pi}{2} - \arccos(\sin\tau \sin\theta) \tag{6}$$

with τ ranging from $\tau_{min} = 76^\circ$ to $\tau_{max} = 104^\circ$ and θ from $\theta_{min} = 6^\circ$ to $\theta_{max} = 34^\circ$. To obtain the total correction factor the following integral must be calculated:

$$\beta(E, \phi) = \frac{1}{\Omega} \int_{\theta_{min}}^{\theta_{max}} \int_{\tau_{min}}^{\tau_{max}} \frac{\mu_A(E)}{\mu_T(E) + \mu_T(E_f)\frac{\sin\phi}{\sin\tau\sin\theta}} \, d\tau\, d\theta. \tag{7}$$

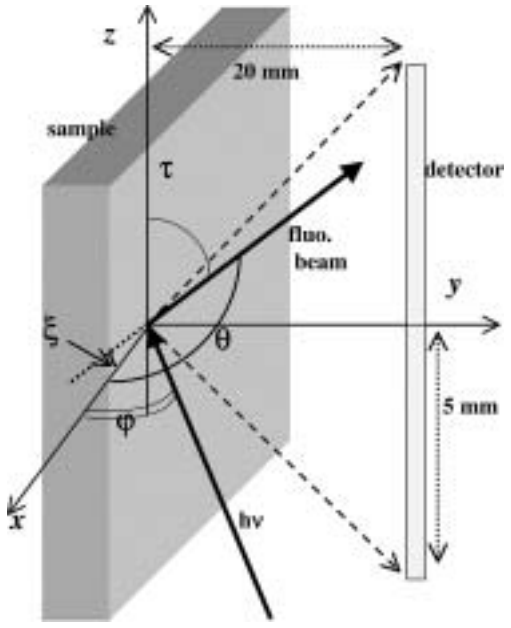

Fig. 2. Experimental geometry.

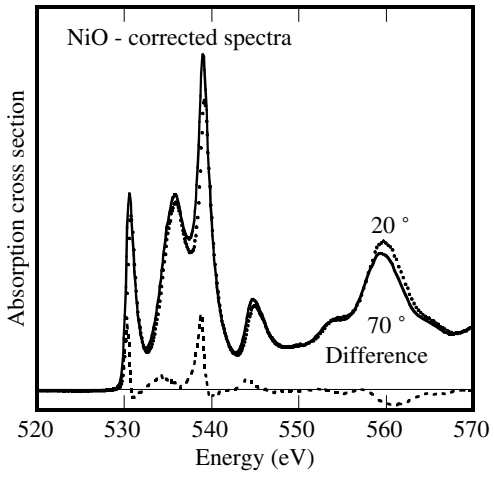

Fig. 3. Corrected O K-edge XANES spectra of the NiO sample at 20°(dots) and 70°(continuous line) incidence angles and their difference (dashed line).

It must be pointed out that the proposed method relies on the accuracy of atomic cross-sections and depends critically on the determination of the experimental discontinuity J.

The above described procedure was applied to the NiO XANES spectra and the result is shown in Fig. 3. As can be seen the differences between the two spectra are significantly reduced, as expected for a cubic structure. In fact, the relative difference in the peak-to-valley ratio is now 12%, a reduction by a factor of 3 with respect to the uncorrected data.

Acknowledgments

We are grateful to the staff of the BEAR beamline, N. Mahne, A. Giglia, M. Pedio and S. Nannarone for their assistance during the measurements and to A. Costa (University of Bologna) and A. Bazzini (University of Parma) for expert technical assistance. Work supported in part by INFM PURS-FLUX project.

Abstract

Sodium niobate based ceramics doped with Mn atoms have been sintered from oxides. The Bi co-dopants were introduced to increase the solubility limit for Mn atoms. Two series of samples were heated at lowered air pressure to produce oxygen nonstoichiometry. X-ray Absorption Near Edge Structure (XANES) spectra at Mn K-edge were measured for samples with and without Bi co-dopants. Theoretical XANES spectra were calculated using the Real Space Multiple Scattering method (FEFF 8 code). The simulation showed that ceramics samples have Pbcm symmetry and all of them have Mn atoms located in a Nb sublattice.

1. Introduction

Sodium niobate ($NaNbO_3$) is scientifically attractive because of its use as a base compound for forming solid solutions that have a combination of electrical and mechanical properties which have been shown to be promising for applications in high-temperature piezoelectric devices and, when ferroelectric properties are induced, acoustic transducers operating in the microwave range [1, 2].

Sodium niobate has a relatively susceptible structure which exhibits a sequence of six phase transformations, with seven possible existing stable phases. The room-temperature phase (called P) is an antiferroelectric phase with symmetry Pbcm [3, 4]. It has been shown that such factors as an induced external electric field [5], variation of pressure [6, 7, 8] or introducing dopant ions such as K, Ag, Ba in the sodium sublattice or Ta, Mn in the niobium sublattice can change internal stresses or electric fields thus affecting the stability of the phases. As a result, shifts in temperatures of the phase transitions and even appearance of new phases have been reported [8, 9, 10, 11].

In this work we investigated the effect of doping the sodium niobate based compound with Mn. There have been conflicting reports about the Mn position in the $NaNbO_3$ crystal lattice. EPR spectra analysis has shown that Mn^{2+} ions replaced Na^{1+} ions [12, 13], Mn_{Na}. On the other hand, recent XPS experiment suggest that Mn ions replace Nb^{5+} ions [14], Mn_{Nb}. However, it should be pointed out that from a stress-strain consideration or from point chemistry rules both the Mn_{Na} and Mn_{Nb} positions are just as probable [7, 8]. This is because the Mn ion can exist in several ionic states Mn^{2+}, Mn^{3+}, Mn^{4+} or may form covalent bonding. The solubility limit for Mn ions in a sodium niobate lattice was found not to exceed one atomic percent [14].

As a result of thermodynamic circumstances at sintering, we expect a certain concentration of oxygen vacancies (V_O). Moreover, by inducing oxygen non-stoichiometry or by co-doping with other ions, electrical stability can be reached. In this work we used bismuth ions to fulfil this stability condition. This is a reasonable choice due to the stability of the Bi^{3+} state and because the crystal radii in 8th fold co-ordination are comparable, meaning negligible strains are created when a sodium atom is replaced [7, 8, 15, 16]. However, there are still questions as to the real or dominant position of Mn ions in the sodium niobate structure.

With the aid of theoretical calculations, XANES (X-ray absorption near edge structure) is a good choice to investigate local structure. The atomic selectivity of this technique and its sensitivity to the geometrical arrangement of atoms around the absorbing atoms can help identify the specific position of atoms in the crystal lattice.

2. Experimental

2.1. *Sample preparation*

A $(Na_{1-x}Bi_x)(Mn_yNb_{1-y})O_3$ ceramic series was prepared by dry sintering, using a two-stage synthesis process [17, 18] where we used the following ratios of x to y : 0.06 : 0.04, 0.24 : 0.16. As a first step, the $(Na_{1-x})(Mn_yNb_{1-y})O_3$ precursor phase was produced from Na_2CO_3 (Sigma, purity ≥99%), Nb_2O_5 (Aldrich, purity ≥99.9%) and MnO (Aldrich, purity≥99%) powders in stoichiometric proportions. The powders were ball mill mixed for 12 hours, pressed lightly and then calcined at 1223 K for 3 hours. The second step consisted of crushing the precursor phase and mixing it with bismuth oxide, Bi_2O_3 (Sigma, purity ≥99%). Five percent more bismuth oxide was added to compensate for evaporation expected during sintering. The mixtures were then milled for 6 hours and calcined at 1173 K for 2 hours. Finally, after 3 hours of milling, the powders were pressed at 25 MPa into pellets ($\varphi = 1$ cm) and sintered in air at 1423 K for 2 hours.

A reference sample doped with Mn ($x = 0$, $y = 0.06$) was also made.

The "A" series samples were cut from these pellets and then placed in a vacuum oven. The "B" and "D" series were additionally treated to change their oxygen stoichiometry [13].

Series "B" samples were heated at 670 K for one hour in a vacuum of 10^{-2} Torr. The heating temperature was chosen ($\ll$1130 K) to prevent bismuth oxide from escaping the ceramic. These samples were expected to exhibit an oxygen deficiency.

The "D" Series were reduced during one hour at 720 K in a vacuum of 10^{-3} Torr. The chamber was then filled with air at ambient pressure and room temperature and then heated at 680 K for 30 minutes. This procedure should allow oxygen ions to be reintroduced into the ceramic crystal lattice and diminish the

oxygen nonstoichiometry. Therefore, these samples are expected to show similar properties to the "A" series.

2.2. *XANES and EPMA*

XANES measurements were performed at HASYLAB, Hamburg, on station A1. Mn K-edge absorption spectra were measured at room temperature using the 4-crystal monochromator in fluorescence detection mode, with an energy resolution of 0.5 eV at 10 keV. The solid samples were mounted on the sample holder using carbon tape.

In addition to the experimental XANES measurements, theoretical XANES spectra were calculated by using the real space full multiple scattering FEFF8 code [19]. The atomic coordinates used in this code were generated by ATOM3.0beta7 using crystallographic parameters from ref. [5], and clusters of 10 Å radii. Full multiple scattering calculations were performed for clusters containing 87 atoms. A 5.7 eV shift towards lower energy was applied to each calculated spectrum to allow comparison to the experimental spectra.

The composition of the "A" series samples (Tab. I) was determined by a Cameca Electron Probe MicroAnalyser (EPMA), model SX50 using a Si : Li detector, at a fixed electron beam energy of 20 keV.

3. Results and discussion

3.1. *"A" Series – samples obtained from sintering*

Theoretical calculations for Pbcm structure at the Mn K-edge were made for two cases, for a Mn atom replacing a Nb absorbing atom (Mn_{Nb}) and for a Mn atom replacing a Na absorbing atom (Mn_{Na}). Results show that XANES spectra are clearly different for both cases, see lower part of Fig. 1. The experimental spectra with Bi co-doping are quite similar to the theoretical spectrum calculated at the Mn_{Nb} K-edge, but are completely different than the K-Mn_{Na} results. This suggests that for both the Bi6-Mn4A and the Bi24-Bi16A samples, Mn atoms are located in a Nb sublattice. Further calculations made by replacing one of the Na atoms in the second shell with a Bi atom did not reveal a significant difference in the theoretical K-Mn_{Nb} XANES spectrum which is in agreement with our predictions.

Relative to the other samples, an XANES spectrum of the Bi0-Mn4A sample without Bi co-doping shows differences in the relative energy position of the absorption edge and for the intensity of the observed peaks (Fig. 1). Neither the theoretical K-Mn_{Na} spectrum nor the sums of various weights of K-Mn_{Na} and K-Mn_{Nb} spectra converges to the experimental spectrum. However, the theoretical K-Mn_{Nb} spectrum seems to be a closer match to the experimental data than the others, and allows us to draw the conclusion that Mn ions are not located in the sodium sublattice but in the nobium sublattice.

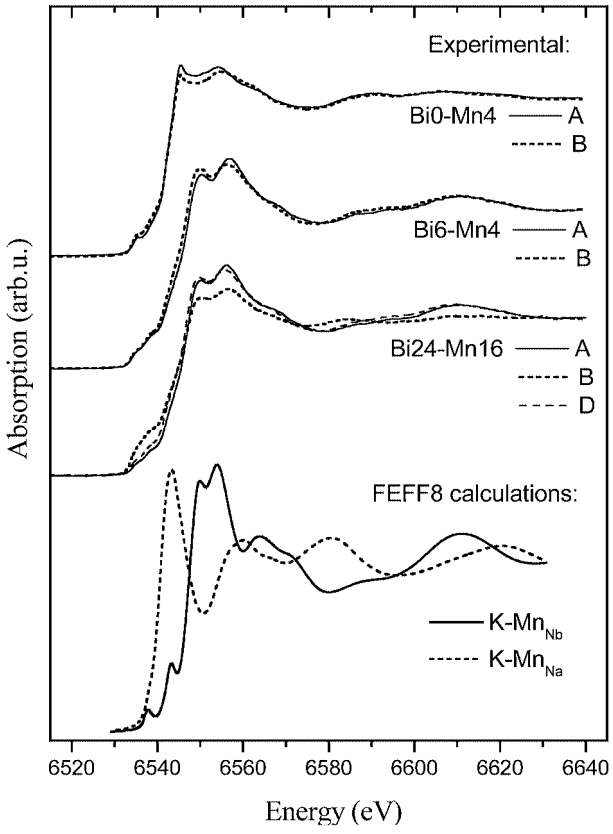

Fig. 1. Mn K-edge spectra calculated for a Mn absorbing atom located in Nb and Na sublattices and measured for samples with and without Bi co-doping (see text for details).

The first sub-shell consists of six oxygen atoms surrounding a Mn atom. Therefore, we expect the spectral shape of the K-Mn absorption edge to be very sensitive to oxygen atom vacancies and for any changes in their geometrical arrangement. Simulations made for Mn-O5 clusters located in the Pbcm structure confirm this assumption. The oxygen vacancy and rearrangement of one of the remaining oxygen atoms causes significant changes in the calculated spectrum. This indicates that oxygen non-stoichiometry and formation of Mn-O5 clusters are a possible cause of the observed differences between the measured and calculated spectra.

It can be concluded that all three ceramic samples (Bi0-Mn4A, Bi6-Mn4A, Bi24-Mn16A) have Pbcm symmetry and all of them have Mn atoms located in a Nb sublattice. However, in the case of Bi0-Mn4A, the crystal structure seems to be deformed because of oxygen defects which provide a charge compensation of Mn presence in the Nb sublattice. For the Bi6-Mn4A and Bi24-Mn16A ceramics, Bi atoms located in a Na sublattice appears to help the charge compensation that stabilizes the crystal structure.

3.2. *"B" series – samples with reduced oxygen content*

For the "B" series samples we expected an increased concentration of oxygen vacancies. This means that the absorption spectra of the "B" series samples should differ from their "A" series prototypes.

However, only the Bi24-Mn16B sample agrees with this prediction (Fig. 1). One can deduce that a significant amount of oxygen vacancies was created during the reduction process and the oxygen reduction procedure was effective. Furthermore, the

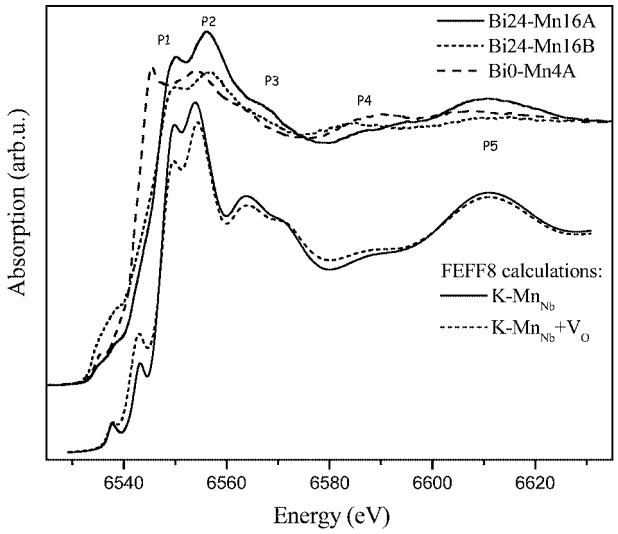

Fig. 2. Experimental Mn K-edge spectra for Bi24-Mn16A, Bi24-Mn16B and Bi0-Mn4A samples in comparison with theoretical calculations for a Mn absorbing atom located in an Nb sublattice (Mn-O6) and for a sublattice with one oxygen vacancy (Mn-O5).

similarity of the Bi24-Mn16A and Bi24-Mn16D spectra indicates that the process is reversible as was expected.

In Fig. 2 we show experimental XANES spectra for the Bi24-Mn16A and Bi24-Mn16B samples and theoretical spectra of an undefected K-Mn_{Nb} cluster and a theoretical spectrum of the same K-Mn_{Nb} cluster with one oxygen atom removed from the first shell without moving other atoms in the cluster. The changes in corresponding peak intensities are shifting in the same directions for all peaks from P1 to P5 which seems to indicate that oxygen vacancies are responsible for the noticed effect and the oxygen reduction procedure in the "B" series was effective.

As compared to the spectrum of Bi24-Mn16A, the tendencies for peaks P2 to P5 for Bi0-Mn4A are the same. This seems to confirm the importance of the role that oxygen defects play in deformation of the structure of the Bi0-Mn4A sample.

The lack of essential differences between the Bi0-Mn4A and Bi0-Mn4B spectra (Fig. 1) suggests that the amount of existing Mn-O5 clusters was close to the saturation level and the heating process used in making the samples may have caused only a slight change in defect concentration.

The Bi6-Mn4A and Bi6-Mn4B spectra are also similar. It seems that undefected Mn-O6 octahedra dominate the structure. It is also probable that the oxygen vacancies are located around Nb atoms forming Nb-O5 clusters and therefore are not visible from a K-Mn edge perspective. However, it is unclear why the amount of defected Mn-O5 clusters did not increase as in the case of the Bi24-Mn16B sample. We can only speculate that this is connected with the exceeded amount of Bi atoms with respect to Mn atoms in the Bi6-Mn4 sample (see Table I). Apparently, the role that Bi atoms play in the stabilization of the crystal structure is larger than expected.

4. Conclusions

XANES measurements, FEFF8 calculations and their analysis lead to the following conclusions:

1. For $(Na^{1+}Bi^{3+})(Mn^{k+}Nb^{5+})O_{3-z}$ ceramics, Mn atoms are located in a Nb sublattice.
2. Co-doped Bi ions help stabilize the crystal structure of the investigated samples.
3. In ceramics with only Mn dopants their presence seems to be compensated by a high amount of oxygen defects.

Abstract

We have constructed an ultra soft X-ray absorption spectroscopy beamline at BL-2 and an XAFS spectrometer at BL-4 using a compact superconducting radiation source of the Ritsumeikan University. BL-2 is composed from an Au coated pre-focusing mirror and a concave diffraction grating with 1200 groves/mm and provides VUV absorption spectra by total electron yield method in the energy range 50–250 eV. BL-2 covers the K-edge absorption energies of elements from lithium to boron in the periodic table. BL-4 is composed of a double crystal monochromator with a working range from 15 to 75 deg and Si(220), Ge(220) and InSb(111) crystals. It covers the energy range of 1700–10500 eV, which corresponds to the K-edge absorption energies of elements from silicon to zinc.

1. Introduction

The X-ray absorption fine structure method is now widely used for structure and electronic state determination of many substances since synchrotron radiation has come to be used for XAFS measurements. Soft X-ray XAFS with K-edge absorption of light elements brings very profitable information in various fields and XAFS stations using soft X-ray have been constructed and developed in many SR facilities.

In 1996, a compact superconducting ring, AURORA, was installed at Ritsumeikan University [1]. Ultra Soft X-ray Absorption Spectroscopy beamline (BL-2) and XAFS beamline (BL-4) were constructed and have been used for research and education [2]. This paper reviews the outlines and measurement results of several standard samples at BL-2 and BL-4.

2. Outline of XAFS beamlines

2.1. *Storage Ring*

AURORA is a superconducting weak-focusing single-body magnet ring. The electron beam that is injected by a race-track-type microtron is boosted up to 575 MeV, and the field strength of the magnet is 3.8 T. The initial stored beam current is 300 mA [3]. As a result, the electron beam radius is 0.5 m and the critical energy of radiation is 844 eV. The electron beam size is 1.3 mm in horizontal and 0.14 mm in vertical direction. AURORA provides intense VUV light and soft X-rays as depicted in Figure 1, and it is very suitable for investigations in VUV and soft X-ray regions.

2.2. *Ultra Soft X-ray Absorption Spectroscopy beamline (BL-2)*

BL-2 is an instrument for ultra soft X-ray absorption spectroscopy in the energy range 50–250 eV, which corresponds to the K-edge energy range from lithium to oxygen in the periodic table. The beamline consists of an Au coated pre-focusing mirror and a concave diffraction grating (1200 groves/mm). The grating, an entrance slit and an exit slit are mounted on a Rowland circle. Absorption spectrum is measured by a total electron yield method that collects electrons emitted from samples with a channeltron detector (Murata Celatron EMT-6081B) or an electron multiplier (Hamamatsu R595).

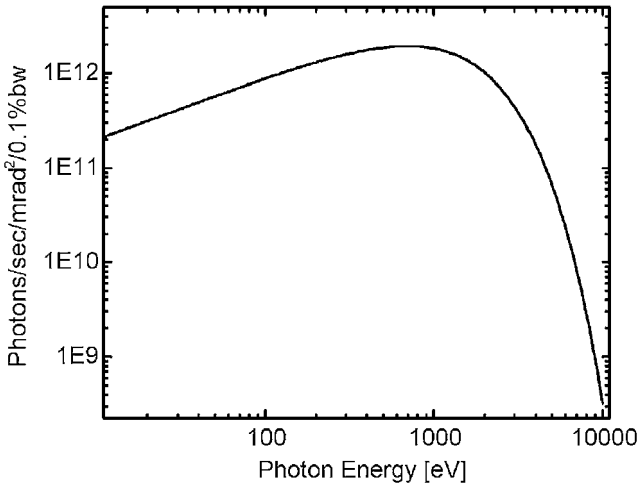

Fig. 1. Spectrum of the radiation emitted from the storage ring, AURORA, at Ritsumeikan SR Center.

The energy resolution is 10000 in $E/\mathrm{d}E$ and the photon flux is 5×10^{10} photons/s at 200 eV. Unfortunately, as shown in Figure 2, it is not possible to neglect the contamination of carbon compounds on grating and X-ray mirror because of the effects of long-time use and contamination of second order harmonics in the region from 50 to 100 eV. However, data with enough quality can be obtained by using energy spectroscopic detectors as channeltrons.

2.3. *XAFS spectrometer (BL-4)*

BL-4 consists of a slit, a double-crystal monochromator (Toyama, Golovchenko type) and detectors [4, 5]. The mechanical movement of the monochromator is in a range from 75° to 15°. The detectors are three ionization chambers (55 mm, 150 mm and 310 mm in length, OKEN), two scintillation counters (SC-50, Rigaku), high purity Ge SSD (Canberra), and Electron multiplier (Hamamatsu). The energy resolution is at least more than 10000 in $E/\mathrm{d}E$ by using Si(220) double crystal and photon flux passing through a 2 mm × 9 mm aperture is 1×10^{10} photons/s at 2400 eV by using InSb (111), as shown in Figure 2. The values, normalized to 1 mm^2, are a few orders of magnitude smaller than those of BL7C at the Photon Factory [6]. However, the quality of XAFS spectra is often degraded by contamination of higher-order harmonics. As shown in Figure 1, the steep decrease of

*e-mail: handa@se.ritsaumei.ac.jp

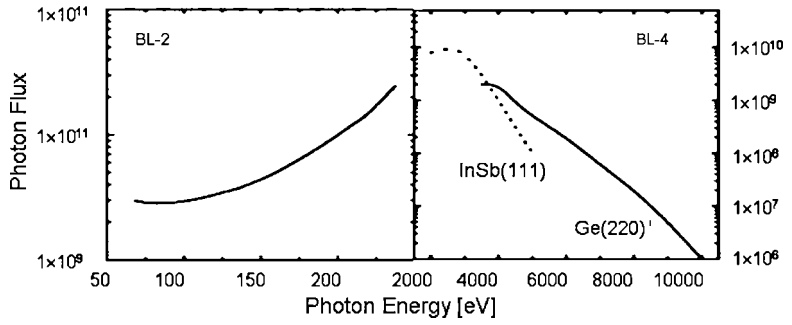

Fig. 2. Photon Flux.

X-ray intensity above 9–10 keV is characteristic of the X-ray spectrum emitted from AURORA. Even for measurements in soft X-ray regions using InSb(111) monochromator, the amount of the second-order harmonics must be negligible small because of the reflection intensity by InSb(222) is related with $(f_{In}-f_{Sb})^2$ for the crystal structure for InSb [7, 8]. Thus, users of this XAFS spectrometer need not to be serious about the contamination of higher-order harmonics. By using Si(220), Ge(220) and InSb(111) crystals, the XAFS spectrometer covers the K-edge absorption energies of elements from silicon to zinc, and the L_{III}-edge from Rb to W.

3. Standard Measurements at BL-2 and BL-4

Figure 3 shows a Li K-edge XANES spectrum of lithium halides, and Figure 4 shows a B K-edge XANES spectrum

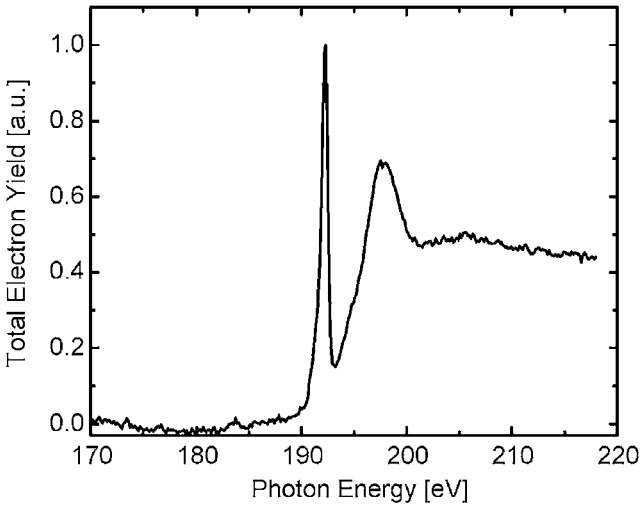

Fig. 4. B K-edge XANES spectrum of B_2O_3 crystal by TEY method at BL-2.

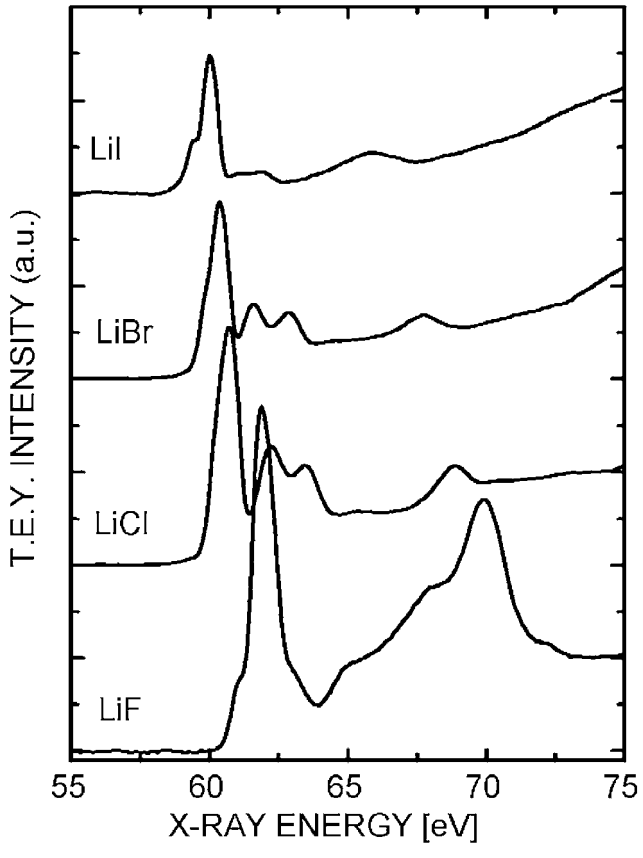

Fig. 3. Li K-edge XANES spectrum of lithium halides by TEY method at BL-2.

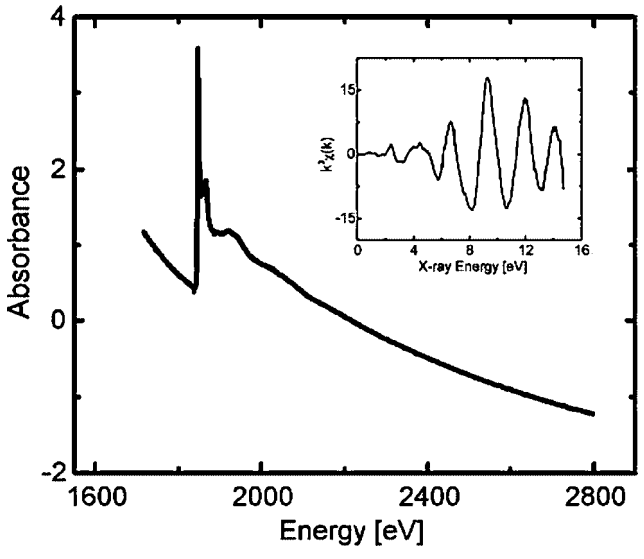

Fig. 5. Si K-edge EXAFS oscillation spectrum of Leucite $K[AlSi_2O_6]$ by transmission mode at BL-4.

of crystalline B_2O_3 powder using BL-2. The measurements were done by TEY method with EM as a detector. These data are in good agreement with the results at the other facilities [9].

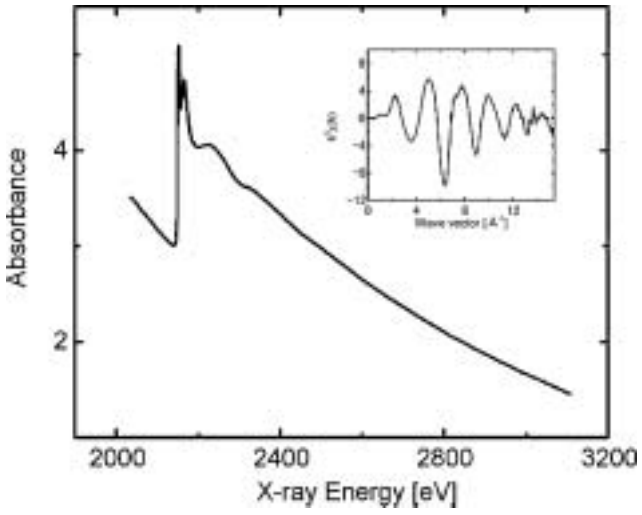

Fig. 6. P K-edge EXAFS oscillation spectrum of triethyl phosphate solution by transmission mode at BL-4.

At BL-4, it is possible to measure K-edges of light elements such as Si, P, and S under atmospheric pressure, and can therefore be applied to solution samples. Figures 5 and 6 depict a Si K-edge EXAFS oscillation of Leucite ($K[AlSi_2O_6]$), and a P K-edge EXAFS spectrum of triethyl phosphate (TEP) by transmission mode at BL-4. These spectru show that high quality data can be obtained at a compact ring.

Abstract

Sagittal focusing is known as one of the most efficient focusing methods for synchrotron X-rays which increases the photon density at the sample position. Results are reported on the performance of a fixed height exit bender with an unribbed silicon (311) crystal. The fixed height exit was achieved by using a 4-point bending mechanism. This bending mechanism is designed for the SPring-8 standard double crystal monochromater (DCM) of bending-magnet beamlines. By using unribbed crystal, the focused beam size was kept at 0.5 mm in the energy range from 35–60 keV. A dynamical sagittal-focusing test was performed around Dy K-edge (53.787 keV). The results underline that 0.5-mm-focus size and beam position are kept during scanning energies; that is, the XAFS measurement can be performed with a sample size = 1 mm.

1. Introduction

The method to focus monochromatic X-rays without losing energy resolution is important for XAFS experiments in order to get higher photon flux. The tunability of photon energy is essentially important especially in the case of X-ray spectroscopy. A sagittally focusing double-crytal monochromator (DCM) was developed by Sparks *et al*. [1, 2] and it is now used in some bending-magnet (BM) beamlines at SPring-8 [3, 4] and many beamlines at other facilities [5, 6, 7]. Higher energy X-rays above 100 keV are easily available from bending magnets of SPring-8. Therefore, the sagittally focusing for a wide energy range (5–150 keV) is preferable. Merits of sagittal focusing by crystal bender compared with focusing by a mirror or lens are wide energy range especially in the higher region, wide horizontal acceptance, smaller size of optical element, and so on.

At SPring-8, it has been three years since crystal benders for sagittal focusing were installed in a standard DCM [8]. The SPring-8 bender consists of a four-point bending mechanism. At first, we used a series of crystal slabs joined by thin hinges, cut parallel to the bending rods. This bender achieved a fixed-exit sagittal focusing for a wide X-ray energy range in adjustable-inclined geometry by only one pair of crystals. Symmetric 311 reflections and inclined 111, 511 and 733 reflections enabled us to focus.

However, the sagittal focus size was sometimes far larger than what the bender users desired. The width of the focused beam is limited by the polygonal nature of the bent crystal. The smallest horizontal size of the focused beam is 3 mm, which is the size corresponding to that of one crystal segment. We tried to solve the problem by using flat crystal instead of the slotted crystal. However, focusing with flat crystals is limited by the anticlastic bending caused by the non-zero Poisson coefficient since the Bragg planes between the first and second crystals lose their parallelism. One proposed solution involves minimizing the anticlastic curvature by using an unribbed rectangular crystal manufactured so that the length to width aspect ratio of the crystal has a particular value and insuring that the modeled boundary conditions are met in the final design. Since synchrotron X-rays test with Si(111) crystal at NSLS [2] confirmed that good sagittal focusing was obtained, the same design crystal was manufactured with Si(311).

Here we report the results of sagittal focusing test using the SPring-8 bending mechanism. The slotted bent crystal is replaced with an Si(311) unslotted (unribbed) crystal. A reasonably good focusing size of 0.5 mm was achieved from 35 keV to 60 keV. Moreover, a dynamic sagittal-focusing (fixed-height exit fixed size focusing with changing energies) is required for XAFS measurements. A dynamic sagittal test was also performed by measuring the Dy-K edge XAFS spectrum.

2. Crystal design

As Kushnir *et al*. have shown [9, 10], the anticlastic curvature can be minimized for a rectangular crystal with "clamped" or "biltin" boundary conditions if the length to width ratio (γ) of the crystal is 1.42. The test crystal used in this study was manufactured from 98 mm × 90 mm × 2 mm float zone silicon. After final etching, the ratio (γ) of the crystal is 1.435, as shown in Fig. 1.

3. Experimental

The focusing test was carried out at BL14B1 of SPring-8, which is a bending-magnet beam-line dedicated to JAERI equipped with

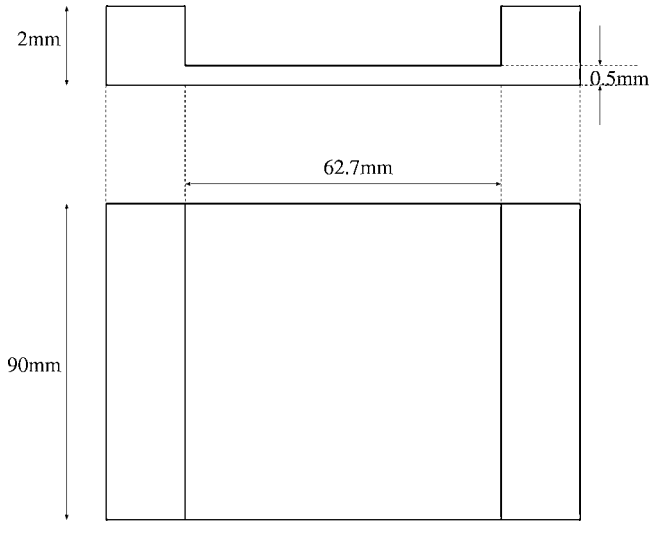

Fig. 1. Schematic diagram of the Si(311) test crystal used in this study. The crystal is machined out of a single Si(111) cylinder 100 mm in diameter by 100 mm thick to leave final rectangular Si(311) crystal dimension of 62.7 mm × 90 mm × 0.5 mm with thick supports.

a SPring-8 standard double-crystal monochromator. The fixed-exit bender was mounted on the second crystal stage of the monochromator. A pair of (311) Si crystals were used both for the first and second crystals. As for the first crystal, an indirect cooled flat plate was used instead of the standard SPring-8 direct fin-cooled crystal. The electron beam current during the test was around 100 mA.

The monochromator was located 36.5 m ($F_1 = 36.5$ m) from the source, where the horizontal beam size of the beam on the first crystal was 50 mm. To observe the focusing properties, beam images were recorded for different bending radii on Polaroid films (type 55) placed at a point 48.5 m from the source, where samples are usually put. Thus, the monochromator-focus point distance, F_2, was 16.5 m. These distances give a focusing ratio ($M = F_2/F_1$) of approximately 1/3. At the optimal bend in radius for each energy, intensity profiles were measured by scanning a 0.5 mm wide slit both horizontally and vertically. The horizontal scan showed the focusing property, whereas the vertical scan gave the beam height fluctuation. A series of tests gave us the optimal radius at each energy. We used the radius data for dynamic sagittal focusing [11], for which an absorption spectrum around the Dy K-edge was demonstrated.

4. Results and discussion

The beam images at the sample position for several values of the bending radius, R, are reproduced in Fig. 2 at 38 keV with 311 reflection. The crystal had $R = 8.0$ m when it was mounted on the bender. The horizontal beam size was 47 mm at the screen position for the maximum bent radius. At optimal focusing ($R = 4$ m), the horizontal sizes of the beam approached 0.5 mm, being larger than the theoretical value (0.2 mm).

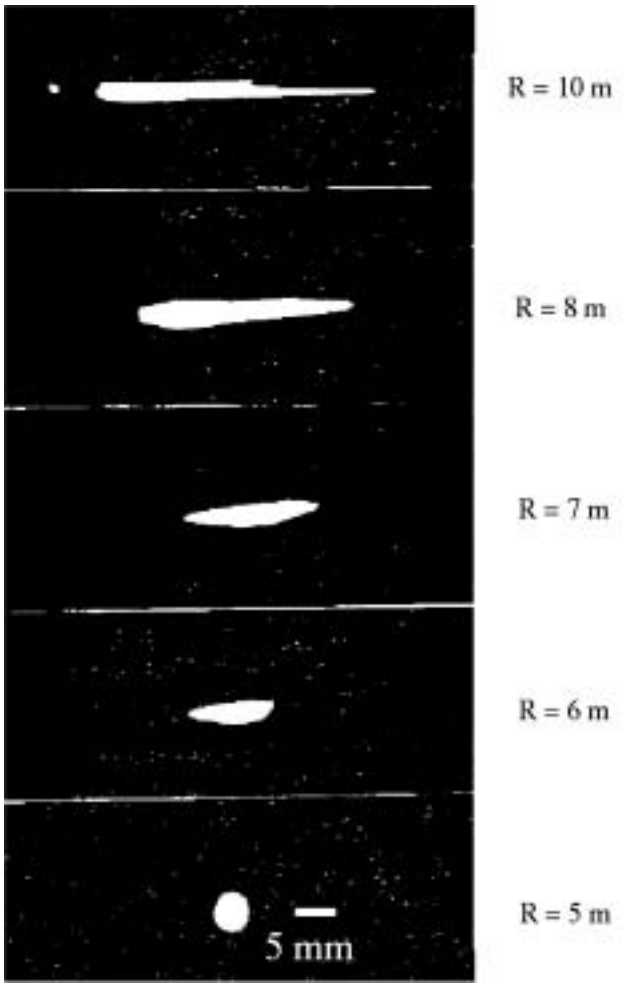

Fig. 2. Beam profiles obtained with the sagitally focusing crystal monochromator at 30 keV. The X-ray beam was focused by decreasing bending radius R.

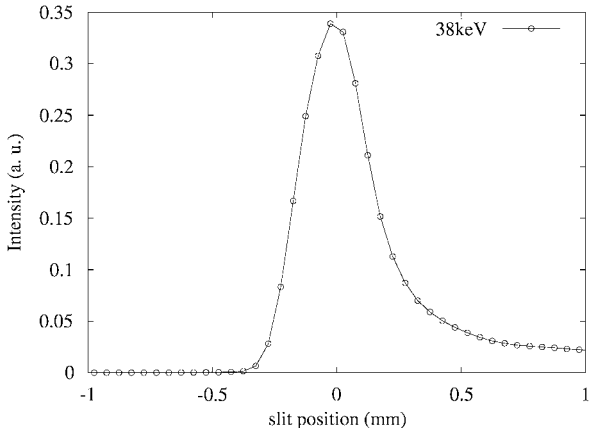

Fig. 3. Horizontal beam profile measured by moving a 500 μm slit on a sample stage, across the focused beam.

Figure 3 shows a spatial intensity profile measured at 38 keV by scanning a slit horizontally at the 3:1 focus position for the bent ($R = 4$ m) crystal. The slit used had 0.5-mm-width and was made of tungsten carbide. The measured increase of the flux density at the focal point was 70 times more than that of the flattened crystal, which is a little less than the ideal value due to the smaller diffraction efficiency of the bent crystal.

Energy resolution was measured with near-edge absorption data runs on the Dy K-edge at 53.787 keV in Dy foil, using the setup shown in Fig. 4(a). The 0.5-mm-focused incident X-rays were introduced through a 1.0 mm pin-hole slit. XAFS measurement was performed by dynamic sagittal focus mode, which means that the bending radius is optimized at every measurement energy from 53.6 keV to 54.2 keV. In Fig. 4(b)

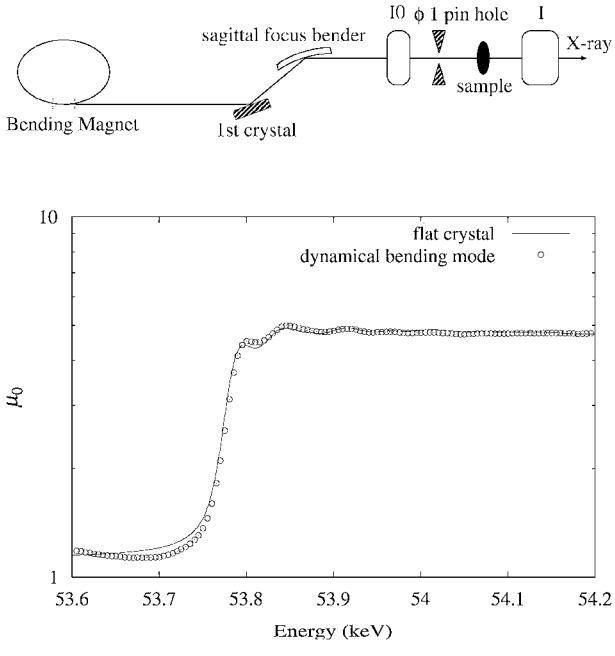

Fig. 4. (a) Experimental setup for XAFS measurement with sub-millimeter focusing beam. (b) Near-edge absorption spectra of Dy foil, registered in a dynamically focusing mode (circles) and with a flat crystal (line).

we compare the near-edge spectrum of Dy foil registered in the dynamically focusing mode on BL14B1 with a normal flat crystal on BL01B1 that is specialized for XAFS measurements at SPring-8 [12]. The two spectra are identical so we conclude that the energy resolution is not affected by sagittal focusing, nor are any distortions introduced.

Sub-millimeter synchrotron X-ray focusing was successfully achieved in the energy range from 38 keV to 57 keV by combining the unslotted crystal and SPring-8 standard bend mechanisms. In this performance test, changing the radius of curvature from 4 to 8 m dose not cause any significant change in the beam intensity.

5. Summary

Sagittal focusing was tested by using unslotted crystal that is designed for the SPring-8 standard benders. The flux density of the focusing X-ray beam was increased by 70 times compared with that using flat-flat double crystals. The dynamic sagittal focusing test was successfully performed with 1.0 mm pin-hole slit. This assures that XAFS measurements with millimeter-size samples are achievable by using the SPring-8 standard bender and the unslotted crystal.

Abstract

A highly strained, curved silicon crystal in the Laue geometry has been used as a large area X-ray fluorescence analyzer for X-ray absorption spectroscopy. The analyzer is able to resolve the Lα fluorescence lines for neighboring actinide elements. A large gain in the signal-to-background ratio has been achieved for low levels of Mo, Np, and Pu in a UO_2 matrix. We have determined the chemical state of these elements in approved testing materials of uranium oxide spent nuclear fuel. Due to inelastic scattering from the predominant uranium, the concentration of Np measured, 0.6(2) mg Np/gram U, may be approaching the sensitivity limits for quantitative structural spectroscopy measurements.

1. Introduction

The primary limitation to using X-ray absorption fine-structure (XAFS) spectroscopy for many interesting environmental and biological problems is the presence of a high level of background radiation from a variety of sources, such as elements with lower energy absorption edges, radioactive elements, or scattered radiation from other beam interactions with the sample. We have demonstrated the effectiveness of a bent silicon wafer curved to a logarithmic spiral in the Laue geometry (bent Laue analyzer or BLA) to resolve neighboring actinide Lα lines and to measure the XAFS spectra of as low as 0.6 mg Np/gram U. In the process of making these measurements, we have found that inelastic scattering attributable to the uranium may pose an ultimate limit to quantitative XAS measurements on Np.

The design concept of the BLA has been discussed previously [1, 2]. The essential property of such an analyzer is that bending the crystal to a logarithmic spiral solves the mismatch between the narrow acceptance angle of a perfect crystal and the large divergence of fluorescence from the sample [1, 3, 4]. Except for the case in which the asymmetry angle is equal to the Bragg angle and the logarithmic spiral becomes a cylinder, the correct form is difficult to produce accurately with dynamical bending [1]. Therefore, we have used a fixed bender form, a CNC-milled aluminum block, over which the silicon wafer was bent. The instrument used for this experiment, with the exception of the silicon wafer, is described elsewhere [5].

2. Experiment

Measuring the L-edge fluorescence XAFS in mixed actinide samples is a challenging problem. For the samples we report here, excellent energy resolution is required, as the Lα_1 fluorescence lines for U, Np, and Pu are separated only by ca. 350 eV; the Lα_2 lines are separated by less than 150 eV from neighboring Lα_1 lines. We have used the BLA to study an approved testing material (ATM) of spent uranium oxide nuclear fuel that is primarily uranium(IV) oxide. This sample also contains small quantities of fission products [6–9]. We have also studied oxidized alteration phases that formed on the surface of this ATM during aqueous corrosion testing [6]. The matrix in the alteration phases is predominantly uranium(VI) oxide [8], easily distinguishing these particles from the unaltered spent fuel. We did not observe Np incorporated into the alteration phases, with an estimated sensitivity of better than 0.3 mg Np/gram U [8].

All measurements reported here were carried out on the MR-CAT undulator beamline, 10-ID, at the Advanced Photon Source (APS), Argonne National Laboratory. A cryogenically cooled Si(111) double-crystal monochromator was used to select the incident energy. An uncoated ULE glass mirror was used to reject higher-order harmonic content of the beam, so as not to rely upon the focusing mirrors for this critical function [10]. Kirkpatrick-Baez mirrors, positioned downstream of the harmonic rejection mirror, provided a focused beam smaller than 10 μm × 10 μm from an incident beam of ca. 250 μm × 250 μm (about 5% of the total incident beam).

The 140 μm Si wafer used for the BLA had a ⟨100⟩ surface normal and the ⟨111⟩ planes were used as the diffracting planes, resulting in a 35.3° asymmetry angle. The active area was a 30 mm × 120 mm rectangular window cut into the bender form to allow the X-rays to pass through to the detector. Direct X-rays were rejected by 70 mm long stainless-steel Soller slits, spaced at 1° intervals (about 3.6 mm apart at the analyzer center). Two NaI scintillation detectors were used to detect X-rays. The highest energy resolutions achieved for the analyzer were 71 eV and 79 eV (FWHM) at the positions of the two detectors, at the uranium Lα_1 fluorescence line (13615 eV).

3. Results and Discussion

3.1. *X-Ray Absorption Spectra*

Figure 1a shows a scan of the intensity vs. energy for the ATM sample as the incident energy is held fixed both below and above the Pu L_3 edge while the analyzer angle is scanned. Strontium Kα fluorescence is visible in both scans. The U Lα_1 fluorescence line is suppressed slightly by self-absorption as well as detector saturation. The Np Lα fluorescence is not visible on this scan due to the noise level. Figure 1b shows the fluorescence spectrum with the incident energy above and below the Mo K edge. The analyzer position and slits were optimized for Mo Kα radiation; as a consequence, the analyzer is clearly not aligned properly for the U Lα lines on the far left of the scan. Five fluorescence peaks are identified as the uranium Lβ lines, while the Mo Kα line appears, fortuitously, between two uranium Lβ lines. The resolution of this detector gives us unprecedented sensitivity to such minor constituents.

†email: kropf@cmt.anl.gov

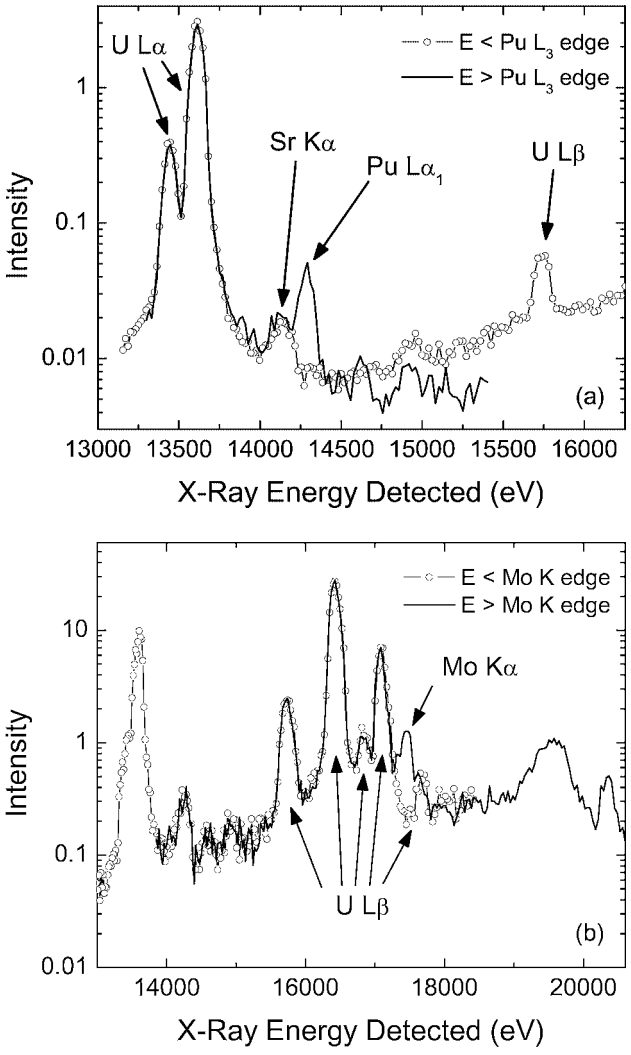

Fig. 1. Bent Laue analyzer angle scans with ATM sample. (a) Incident X-ray energy above and below the Pu L_3 edge, optimal tune for Pu Lα_1. (b) Incident X-ray energy above and below the Mo K edge, optimal tune for Mo Kα.

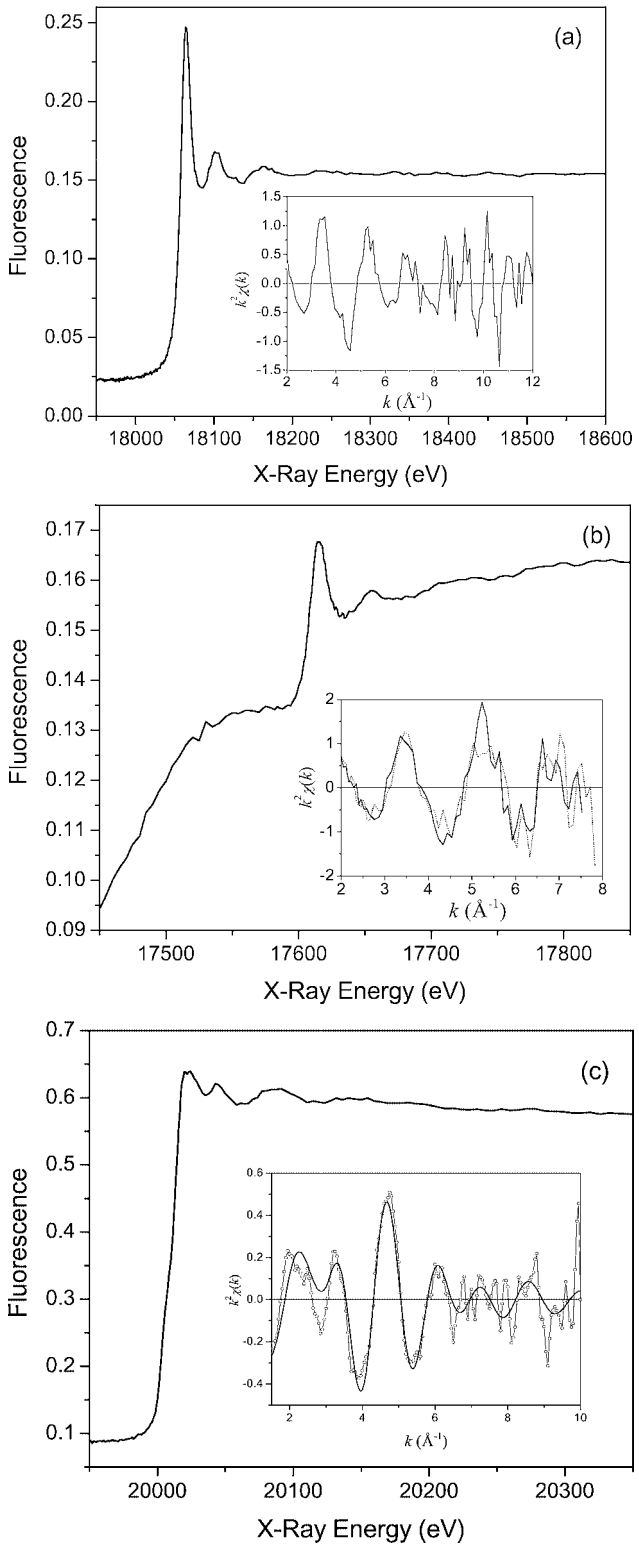

Fig. 2. X-ray absorption spectra of ATM sample using the BLA. (a) Pu L_3 edge and $\chi(k)$ data (inset). (b) Np L_3 edge and $\chi(k)$ data from the two detectors (inset), and (c) Mo K edge data with $\chi(k)$, dotted line and fit (inset).

Figure 2 shows the absorption spectra for Pu, Np, and Mo in the ATM sample. Plutonium, with the highest concentration (8.3 mg Pu/gram U [9]), gives the best signal. The $\chi(k)$ data clearly identifies the Pu in a PuO_2-like phase [11]. Fitting using methods similar to ref. [11] results in $R_{\text{Pu-O}} = 2.33(1)$ Å and $R_{\text{Pu-Ac}} = 3.86(2)$ Å, where Ac stands for Pu or U, which have similar backscattering amplitudes and phase shifts. This is quite similar to bulk PuO_2 from [11]: crystallographic structure fm-3m, $R_{\text{Pu-O}} = 2.344$ Å and $R_{\text{Pu-Pu}} = 3.833$ Å. Far more likely than the existence of a separate PuO_2 phase, is the incorporation of the Pu into the UO_2 matrix (also fm-3m).

The Mo is present in a lower concentration (3.0 mg Mo/gram U [9]) and the Fourier transform reveals some Mo-O ($R = 2.14(5)$ Å) and a larger number of Mo-metal ($R = 2.61(4)$ Å) scattering paths, indicating that the Mo is present in both oxide and metallic forms. Analysis of this spectrum is continuing as the Mo-metal Debye-Waller factor is large and may be contributing to an unusually short distance. At this point it is not possible to distinguish between two different phases or a phase containing both oxygen and metal bonds.

The Np is present in an even smaller amount: 0.4 mg Np/gram U calculated by Guenther *et al.* [9], or 0.6(2) mg Np/gram U as measured from the fluorescence spectra. The background on which the Np L_3-edge spectrum rides is comprised of the uranium fluorescence that makes it through to the detector and an unexpected contribution from inelastic scattering attributable to the uranium, to be discussed below. At 1 part in 1700, the Np signal to background ratio is 0.15, barely large enough to measure a usable EXAFS signal. The data shown are summed from 24 hours of data acquisition. Clearly much better counting statistics are needed to truly reveal the Np coordination environment. Nevertheless, from comparing the XANES to published spectra it seems reasonable to assign to the Np a +4

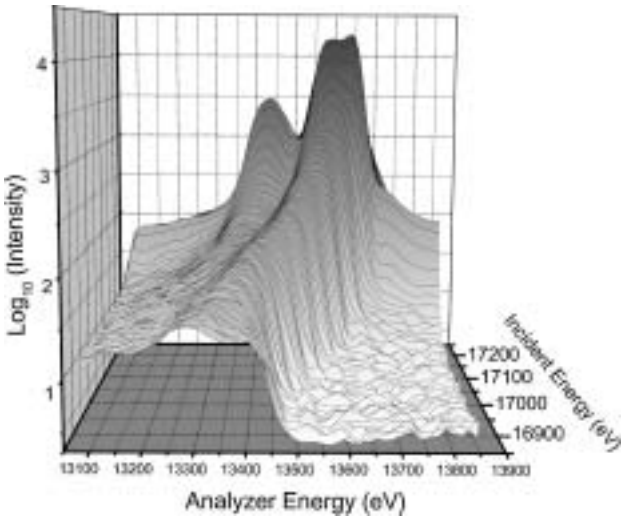

Fig. 3. X-ray fluorescence and inelastic scattering. Log_{10}(intensity) vs. incident energy and analyzer energy.

oxidation state [12]. The $\chi(k)$ data for the two detectors (inset, Fig. 2b) is also suggestive of Np in a UO_2-like phase given the similarity to the PuO_2 and UO_2 spectra ($R_{\text{Np-O}} = 2.34(3)$ Å and some evidence for $R_{\text{Np-Ac}} = 3.85(4)$ Å). Higher quality data to $12\,\text{Å}^{-1}$ would make this a much more convincing argument. If these data are corroborated by further evidence, the Np is also likely dispersed in the UO_2 on the U sites.

While the resolution of the analyzer is quite good, and the Np and U Lα peaks are well-resolved, the Np fluorescence at 13944 eV still sits on a background of uranium fluorescence. The tail of the uranium fluorescence distribution, at the position of the Np Lα_1 peak, is down by a factor of ca. 300 from scans (not shown) in which the uranium peak has not saturated the detector and self-absorption has been minimized. A higher resolution analyzer could potentially lower the background level and improve the sensitivity to Np.

3.2. *Inelastic scattering*

Figure 3 shows the X-ray intensity vs. the incident X-ray energy and the analyzer (output) energy. The two largest peaks are the uranium Lα_1 and Lα_2 fluorescence lines. One can clearly see the long tails to these peaks when the incident energy is *below* the U L_3 absorption edge threshold, where these U core levels are not excited. This is not due to an impure incident energy spectrum. Moreover, since the outgoing photon energy is different than the uranium fluorescence energies, these X-rays are not due to fluorescence decay. In fact, the energy of these background photons corresponds to the energy of the incident photons minus the uranium $M_{4,5}$ edge energies. As the incident energy approaches the U L_3 edge, the inelastic scattering appears to be resonantly enhanced, until it merges with the uranium Lα fluorescence line. As an aside, with an analyzer of high enough resolution, one could measure the uranium M edge spectra using high-energy X-rays by scanning the analyzer energy or by fixing the analyzer energy and scanning the incident energy.

Inelastic scattering could prove to be a fundamental limit for sensitivity to Np in a uranium matrix, or in similar systems, as it creates a background that cannot be discriminated against by any method, since the photons are, in fact, at the same energy as the photons of interest. With a higher resolution detector, the background level could be reduced, since fewer photons would be within the detector bandwidth. On the other hand, a smaller bandwidth means that the M edge structure would not be convoluted with a low resolution analyzer. Therefore, the M edge white line or EXAFS oscillations could contaminate the Np edge data. Figure 2b shows the uranium inelastic scattering that appears at lower energy than the Np L_3 edge. The onset energy of this feature can be altered by adjusting the angle of the analyzer. This property combined with the width of the inelastic scattering feature unambiguously distinguishes it from the Np fluorescence.

4. Conclusions

The bent Laue analyzer has exhibited promising results for a very difficult system. In fact, the high background rejection observed could recommend this type of detector for other applications. A bent Laue analyzer with a peak-to-valley ratio of better than 500 : 1 extends the useful spectroscopy limits by as much as a factor of 50 times compared to current state-of-the-art multielement germanium detectors, when used for mixed actinides. With a higher resolution analyzer (thinner crystal) and slightly more efficient Soller slits, it is likely that an additional factor of 3 in sensitivity could be achieved. However, given the interference of inelastic scattering, it is difficult to envision taking useful EXAFS spectra at concentrations lower than 0.05 mg Np/gram U.

Received June 26, 2003; accepted November 4, 2003

Abstract

The Institut für Nukleare Entsorgung (INE) at the Forschungszentrum Karlsruhe is presently constructing and will commission and operate an X-ray spectroscopy beamline dedicated to actinide research at the new synchrotron source ANKA. One great advantage of the INE-Beamline is that on-site, in situ actinide research is possible for studying, e.g., solid-water interface chemical reactions, which are not possible at other facilities. The design is for a multi-purpose beamline, i.e., a number of methods (XAFS, surface sensitive and spatial resolved techniques) are possible on one and the same sample. Planned is a safe and flexible containment concept for activities up to 10^6 times the limit of exemption. The design will allow spectroscopic investigations using photon energies from the K edge of S (2477 eV) to the Rh K-edge (23220 eV). The optics include collimating and focusing mirrors for a sub-mm beam dimension at the sample position. A later upgrade is planned to install auxiliary μ-focusing optics (e.g., a single bounce elliptical monocapillary or planar compound refractive lenses). The monochromator at the INE-Beamline is a Lemonnier type double-crystal X-ray monochromator (DCM), built at the Universität Bonn, Physikalisches Institut. The pressure inside the small diameter (380 mm) vacuum housing is $\sim 10^{-6}$ mbar, allowing fast changes of crystals, avoiding long pumping times. Multi-layer mirrors can be used in the DCM for wide band-pass experiments, e.g., for X-ray fluorescence analysis measurements. Installation of beamline components has been completed in October 2003. Operation begin is targeted for 2004.

1. Introduction

The Institut für Nukleare Entsorgung (INE) is designing, constructing and will commission and operate an X-ray spectroscopy beamline dedicated to actinide research at ANKA. There is a deficit of synchrotron facilities, where the infrastructure, safety equipment and expertise are available for performing research on radioactive samples. The INE-Beamline will help meet the growing demand for these investigations. One great advantage of the INE-Beamline is that the ANKA facility and INE's active laboratories are both located at the Forschungszentrum Karlsruhe. This not only minimizes hazards and simplifies administrative obligations associated with transporting radioactive samples to and from a controlled area laboratory and the synchrotron but also optimizes sample preparation and can allow for investigations of dynamic systems within a time-frame of hours. Samples can be prepared, characterized and analyzed using the spectroscopic, microscopic and structural methods available in INE before being investigated using synchrotron based methods at the INE-Beamline within a short time. The samples are also retrievable, so that sample characterization in INE laboratories shortly following the experiments at the beamline is possible.

2. The ANKA Light Source and the INE Beamline

The ANKA storage ring is operated at 2.5 GeV with a characteristic energy of 6.0 keV and presently with a beam current of ∼200 mA. The ring is refilled twice a day. The beam lifetime ranges from 15 to 30 h. The overview of the ANKA light source with the accelerator components and the beamlines installed in the $60 \times 60\,m^2$ experimental hall is depicted Fig. 1. The INE-Beamline is located at the bending magnet port designated 3.2–5 at the east side of the building. The envelope of the radiation protection hutch and the control cabin with integrated lock room bordering the experimental section of the radiation protection hutch is shown in Fig. 1.

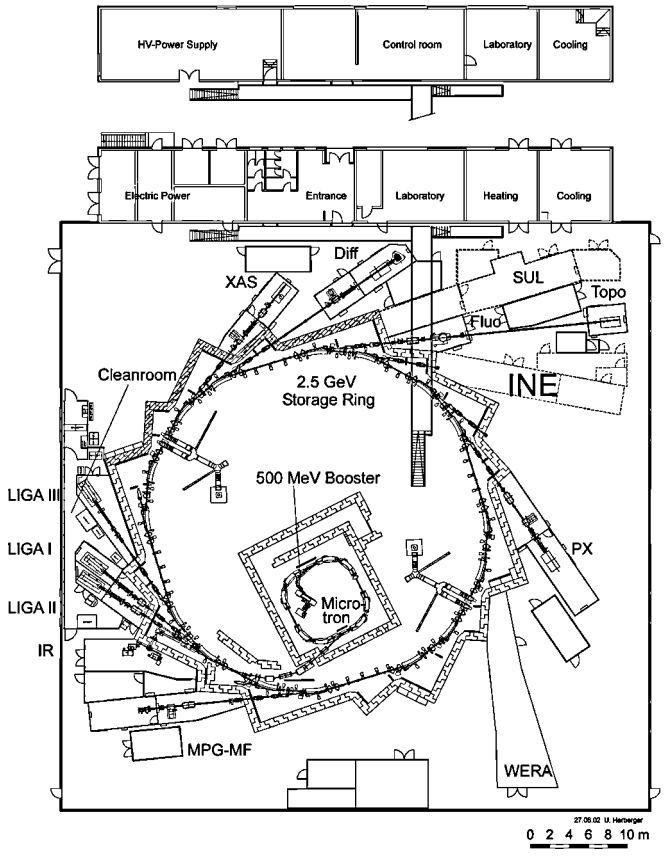

Fig. 1. Overview of the ANKA light source with the main accelerator and the beamlines installed in the $60 \times 60\,m^2$ hall. The location of the INE-Beamline (port 3.2–5) is indicated on the right.

3. INE-Beamline design and X-ray spectroscopic methods available for actinide speciation

The research and development at INE is largely aimed at safety assessment of proposed deep geological repositories for high-level, heat producing nuclear waste disposal. To ensure valid performance safety assessment, a molecular understanding of processes determinant in the fate of radionuclides, notably the actinides, is essential. A major portion of research at INE is concerned with

*e-mail: melissa@ine.fzk.de

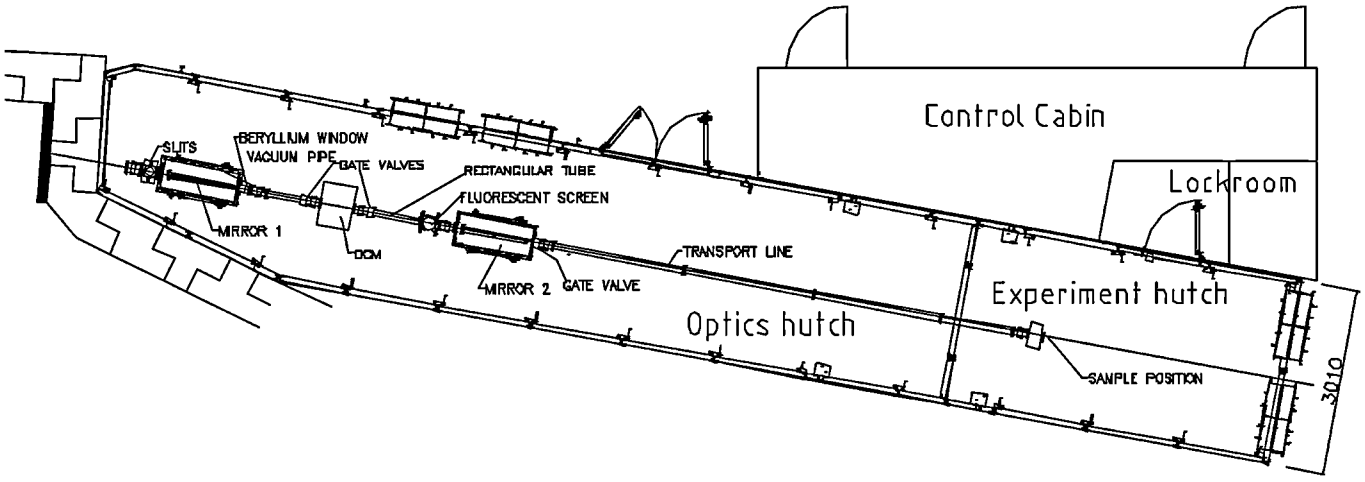

Fig. 2. INE-Beamline design layout. The beamshutter between optics and experiment hutch is not shown.

actinide speciation, including coordination and redox chemistry of actinides, determination and characterization of actinide cations sorbed onto surfaces (e.g., at the mineral-water interface), investigation of actinide containing precipitates, colloids and secondary phases, as well as glass and spent fuel corrosion. Because actinide speciation associated with nuclear disposal concerns is manifold, the INE-Beamline design is for a multi-purpose experimental station, i.e., a number of methods are possible on one and the same sample. The methods available are standard, surface sensitive and spatially resolved methods. The standard X-ray methods X-ray absorption fine structure (XAFS) and X-ray fluorescence (XRF) are available and it is possible to combine XAFS with X-ray diffraction (XRD). Because many reactions of actinides in the hydro- and geospheres are at interfaces and junctions, emphasis at the INE-Beamline is being placed on surface sensitive techniques based on grazing incidence (GI) geometry such as GI-XAFS, X-ray reflectivity and total external reflection X-ray fluorescence analysis (TXRF). In addition, a micro-focus option will be available after a planned future upgrade to offer spatially resolved measurements. This will allow chemical state imaging (μ-XAFS), elemental mapping (μ-XRF) and, to a limited extent, identification and distribution mapping of phases (μ-XRD).

Investigation of samples with activities up to 10^6 times the limit of exemption will be possible. The necessary infrastructure and safety equipment is available for active experiments. For example, the experimental section of the radiation hutch is equipped with a special ventilation/filter system, specially sealed chicanes, easily decontaminated surfaces and a personnel lock room with a hand-foot monitor for entry and exit. During the experiments, the samples themselves are contained within two levels of containment. The first is typically a sealed sample cuvette, vial or plastic bag. The second containment generally is a mechanically stable box or cylinder having sealed windows for beam entrance, transmitted beam and fluorescent beam, into which a sample or a number of samples on a sample changing stage are mounted. The windows are made of low-Z material, e.g., Kapton® or polycarbonate. A special protocol for working with radioactive samples at the INE-Beamline exists and must be adhered to. A portion of annual beamtime will be available at the INE-Beamline via the standard ANKA proposal procedure. Experiments are also possible through cooperation with INE. The INE-Beamline is also a pooled facility in the European ACTINET Network of Excellence.

3.1. *Optics*

The layout of the INE-Beamline design is given in Fig. 2. The design will allow spectroscopic investigations using photon energies from the K edge of S (2472 eV) to the Rh K-edge (23220 eV). The optics include Rh-coated collimating and focusing mirrors for a sub-mm beam dimension at the sample position. The synchrotron radiation beam is vertically collimated through the cylindrical mirror (M1) prior to entering the double-crystal monochromator (DCM). Upstream from the DCM, the beam is focused horizontally and vertically through a toroidal mirror (M2). A later upgrade is planned to make auxiliary μ-focusing optics available within the experimental hutch, e.g., a single bounce elliptical monocapillary or planar compound refractive lenses. These have the advantage for working with radioactive samples within their an air-tight containment barrier in that the focal length can be a number of centimeters.

3.2. *Monochromator*

The monochromator at the INE-Beamline is a Lemonnier type DCM. It is already built and accessory components are being installed at the Universität Bonn, Physikalisches Institut. The pressure inside the vacuum housing is $\sim 10^{-6}$ mbar and the vacuum housing only 380 mm in diameter, allowing fast changes of crystals, without long pumping times. Four pairs of crystals are available, Si(111), Si(311), Ge(220) and Ge(422). The DCM can also accommodate multi-layer mirrors for wide energy band-pass experiments, e.g., for XRF analysis measurements requiring high flux.

3.3. *Experimental station*

The optical tabletop in the experimental hutch is $1.2 \times 3\,\mathrm{m}^2$ breadboard, large enough to accommodate most any experimental set-up. Three ionization chambers (HASYLAB Design) and a LE-Ge five element fluorescence detector (Canberra) are available for recording XAFS spectra in transmission and fluorescence mode. The grazing incidence equipment consists of two goniometer cradles with a common center of rotation, a z-stage and a rotation stage (HUBER Diffraktion-stechnik GmbH). The first goniometer

cradle is for adjusting the relative incident angle (θi) of the impinging beam onto the sample surface. The other cradle is at right angles to θi and is used to adjust the sample surface to be plane-parallel with the storage ring orbit if necessary. The goniometer cradles are mounted on z-stage (vertical) for sample height adjustment. An additional motor for rotating around the sample surface normal is provided in order to change the sample surface orientation relative to the synchrotron beam polarization vector (ε) during polarization dependent measurements. The GI-equipment has been successfully employed at both HASYLAB (Beamline X1) [1] and ANKA (XAS-Beamline). A position sensitive detector array will be used for combined XAFS-XRD measurements.

4. Target dates

The front-end was installed in 2002. Radiation hutches were built in March 2003. The control cabin and media were installed in June/July 2003. The installation of the beamline optic components has been completed in October 2003. Commissioning of the INE-Beamline and first pilot experiments have begun in 2004. The INE-Beamline will be operational in 2005.

Abstract

For high throughput and energy-resolution florescence X-ray absorption spectroscopy (XAS), a novel Ge pixel array detector (PAD) with 100 segments has been developed. Two sets of PAD having different thickness values, *i.e.*, 10 mm (#1) and 7.5 mm (#2), were constructed and installed at Spring-8 (BL10XU) and Photon Factory (BL13B). Using a monolithic approach, a nearly perfect packing fraction (>88%) and commission rate (99%) were achieved, resulting in a significant improvement over a previous Ge multi-element detector. In the present PAD design, each segment is square-shaped having an active area of 22 mm^2. The average energy resolution at 5.9 keV was 220 eV (6 μs shaping time) and 240 eV (0.5 μs) in a high throughput mode. High efficiency X-ray detection over a wide energy range (5–60 keV) was confirmed. The present electronics-limited throughput maximum is 100 kcps per channel or 10 MHz in total. We will describe unconventional applications in fluorescence XAS demonstrating the capability of PAD. The recent *in-situ* XAS study under laser light required a small amount of specimen (less than 10^{-3} g).

1. Introduction

For X-ray absorption spectroscopy applications in dilute systems, a fluorescence detection technique [1] is used to overcome limitations in sensitivity. The bulk sensitivity limit in fluorescence XAS depends on both the flux of incident X-ray beam and detector performance, *i.e.*, energy resolution, efficiency and throughput. Rapid and sensitive measurements of surface XAS became feasible using a dense-packed solid state detector array [2]. For surface studies where the typical density of adsorbed atoms is in the order of $10^{14}/cm^2$, a grazing-incidence geometry can provide a means of surface-sensitive measurement. Moreover, fluorescence yield can be used in XAS applications to photo-induced phases using thin films or fine powders, solving a problem of mismatch between X-ray probe and visible photo penetration depth [3]. A large number of segmented X-ray detectors can control the systematic (nonstatistical) error by eliminating channels that suffer from strong scattering. A segmented X-ray detector is needed to minimize statistical and nonstatistical error.

The effective throughput of a solid state detector (SSD) can be increased by assembling detector elements with a close packing geometry. Various types of multi-element SSD arrays have been designed for this purpose [4–6]. A monolithic approach should be adopted in order to further improve the packing density beyond the present limit. Note that modern high energy photon sources (6–8 GeV) require detector efficiency over a wide range in energy (5–60 keV). This energy range is hardly covered by a silicon drift diode detector which has a superior performance in count rate and energy resolution [7]. To meet newly emerged requirements, a novel Ge pixel array detector (PAD) was designed and built. In this report, we describe basic specifications and performance of the first 100 segment Ge PAD.

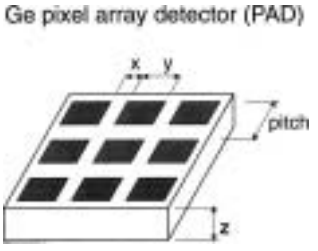

Fig. 1. Schematic of Ge pixel array detector and dimensional parameters, *i.e.*, pitch, pixel length, interpixel length and thickness.

2. Specifications of the PAD

The schematic arrangement of Ge PAD is shown in Fig. 1 where a part of the 10 × 10 array is shown. Two types of Ge PAD were fabricated. The two PADs have the same pixel length (y) and pitch (p) dimensions but different thicknesses (z), *i.e.*, the first PAD (PAD #1) has $z = 10$ mm while the second one (PAD #2) has $z = 7.5$ mm. PAD #1 with thicker z was designed for use with a higher energy storage ring (8 GeV *vs* 2.5 GeV) while PAD #2 was aimed at minimizing the incomplete charge collection event. One component of the electronic noise of the PAD is proportional to the input capacitance at the FET, which is a sum of the detector and FET capacitance (∼0.9 pF). Thus the strategy to maximize the energy resolution was to minimize the total capacitance as a function of p, x and z as much as possible. The fluorescence signal taken over a cone-like limited solid angle away from the scattering plane gives the lowest scattering intensity. From geometrical consideration, we have first determined the pitch p as 5 mm. However, the pixel-to-pixel capacitance increases sharply as a function of x below 300 microns and x was compromised. The pixel-to-ground capacitance also increases with thickness z.

3. Performance

The Ge pixel array is attached to contact pins and cooled by liquid nitrogen. Each output is fed into a separate analog preamplifier board. The transistor reset preamplifier was developed for the following reason. In resistor feedback preamplifiers, the need for large feedback resistances (>10^9 ohms) to reduce the noise induced by the resistor imposes a limit on counting rate.

*e-mail: h.oyanagi@aist.go.jp

Pulsed-light feedback has drawbacks such as slow diffusion in the input FET of the charge generated by the infrared flash upon preamplifier reset.

The PSC 741-N preamplifier consists of two components; an input circuit contained in the cryostat and cooled to a temperature slightly higher than 77 K, including the field-effect transistor, the reset transistor and the feedback capacitor. An external part contains a main board which processes the input pulses. To evaluate the performance, the analog-digital "hybrid" CAMAC module was developed. Each double width module accommodates linear amplifier circuits, SCA and histogram memory for eight channels. Totally thirteen CAMAC modules were built and accommodated into two CAMAC powered crates.

The performance of the detector was evaluated by the measurement of energy resolution, throughput and quality of fluorescence spectra for some dilute samples. The test was performed at the 27-pole wiggler beam line BL13B at the Photon Factory. An unfocused X-ray beam from a directly cooled Si(111) double-crystal monochromator was used. The energy resolution was determined for each channel from the full width at half maximum (FWHM) of the Mn K_α peak (5.9 keV) using a standard source (^{55}Fe). The best energy resolution was 215 eV at a low count rate using a shaping time of 6 μs as shown in Fig. 2. A slight degradation of energy resolution might be due to insufficient cooling efficiency and/or cross talks between the channels. The average energy resolution evaluated from FWHM values of Mn K_α peak (5.9 keV) was 235 eV with $z = 10$ mm (PAD #1). The average FWHM value for $z = 7.5$ mm (PAD #2) degraded to 245 eV due to the increase of pixel-to-ground capacitance.

Amplifier dead time degrades the throughput due to the pulse pile-up. We evaluated the amplifier throughput for each channel from the nonlinearity of the detector output rate as a function of input beam intensity evaluated from the incident beam flux i_0. Figure 3 shows a throughput curve (open circles) for the Cu K_α peak as a function of i_0 which was obtained by the single-channel analyzer output for a shaping time of 0.5 ms. Linearity of i_0 in this energy range is established by a simultaneous measurement of the beam intensity using a calibrated ionization chamber.

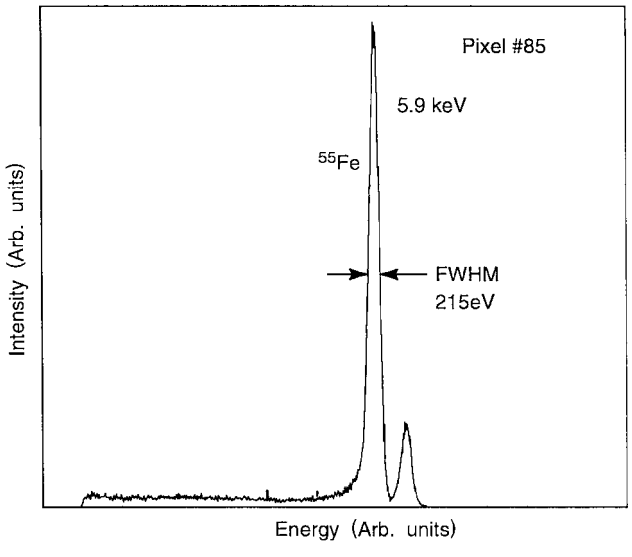

Fig. 2. MCA output (phase height distribution) for the Ge pixel array detector for ^{55}Fe (5.9 keV) using 6 μs shaping time.

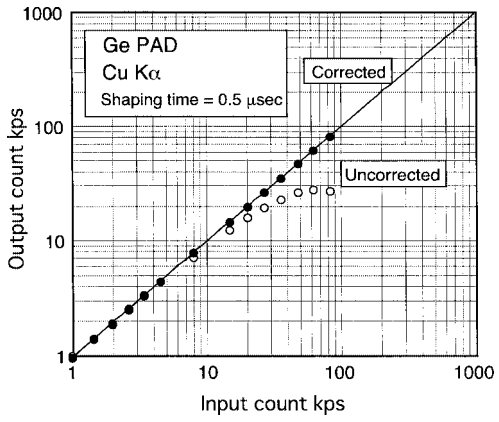

Fig. 3. Throughput curve for the Ge pixel array detector using Cu Kα (8.07 keV) and 0.5 μs shaping time.

The "hybrid" electronics output starts to deviate from a linear function for $i_0 > 10$ kcps. This shows that even with a fast shaping time (0.5 μs), it is required to correct the nonlinearity caused by the detector dead time effect. The fit seems to be valid for $i_0 < 100$ kcps above which the corrected curve does not give a good fit. After a dead time correction on a computer, a linear response is obtained below a count rate of 100 kcps. The total maximum count rate is thus evaluated to be maximum *ca.* 10 MHz. The present maximum throughput is limited by both analog (amplifier dead time) and digital (SCA and memory) circuits. If a digital signal processor (DSP) is used, the total throughput can be upgraded to 50 MHz [8]. Recent progress in DSP technology has made the maximum count rate 800 kcps per channel [9]. Combined with such a rapid data acquisition system, the potential of Ge PAD as a high throughput detector (*ca.* 100 MHz) would be fully utilized. In Fig. 4, Fe K-XANES spectra measured for fine powder specimen under photo-excitation (PIP), high temperature phase (HTP), and low temperature phase (LTP) of a typical spin-crossover complex $[FeII(2\text{-pic})_3]Cl_2EtOH$ (2-pic = 2-aminomethyl-pyridine) are compared. The spectral variation is consistent with the FeN_6 octahedron which expands by 0.2 Å upon photo-induced spin transition from $S = 0$ to $S = 2$ states. It was demonstrated that Ge PAD can provide high-quality excited state XAS spectra in fluorescence mode, solving an intrinsic mismatch problem between hard X-ray and visible photons.

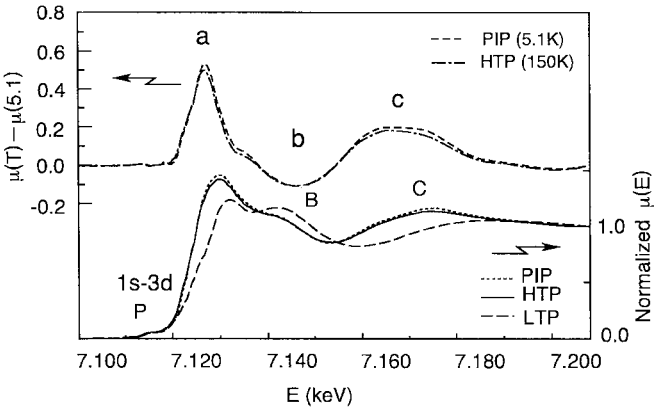

Fig. 4. Fe K-edge XANES spectra for $[Fe(2\text{-pic})_3]Cl_2EtOH$. The dotted line, dashed line and solid lines indicate the specra for high-temperature phase (HTP), low-temperature phase (LTP) and photo-induced phase (PIP).

4. Conclusions

A monolithic Ge 100 pixel array detector was developed. High performance in packing density, energy resolution and throughput was confirmed. 99% of pixels were found to be working. High efficiency over a wide energy range (5–60 keV) was demonstrated. Combined with laser excitation, XAS using Ge PAD provides new opportunities as a local probe of excited or photo-converted states.

ATHENA and ARTEMIS: Interactive Graphical Data Analysis using IFEFFIT

B. Ravel[1] and M. Newville[2]

[1]Naval Research Laboratory, Washington, DC 20375, USA
[2]The University of Chicago, Chicago, IL 60637, USA

Abstract

We introduce a new software package for analysis of XAS data. This package is based on the IFEFFIT library of analytical and numerical algorithms and uses the perl/Tk graphics toolkit. The two main components are ATHENA, a program for XAS data processing, and ARTEMIS, a program for EXAFS data analysis using theoretical standards from FEFF. These programs provide high quality analytical capabilities in a manner that is accessible to novices yet powerful enough to meet the demands of an expert. The programs run on all major platforms and are freely available under the terms of a free software license.

1. Software package

In this article we introduce a new software package for interactive, graphically-driven analysis of X-ray Absorption Spectroscopy (XAS) data. The two programs described here in detail are ATHENA, a program for XAS data processing, and ARTEMIS, a program for analysis of extended X-ray absorption fine-structure spectroscopy (EXAFS) data using theoretical standards computed [1] by FEFF. Both programs are based on the analytical algorithms of the IFEFFIT library [2] and both programs are written in the Perl programming language [3] and use the perl/Tk graphical toolkit [4] for all graphical interactions.

We recognize that users of XAS beamlines and practitioners of the spectroscopy require software that meets a broad range of analytic, programmatic, and social goals, which we describe below. In later sections we describe the main features of the two programs and discuss the relationship of free source code for data analysis software with the scientific method. Finally, we explain how to obtain these programs.

Here are our goals in this project:

High-quality analytic algorithms
ATHENA and ARTEMIS use the programmers interface to IFEFFIT, as described in reference [2]. Thus both programs have complete access to all the features of IFEFFIT, including all the capabilities of the programs AUTOBK [5] and FEFFIT [6]. In this article, any analytic feature ascribed to ATHENA or ARTEMIS is actually performed by IFEFFIT and the result is used via IFEFFIT's programming interface.

Highly usable GUI
The perl/Tk toolkit provides a full-featured, forms-based environment for interacting with and processing data. Plotting of data is handled using the PGPLOT plotting library [7].

Useful to novices, powerful for experts
Those already familiar with analysis of XAS data should find ATHENA and ARTEMIS quite easy to begin using. Novices to absorption spectroscopy find that a usable GUI combined with excellent analytic algorithms considerably lowers the barrier of beginning work in their new field. For the expert, ATHENA and ARTEMIS offer sophisticated options which allow the user to the most from measured data.

Free of cost, free source code
IFEFFIT, ATHENA, and ARTEMIS are available on the web for free download. Thus high-quality XAS analysis is available even to students and to researchers in developing countries. The availability of source code for data analysis software is very important philosophically. Because the code is licensed under very liberal terms, users are free to examine the code, understand its algorithms, modify the code to better suit their research needs, and share the codes with their colleagues.

Portability
ATHENA and ARTEMIS work on most common computer platforms including Microsoft Windows, Macintosh OSX, Linux, Solaris, and other common unixes. This is possible because all of the tools which they rely upon, IFEFFIT, Perl, perl/Tk, and PGPLOT, themselves operate on all these platforms. Additionally both programs save data to project files which are easily transferable between users, even those working on different platforms.

2. Features of ATHENA

ATHENA addresses all aspects of data processing including conversion of raw data to $\mu(E)$ data, background subtraction, Fourier transforming, and plotting. As such it is useful for data visualization at the beamline as well as for processing of data in preparation for data analysis. The normal view of the ATHENA window is shown in Fig. 1.

Data conversion from beamline format is handled in a flexible manner that allows conversion of column data from transmission, fluorescence, or electron yield experiments into $\mu(E)$ data. The conversion utility allows for on-the-fly summation of data from a multi-element detector. Alternately, each column of multi-element data can be imported as individual data groups for later inspection and summation. ATHENA also supports data preprocessing capabilities, including automated deglitching, alignment, truncation, and constraint of analysis parameters as a data file is imported.

Background subtraction is performed using the AUTOBK algorithm [5] which determines an empirical background spline based on a distinction between data and background in terms of Fourier components. Edge step normalization of the data is determined by a linear pre-edge subtraction and regression of a quadratic polynomial beyond the edge. Alternately, the data may be normalized by comparison to the isolated atomic background

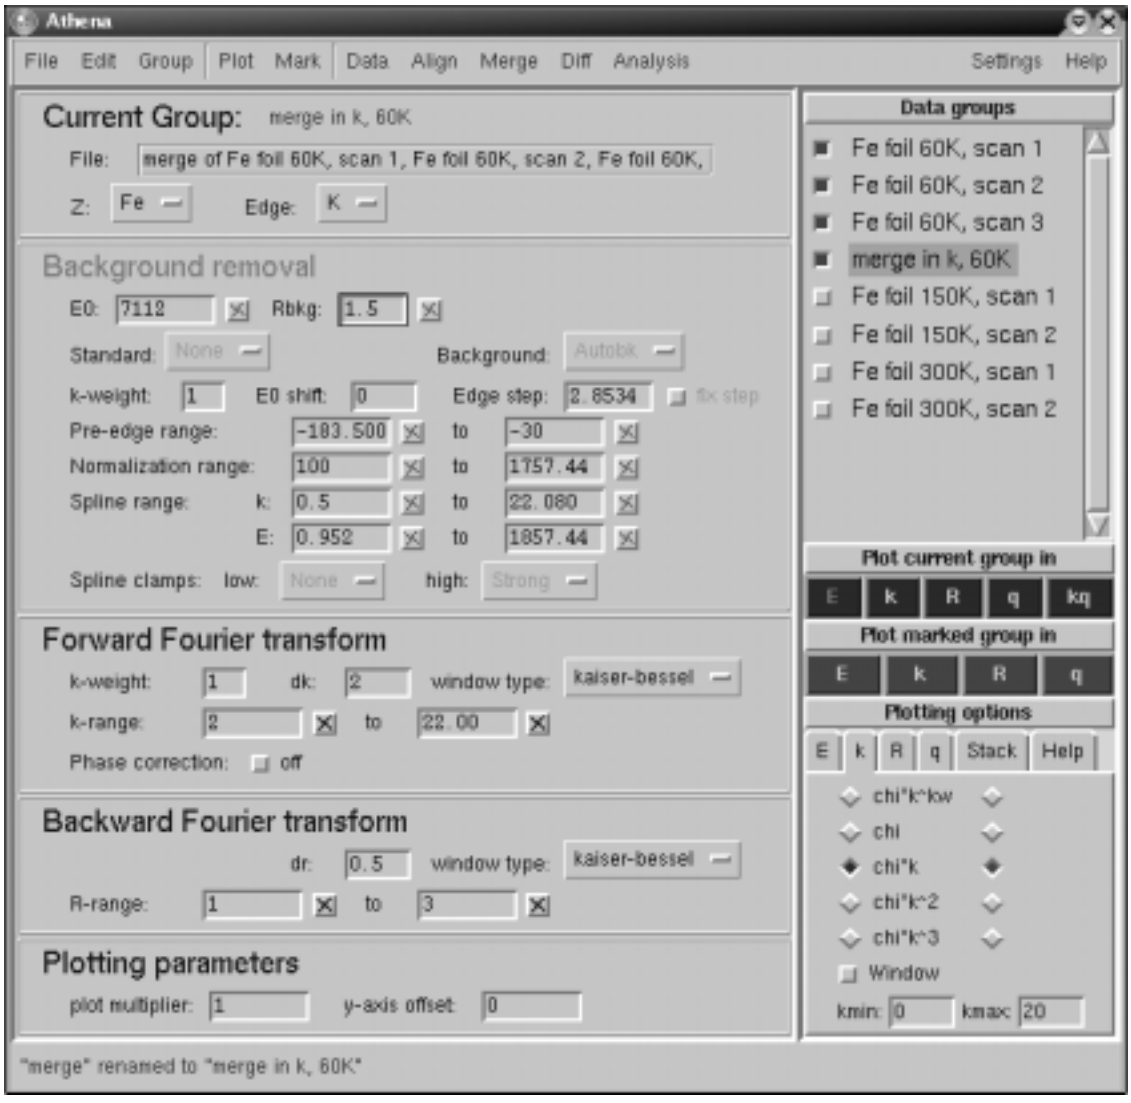

Fig. 1. ATHENA with several data scans imported. The list of imported scans is shown in the upper right corner. The left portion of the window displays the background removal and Fourier transform parameters for the selected data group, which is the one highlighted in the list. Parameters for configuring plots are set in the tabs in the lower right corner of the window.

computed using the Cromer–Liberman calculations [8]. This second normalization method is particularly attractive for XANES studies where consistency of normalization is very important. For comparison to XANES data, ATHENA can also import and display FEFF8 calculations [9].

One powerful feature of ATHENA is that processing and displaying many data sets simultaneously is as simple as for a single data set. In Fig. 1, the upper row of buttons labeled with the letters E, k, R, and q are for plotting single data sets in energy, k-space, R-space, or back-transformed k-space, respectively. The lower row of buttons will plot multiple data sets. ATHENA always keeps track of whether any parameters have been changed and will automatically perform background removals and Fourier transforms as needed. Background removal and Fourier transforming parameters can be adjusted for each data set individually or flexibly constrained between data sets.

Along with the basic chores of background removal and Fourier transforming, ATHENA provides a number of other features for data processing and analysis of XAS spectra. Some of the most significant are

1. Edge energy calibration.
2. Alignment in energy of spectra.
3. Deglitching, i.e. removal of spurious data points from $\mu(E)$ spectra, by an automated procedure or by manual selection of spurious points.
4. Merging of multiple data sets is energy or in k-space and computation of standard deviation spectra.
5. Log-ratio/phase-difference analysis [10] of back-transformed spectra.
6. Fitting of analytic functions (arctangents, Lorentzians, Gaussians) to near-edge spectra.

Features which are currently planned for and being implemented in ATHENA include principle component analysis, analysis of near edge spectra by linear combination of standard spectra, self-absorption corrections for fluorescence data, and dead-time corrections.

3. Features of ARTEMIS

ARTEMIS works within the framework of FEFF's multiple scattering path expansion [1, 11]. This means that the data is described as a summation of one or more scattering paths as computed by FEFF. For each path, the XAFS equation much be evaluated. This means that values of the parametric terms in the EXAFS equation – N, S_0^2, E_0, ΔR, and σ^2 – must be specified for each path

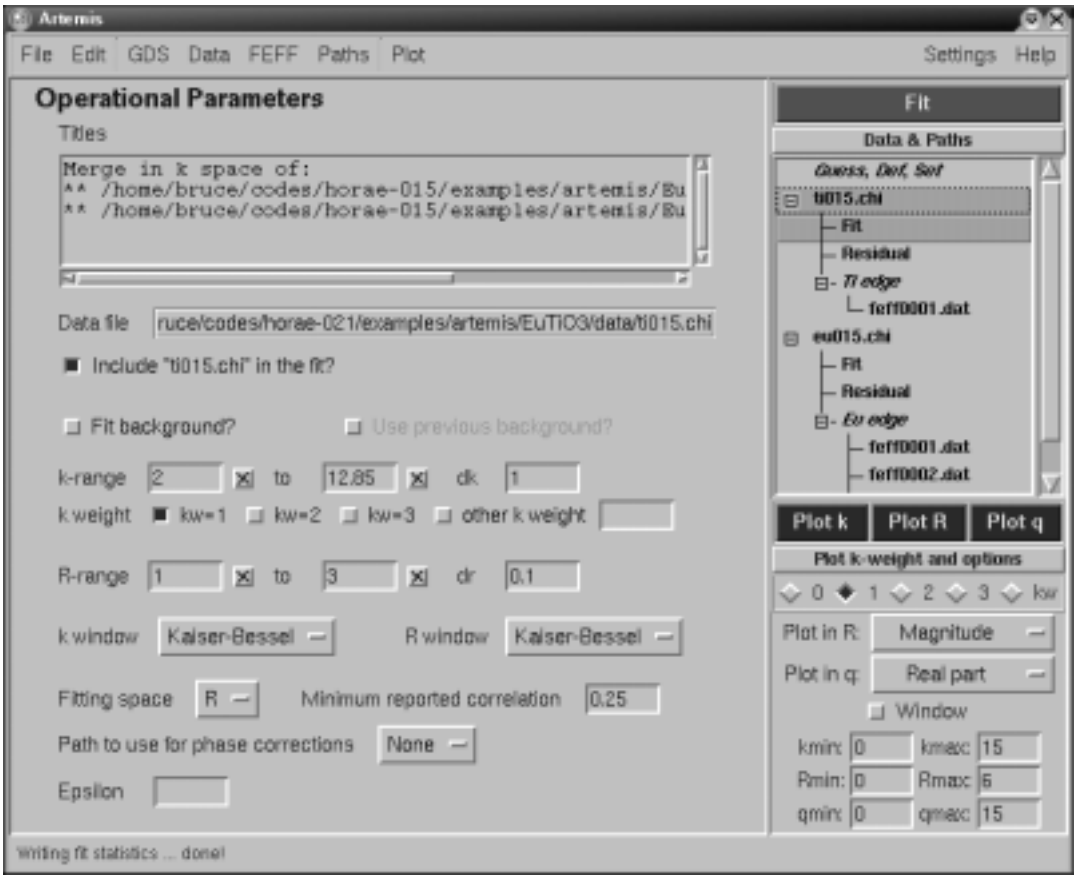

Fig. 2. ARTEMIS with data and FEFF calculations imported for a multiple-edge fit to $EuTiO_3$. The view displayed, shows how fitting ranges and Fourier transform parameters are set for the Ti edge portion of the fit. Parameters for configuring plots are set in the lower right corner of the window.

included in the fit. The path expansion and how it is parameterized and used in a fit is described elsewhere [6, 12]. As discussed in those references, EXAFS analysis can be quite subtle and complicated. By providing a graphical, forms-based mechanism for handling the many bookkeeping chores imposed by FEFF and IFEFFIT, ARTEMIS makes basic analysis chores simple and very sophisticated analysis problems tractable.

Shown in Fig. 2 is the ARTEMIS window in its data view. Other views (not shown) allow the user to set fitting parameters, to manage FEFF calculations, or to manage individual FEFF paths and the math expressions used to evaluate the terms in the EXAFS equation.

While ARTEMIS certainly is well-suited to simple, first-shell analysis of single data sets, it provides many advanced features, including

1. Multiple data set refinements.
2. Refinement using multiple *k*-weightings for any data set.
3. Use of multiple FEFF calculations in a single fit.
4. Co-refinement of a background spline to reveal correlations between the spline and the fitting parameters.
5. Arbitrary constraints between and restraints on parameters.
6. Error analysis, including uncertainties in and correlations between parameters.
7. Convenient plotting of the data, the fit, and any number of the individual paths used in the fit.

4. Free source code and the scientific method

Full disclosure of experimental procedures and results is one of the cardinal rules of the scientific method. We, as scientists, cannot and should not except results which cannot be reproduced by independent investigators. Consequently, we are obligated to explain enough detail of sample preparation, experimental procedure, theoretical background, and interpretation of the data that any reader with adequate background and inclination can fully reproduce a result. Most journals would refuse to consider publication of an article that hides details behind a veil of secrecy.

We believe that full disclosure is essential to science and to the dialogue between scientists, and that full disclosure applies to the software that is used in data analysis. In this day, most scientific disciplines depend on computer technology for many aspects of data collection and analysis. In particular, XAS is heavily dependent on computerized control for its data collection and on computer algorithms such as the Fast Fourier Transform [13] and general non-linear modeling algorithms [14] for its analysis.

It is essential that any reader of a scientific publication who has the necessary background and inclination be able to scrutinize the details of the codes used for the analysis. This requires that source code be freely available.

Freely available source code allows independent scrutiny of the procedures used and also allows scientists to modify and improve these procedures for their own needs. By using an Open Souce Software [15] license, such modifications can be dissemenated to the community either by the original authors or those making the modifications. In this way, new ideas and algorithms can build on and improve earlier work in an open and peer-reviewed manner to enrich the entire scientific community.

5. Resources

A project page for IFEFFIT exists at SourceForge.net, http://sourceforge.net/projects/ifeffit/. The source code for IFEFFIT can

be found at http://cars.uchicago.edu/ifeffit. You will also find IFEFFIT installer packages for Windows which also include ATHENA, ARTEMIS and a few other programs. ATHENA and ARTEMIS have their own web page, http://feff.phys. washington. edu/~ravel/software/exafs/. ATHENA and ARTEMIS as well as IFEFFIT are actively being developed and improved.

Acknowledgments

We would like to thank S. Kelly and everyone on the IFEFFIT mailing list for their enthusiasm and support for this project. Versions 0.8.020 of ATHENA and 0.6.005 of ARTEMIS are discussed in this paper.

SIXPack: a Graphical User Interface for XAS Analysis Using IFEFFIT

S. M. Webb*

Stanford Synchrotron Radiation Laboratory, Menlo Park, CA, 94025, USA

Received June 26, 2003; accepted November 4, 2003

PACS number: 07.05.Kf

Abstract

SIXPack (Sam's Interface for XAS analysis Package), a graphical user interface that allows users simple manipulation and analysis of data, is presented. The modules of SIXPack allow users to: (1) load, calibrate, and average raw data files; (2) perform background subtractions; (3) perform principal component analysis and target transforms; (4) perform least squares fitting of data to standards and functions; (5) perform EXAFS fitting to FEFF phase and amplitude files; (6) create single scattering FEFF phase and amplitude files using a periodic table interface. Novel features of the program allow for the fitted correction of XANES spectra due to self-absorption effects in unknown matrices, which is particularly useful for analysis of geochemical and environmental systems. The core of the XAS analysis routine uses IFEFFIT. SIXPack is developed in Python, is installable across many operating systems and platforms, and is freely available with an Open Source license.

1. Introduction

As synchrotron facilities are inspiring new applications for XAS experiments, they are also reaching broader user bases than in the past. Many of these users are new to the methodology and physics of XAS analyses and bring highly complex materials requiring sophisticated data analysis techniques. This has led to the need for simple data analysis packages that are easy to use for beginners, yet powerful enough to tackle complex problems for advanced users.

IFEFFIT is a well-tested, reliable, interactive scriptable library of EXAFS algorithms [1]. An additional strong quality of IFEFFIT is that is can used easily from high level scripting languages, such as Python. In this fashion, easy to use graphical user interfaces (GUIs) can be built to aide in the analysis of XAS data. SIXPack (Sam's Interface for XAS analysis Package) is a GUI that is designed with this in mind, utilizing IFEFFIT as it analysis "kernel" and supplemented with many other routines for data input and other analysis.

SIXPack has been developed for use initially with the environmental and geochemical fields in mind, but has been shown to be useful in a wide range of XAS applications. SIXPack was written in the Python scripting language [2] and is distributed primarily as a Windows application. In addition, the source code may be compiled on Linux, UNIX and Apple platforms. The application and source code is available online as part of the IFEFFIT installation [3] or stand-alone [4]. HTML documentation is also available online [4].

2. Program Description

SIXPack is divided into six modules with each GUI performing a specific task in the data reduction process.

2.1. *SamView Module*

The SamView module is used to import raw data into the program and perform tasks such as averaging, energy calibration, and dead-time corrections. The module auto-recognizes the header of many raw file formats including SSRL, NSLS, and some ALS and APS beamlines. If the format is not recognized, it will revert to a generic ASCII file reader. The GUI provides an easy way to screen data files and eliminate problem channels and perform most pre-processing procedures.

2.2. *Background Subtraction Module*

The background subtraction module performs unit step edge normalization of XANES edges and the extraction of EXAFS from averaged data. The EXAFS $\chi(k)$ is isolated using the IFEFFIT-AUTOBK algorithms. A data editor also exists in this module to assist in deglitching data. The pre-edge region can be modeled as a gaussian tail to eliminate the effects of scattering leakage from energy dispersive detectors. A background subtraction parameter set optimized for a given sample can be applied easily across all loaded data sets to efficiently maintain consistent background removal over a large range of data allowing simple batch processing of data. Options also include saving normalized derivative spectra, in addition to $\mu(E)$, $\chi(k)$, and RDF.

2.3. *Principal Component Analysis Module*

The PCA module performs statistical analyses on a set of spectra to determine the number of "significant" or principal components required to describe the variation in the data. A number of criteria can be used to determine the proper number of principal components. Several of these criteria, including both visual and statistical methods, are provided in the module. The most robust, using the IND function of Malinowski, reaches a minimum at number of principal components [5].

The PCA result can then be used with a target transformation. The target transformation projects the spectrum from a reference compound onto the vector space defined by the components. If the target vector lies with this component space, then this reference compound is likely to be present in the dataset. A linear least-squares approach can then be used to determine the fractional amount of each reference compound in the unknown. The quality of the target transform is given by three parameters: χ^2, r-value, and SPOIL value [6]. The SPOIL value for an excellent target typically ranges from 0 to 1.5, good from 1.5 to 3, fair from 3 to 4.5, poor from 4.5 to 6, and unacceptable for values greater than 6 [7]. To assist in screening reference compounds, a library of compounds can be created from which the module will transform each one and report the outcomes in a table.

*e-mail: samwebb@slac.stanford.edu

2.4. *Least Squares Fitting Module*

Fitting experimental EXAFS data to calculate bond distances and coordination numbers becomes increasingly difficult in systems that are comprised of more than only a few components. In the natural environment, few elements will exist as pure phases due to chemical and physical inhomogeneities in samples such as soil fractions and sediment cores. Thus it becomes important to be able to examine the sample composition as a linear combination of standard components. This is accomplished through the linear least-squares fitting module of SIXPack.

The fitting module of SIXPack allows the user to fit data to any number of reference compounds and/or functional forms, including linear and quadratic forms, exponential and logarithmic forms, arctangents and error functions, and peak functions. Variables in the functional forms may be floated or kept constant. Constraints on the proportions of reference compounds, such as non-negativity and sum-to-one, may also be applied. The fitting routine is generic, requiring only a two-column ASCII file as input, and may be applied to data sets other than XAS, such as X-ray diffraction or UV-Vis spectroscopy.

A novel feature of the module is a parameterized correction for self-absorption (SA) effects in XANES spectra. This option applies a correction factor derived from the mathematics expressing the SA in the sample to the data. Assuming an infinitely thick sample at 45-degree incidence/45-degree detection (bisecting geometry), the XAS fluorescence measurement simplifies to

$$I_f/I_0 = \mu_s(E)/(\mu_s(E) + \mu_m) \tag{1}$$

where $\mu_s(E)$ is the rapidly changing absorption coefficient of the sample (*i.e.* the XANES or EXAFS) due to the element of interest and μ_m is the slowly varying absorption coefficient from other elements in the matrix. Since the desired quantity is the unimpacted absorption coefficient, $\mu_s(E)$, we can solve for this term knowing the measured value of I_f/I_0 (represented by R) giving

$$\mu_s(E) = fR\mu_m/(1 - fR) \tag{2}$$

where f is a scaling factor that accounts for normalization to a unit step-height. In environmental or natural samples, the absorption coefficient of the matrix is largely unknown. Thus in order to apply a correction, we can fit the data to an expression parameterized by two variables that characterize the net effect of the artifact – μ_m and the scaling factor f. These parameters modify the fluorescence data of the sample, where large values of either parameter imply no effect to the sample. An iterative process fits these SA variables to the former fit, followed by a new fit to the SA corrected data. After several iterations, the two fits will converge if a correction factor is needed. An example of this procedure is given in section 3.

2.5. *FEFF Single Scattering Interface Module*

SIXPack contains a module to interactively create single-scattering FEFF phase and amplitude files. This provides a quick way to test scattering paths without building large complex FEFF models. The GUI consists of an easy to use clickable periodic table from which the scattering and absorbing elements are chosen. The user may control several of the standard FEFF parameters, and chooses a distance and geometry of the complex. The module is compatible with FEFF versions 6 through 8 [8, 9].

2.6. *FEFF EXAFS Fitting Module*

The IFEFFIT core engine provides a quick, robust fitting procedure for EXAFS. The SIXPack GUI gives a simple form interface where the model is built in the traditional FEFFIT manner of terms and variables. Several templates are provided to assist the beginner in constructing simple shell-by-shell models. Due to the unconstrained nature of IFEFFIT variable definitions, complex mathematical relationships can be constructed between fitted variables and EXAFS parameters. This leads to the ability to build models of complexity that are limited only by the users

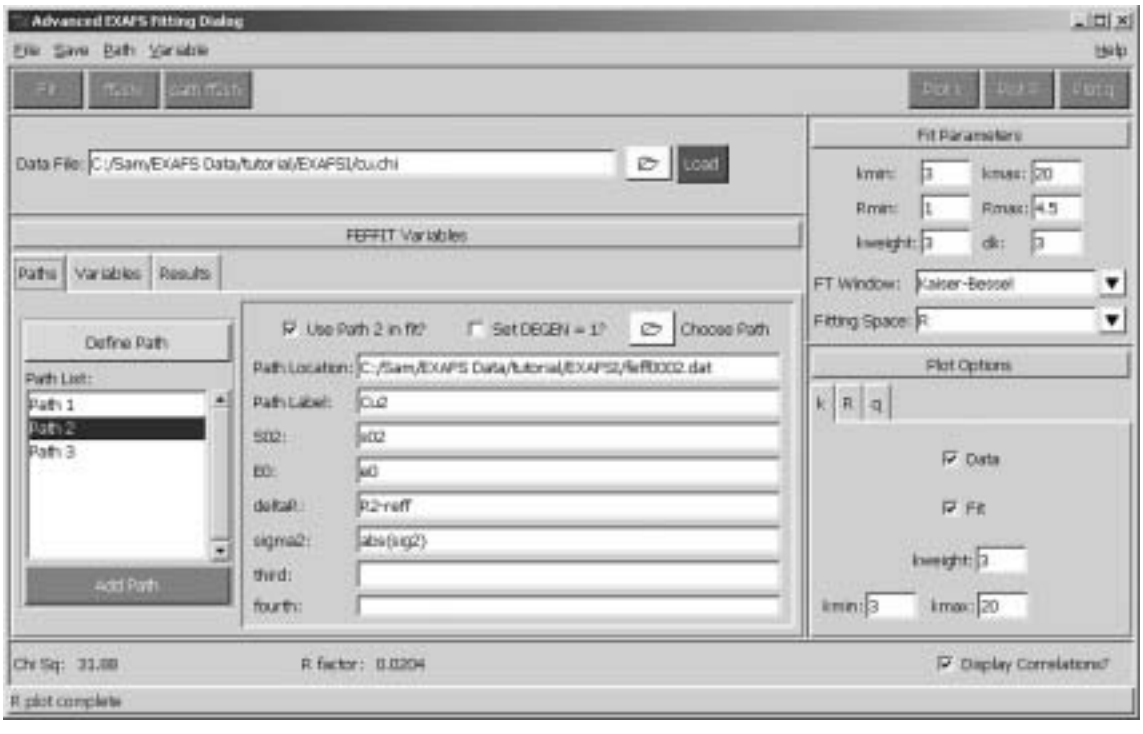

Fig. 1. Screenshot of the paths setup page of the EXAFS fitting module in SIXPack.

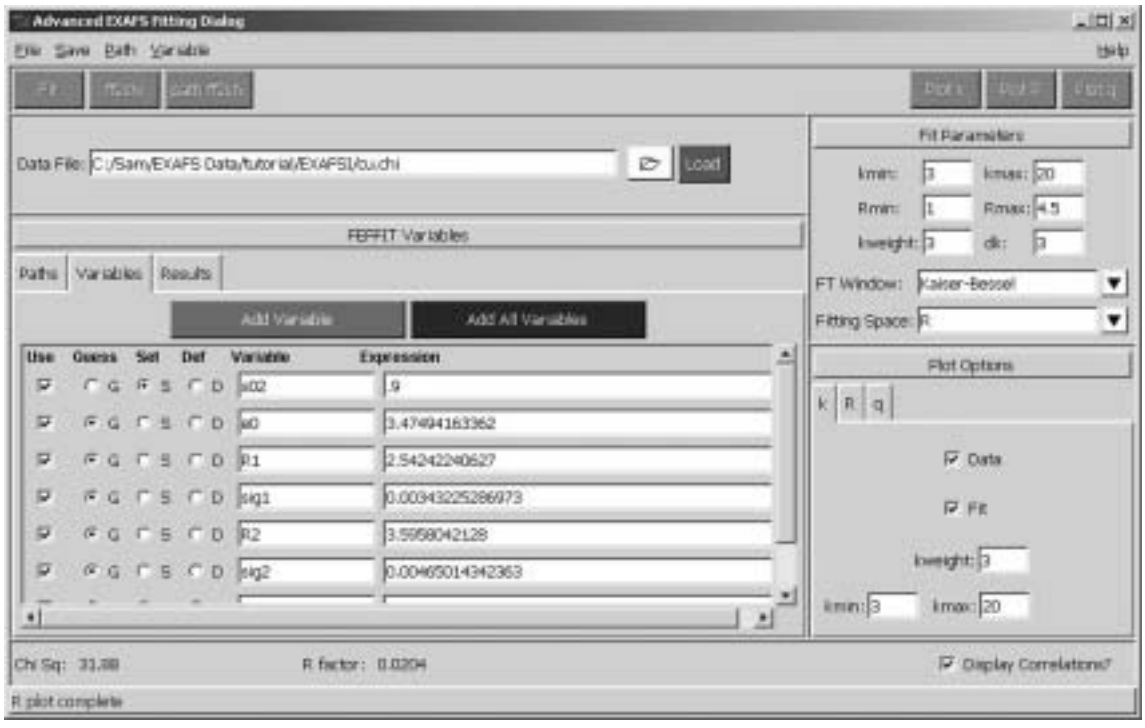

Fig. 2. Screenshot of the variables setup page of the EXAFS fitting module in SIXPack.

imagination. For example, models can include features such as fitting fractional components in the EXAFS, using bond angles as fitted parameters, and interpolating between FEFF paths. The fitting schemes can be saved for later use and altered manually using any text editor. Examples of the EXAFS fitting routine are given in the next section.

3. Examples

3.1. *EXAFS Fitting Example*

The EXAFS fitting module of SIXPack is displayed with the path setup page in Figure 1 and the variable setup page in Figure 2 to illustrate the GUI. The example shown is for sample data collected from Cu metal. The example fit is a simple model incorporating the first three coordination shells of Cu with 3 single-scattering paths. The $S_0{}^2$ parameter is set to a value of 0.9, path coordination numbers are obtained from FEFF, and all other EXAFS parameters are fitted. The resultant fit and data, as a screenshot from SIXPack, are shown in Figure 3.

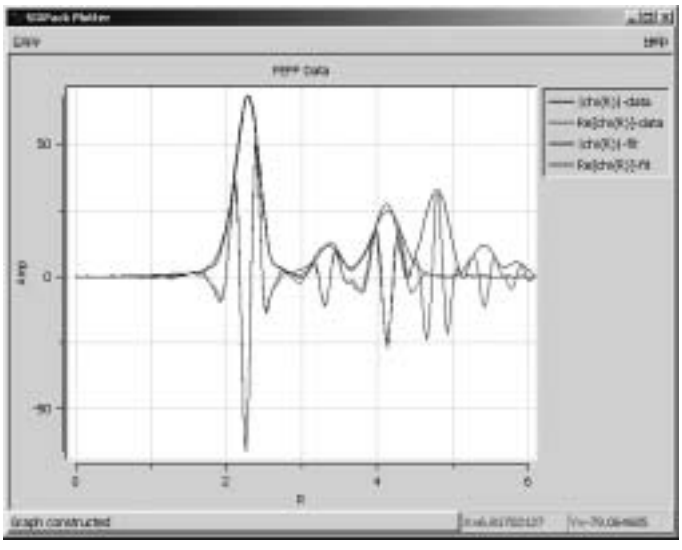

Fig. 3. Screenshot of sample data from Cu metal and its EXAFS fit in SIXPack.

3.2. *Least Squares Fitting with Self-Absorption Correction*

This example illustrates the self-absorption (SA) correction in SIXPack. A sample of a homogeneous biogenic manganese oxide was collected in both fluorescence and transmission geometries at BL 4-3 at SSRL using a harmonic rejection mirror set to a 9 keV cut-off energy. The transmission data can be fitted as a combination of Mn(II) ($MnCl_2$ in aqueous solution) and Mn(IV) (δ-MnO_2) reference compounds measured in transmission. These results are presented in Table I and Figure 4a. The same fit can be performed with the fluorescence data, resulting in a significantly different solution (Table I and Figure 4b). The impact of SA in the fluorescence data is observed by a distortion of the pre-edge, white line, and other features making the pre-edge transition appear larger and the white-line maximum smaller than observed in the transmission geometry. This artifact in the data, when fitted, results in the major component (Mn(IV)) being damped and appear to be less important to the overall fit. When the SA correction is used after approximately 10 iterations, an improved fit results from the fluorescence data with results that agree closely to the transmission fit (Table I and Figure 4c).

4. Conclusions

SIXPack is free software available online [4] and still in the early stages of development. Most basic forms of XAS and general fitting analyses are supported at this time, with many future improvements on the way. Comments and questions from users are encouraged.

PACS numbers: 07.85.Qe; 07.60.Rd

Abstract

Determination of chemical valence state is an important aspect for X-ray absorption spectroscopy (XAS) application. In this work a simple detecting system was developed for measuring the chemical states and recording X-ray absorption spectra of dilute samples. The new device consists of two parts: a Lytle-type ion chamber and a PIN photon diode detector, which are set side by side. The sample and the standard were placed in front of the two detectors respectively. The unfocused incident X-ray beam with certain size, hits on both the sample and the standard. The Lytle-type ion chamber detects the fluorescence signal from the sample while the PIN photon diode records the transmitted signal from the standard separately and simultaneously. Comparing the two spectra, the energy shift of the sample can be calibrated relative to a selected standard. This method is suitable for measuring high quality XANES spectra of low concentration samples at the 2nd generation synchrotron radiation sources exploiting either bending magnets or wigglers with large horizontal divergence.

1. Introduction

X-ray absorption spectroscopy (XAS), including X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) is a valuable tool for studying the local structural environment around an element in varied materials. Furthermore, electronic properties and valence state of the element can be obtained [1].

In the case of low-concentration samples, fluorescence XAS is the preferred technique. In a conventional fluorescence experiment, the incident beam of monochromatic X-rays is monitored by a semitransparent ionization chamber (I_0), and the flux of X-rays fluorescence through the sample is collected by a Lytle-type ionization chamber (I). The X-ray absorption coefficient $\mu(E)$ of the sample is given by $\mu_x = I_0/I$. However, The energy shifts are often unpredictable due to several effects, such as thermal loading of the monochromator crystals, the mechanical error of the monochromator, and orbit shifts etc. [2]. These give errors in valence state analysis and electronic structure simulation. Therefore, a precise *in situ* energy calibration method is needed for X-ray absorption spectroscopy.

In general, the energy monitor comprises three parts: (1) X-rays scattered elastically out of the incident beam (I_0), (2) XAS transmission standard, typically a thin metal or oxide foil, and (3) a detector with a monotonic response over the energy range of the experiment [2]. However the techniques are not suitable for measuring low concentration samples XAS.

Here, we developed a new XAS experimental system, which can collect the data of the standard and the sample simultaneously. Comparing the two spectra, the energy shift of the sample can be calibrated relative to a selected standard, and the chemical state changes of elements in dilute samples can be determined precisely.

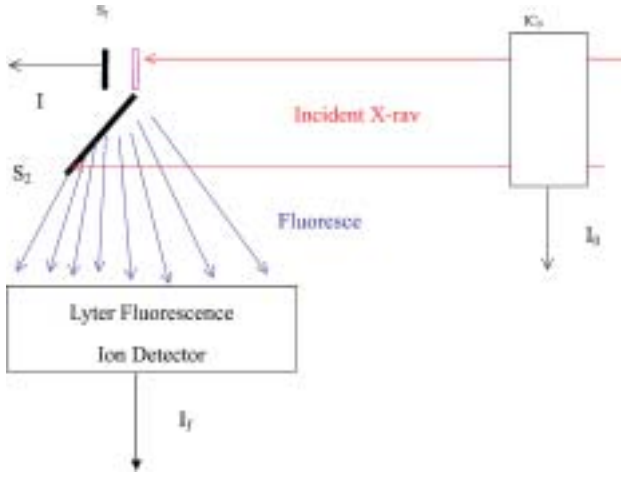

Fig. 1. Configuration of the experimental system.

The solution is free from machine instabilities in the fluorescence detection mode, and is available at 2nd generation synchrotron radiation sources which exploit either bending magnets or wigglers with large horizontal divergence.

2. Structure of the experimental system

The basic configuration of the measurement systems is illustrated in Fig. 1. Using a photodiode, one detects the transmitted signal (I_s) from the standard sample, while a Lytle-type ion chamber detects the fluorescence signal (I_f) from the real sample. Because of the small size and high sensitivity of the photodiode, the transmission detector uses just a part of the incident beam. Therefore the two detectors can be set side by side. The intensity of the incident beam (I_0) is measured by the front ion chamber. The X-ray absorption coefficient $\mu(E)$ of the standard is given by $\mu_x = \ln(I_s/I_0)$, and that of the sample is given by $\mu_x = I_f/I_0$. Comparing the two results, the X-ray absorption edge energy can be calibrated relative to a selected standard. Further, the valence state of the element can be determined precisely. A picture of the detector system is shown in Fig. 2.

3. Experimental set-up

3.1. *Sample preparation*

Saccharomyces Cerevisiae biomass (supplied by Beijing Five Star Brewery Company) was pulverized after lyophilization. 1000 μg Cr/ml of potassium dichromate was added into the lyophilized biomass. The chromium-yeast biomass was homogenized before lyophilization. The chromium compounds and lyophilized yeast powders were homogenized in an agate mortar,

*e-mail: Y.N. Xie xieyn@sun.ihep.ac.cn

Fig. 2. Picture of the detector.

fixed between two self-adhesive Scotch Tapes (3M) and then held on plastic sample holders.

3.2. *XANES set-up*

The XANES spectra at the Cr K edge were collected on the EXAFS station at 4WIB beamline of Beijing Synchrotron Radiation Facility (BSRF). The storage ring was operated at 2.2 GeV with a beam current of 100 mA. The monochromator is a Si(111) double crystal monochromator. By detuning the crystals of the monochromator high order harmonics were rejected. In this geometry, The XANES spectra of standard compound were collected using PIN diodes in transmission mode, while the sample was measured by a Lytle fluorescence ionized chamber with a vanadium filter. The signals from the two detectors were collected simultaneously.

4. Discussion

In order to test the performance of the system, we put standard compounds $K_2Cr_2O_7$ and Cr_2O_3 in front of the Lytle-type ion chamber and the PIN photodiodes, respectively. The unfocused incident X-ray beam with certain size, hit on both samples. The fluorescence signal is obtained from $K_2Cr_2O_7$ while the transmitted signal is from Cr_2O_3 separately and simultaneously. The results are shown in Fig. 3, according to the features of the two references [3, 4], Cr(VI) and Cr(III) can be clearly identified.

Another example demonstrating the advantage of this detector is measuring the valence state of chromium in saccharomyces Cerevisiae. Cr-yest-biomass is in fluorescence mode, while standard Cr_2O_3 is in transmission mode. Fig. 4 depicts the XANES at the Cr K-edge from the sample, along with standard Cr_2O_3. It is immediately apparent that the XANES spectra at the Cr K-edge of the sample is similar to that of standard Cr_2O_3, and different from the spectrum of the standard of $K_2Cr_2O_7$, revealing that the sample has become trivalent, rather than primitive hexavalent. The result can be interpreted as reduction of Cr(VI) to Cr(III) during the process of sample preparation, indicating that yeast can strongly reduce Cr(VI) to Cr(III), which has been used in the bio-sorption of Cr(VI) from environment [5].

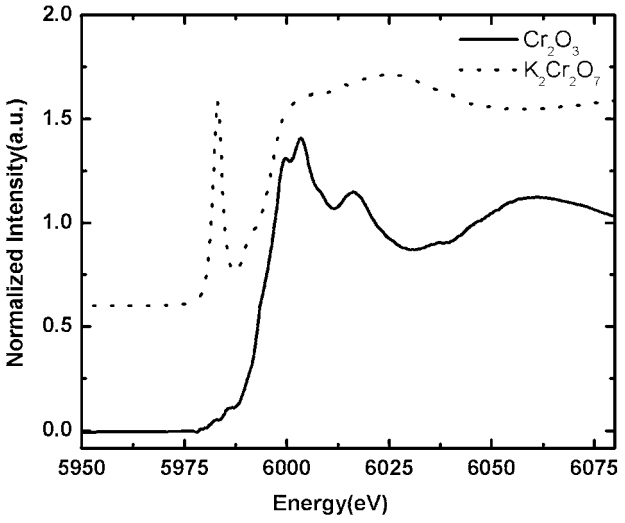

Fig. 3. XANES spectra at Cr K-edge of $K_2Cr_2O_7$ and Cr_2O_3.

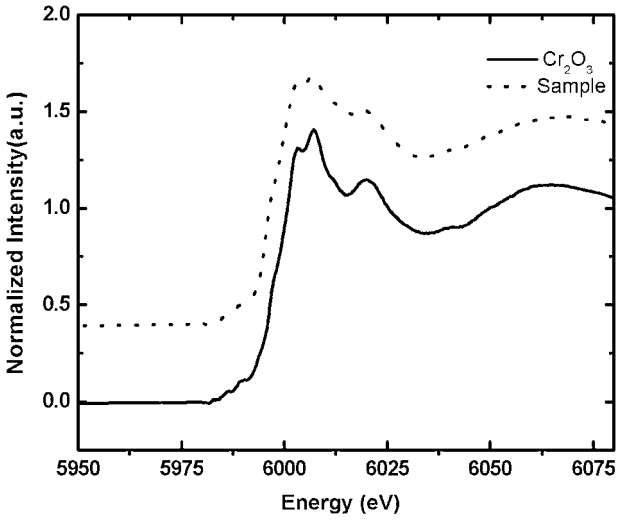

Fig. 4. XANES spectra at the Cr K-edge of yeast sample, standard compound Cr_2O_3.

5. Summary

A new XAS detection system in unfocused incident X-ray beam with large horizontal divergence, has been developed. PIN diodes detector and Lytle-type fluorescence detector simultaneously collect spectra of the standard in transmission and a low concentration sample in fluorescence mode. Comparing the two spectra, the energy shift of the sample can be calibrated relative to a selected standard. Also application to chromium valence state change in Saccharomyces Cerevisiae shows that this technique can be a promising means of characterizing the electronic and local structure of dilute systems.

Abstract

In-house XAFS spectrometers suitable for routine experiments are getting fairly popular today. One of the problems of such apparatus is the capability to study low atomic number materials. In general, elements with atomic number 20 (i.e. Ca) and below is difficult to measure because absorption of air becomes large. In this energy region, very important elements for environmental studies, such as S and P are involved. Either an evacuated or a He-filled X-ray path is required for getting enough photons in the low energy region. Since most in-house XAFS spectrometers apply Rowland Circle configuration, the spectrometer shows fairly complicated movement during energy scan. Varying the distance between the X-ray source and the bent crystal requires bellows for evacuating the X-ray path or substituting by He, but it restricts the spectrometer scanning range, especially on the low angle side. However, the low angle range (i.e. 30 to 60 degree) is most commonly used and X-rays are efficiently collected in this range. We have customized a commercial XAFS spectrometer to be capable for energies as low as 2 keV for sulfur measurement without sacrificing its scanning range.

1. Introduction

XAFS spectrometry is a powerful tool to characterize various materials. An in-house XAFS spectrometer can be used whenever a researcher wants data. That is quite important for interactive innovativeness and this is an advantage to the synchrotron facilities despite of the weakness of photon numbers available. An in-house XAFS apparatus is normally used in air environment, which determines the energy limit of the lower side. Below 5 keV, or lower than Ti K-edge (4,966 eV), the data acquisition becomes harder and harder when the atomic number of the target element decreases by one unit at the time. For instance, the number of photons available for K K-edge (3,607 eV) measurement is 1/8 of what is available for Ca K-edge (4,038 eV) measurement with the same optics under air. Evacuating the X-ray path or replacing air by He can significantly increase the number of photons available by magnitude of 1 or 2. From our experience, He path makes Ca K-edge measurement fairly easy, but K K-edge is still difficult. Thus the low energy limit for the in-house XAFS spectrometer is set for Ti under air and Ca with He path attachment.

In order to measure much lighter elements, such as Al (K-edge; 1,559 eV) or Si (K-edge; 1,838 eV), more effort needs to be spent. In this energy range, even 10 mm air absorbs more than half of the photons. Therefore both sample and detector must be put in vacuum in addition to the evacuation of the X-ray path. Among the light elements (atomic number less than 20), sulfur is quite important for environmental study. We have customized a commercial XAFS spectrometer [1, 2, 3] for sulfur measurement.

2. Design consideration

The most important factor for XAFS experiment is the number of photons available. Especially in the soft X-ray region, it becomes more important. In order to increase the X-ray intensity we considered the X-ray cover, the beryllium window and monochromator crystal.

The XAFS spectrometer we chose was designed for the air ambient and there is neither He path attachment nor vacuum path attachment. Then we had to design from the beginning. The choices were to design

i. Helium or vacuum path attachment
ii. Vacuum chamber
iii. Helium chamber

The first choice seems easy, but as the spectrometer moves in very complicated manner, it is difficult to design the path. Moreover the path restricts the scan range, especially the lower angle, and it reduces the number of elements, which can be measured with a single monochromator crystal. The second and third choices look almost the same. Putting the whole spectrometer in a large chamber sounds serious, but the design is not difficult apart from one point, the connection of inside and outside. Since the X-ray generator applies high voltage, evacuation by a rotary pump causes discharges. Helium ambient leads to the same problem as well. Therefore at least high-tension cables must be exposed to air that is a very good insulator. Figure 1 is a schematic drawing of the spectrometer chamber. The cover consists of two airtight chambers. One is the spectrometer chamber and the other is the sample chamber. In order to overcome the discharge problem, rubber bellows are attached between the X-ray generator and spectrometer chamber so that the high-tension terminal is exposed to the air ambient. Making this chamber evacuative, enormous strength against air pressure is needed. We finally decided making

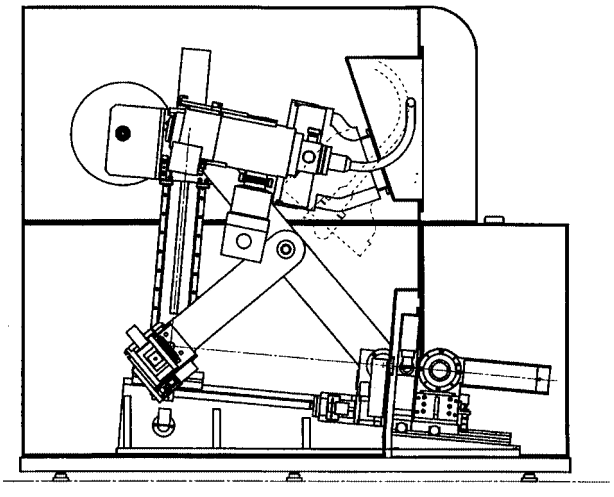

Fig. 1. Schematic diagram of the in-house spectrometer and helium chamber.

*e-mail: takey@rigaku.co.jp

this a helium chamber. The spectrometer chamber and the sample chamber can be filled by helium gas independently. The advantage of using a helium chamber other than its ease of building is that it is possible to examine liquid samples.

The absorption and scattering by air is the main cause of X-ray attenuation, but the secondary cause for the photon loss is due to the X-ray generator. Accelerated electrons hit a metal target in vacuum and produce X-rays. These X-rays are taken out through a beryllium window. Normally the thickness of this beryllium window is 0.4 mm. More than 90% of the X-ray photons are absorbed at 2,500 eV. Even the manufacturer's option of a beryllium window for soft X-rays has a thickness of 0.2 mm and absorbs 3/4 at the same energy. The thickness of the beryllium window is determined by considering the damage caused by the scattering electrons inside of the tube. Because the X-ray tube used for XAFS measurement does not apply as high tube voltage as ordinary X-ray diffraction applies, the energy of the scattered electrons is low. We have worked out the beryllium thickness and the electron energy, and then decided to use beryllium of thickness 0.05 mm, or 50 microns. The 50 microns beryllium transmits more than 70% of the X-rays at 2,500 eV.

For in-house XAFS spectrometer, either silicon or germanium single crystal is used as monochromator crystal. It is bent (Johan type) and shaved (Johansson type) in certain manners. According to Knapp [4], the energy resolution ΔE of the linear spectrometer can be expressed as

$$\Delta E = \frac{E^3(2d)^2}{8RC^2}\left[(W_s + W_f)^2 + \left(\frac{h^2}{8R}\right)^2 + \left(\frac{CE^2 \ln 2}{kd}\right)^2\right]^{1/2}.$$

C is a constant (12.398 keV · Å), d is the lattice constant, R is the Rowland circle radius, h is the height of the X-ray source and the receiving slit, W_s and W_f are the width of those respectively and the absorption coefficient of the crystal is approximated as $\mu = K/E^3$. At a smaller d, the energy resolution becomes better, but the number of photons decreases. As our spectrometer scan range is 30 to 90 degrees in 2θ, the d value must be in the range of $d = 3.65$ to 9.98 Å. Even Ge(111) ($d = 3.265$ Å) does not satisfy this. Possible choices are InSb(111) ($d = 3.74$ Å), EDDT(020) ($d = 4.404$ Å) and Beryl(1010) ($d = 7.985$ Å). We chose Beryl for the preliminary test since it has the largest d value among the three crystal and therefore it is expected to provide the maximum number of photons.

3. Experiment and Results

The X-ray intensity is monitored before and during the He replacement. A large amount of He is flowed in order to force out the air inside the chamber. When the X-ray intensity becomes saturated, regulator bulb is closed and Helium is flowed at constant rate, which is 30 l/min. The gain is measured at a few energy points and compared to the calculated value. At 7,000 eV (near the Fe K-edge), the measured gain was 2.5 and the calculated gain was 2.9. The measured gain was 90 and the calculated was 200 at 4,000 eV (Ca K-edge). The reason for the low gain is presumably due to improper replacement of the air. The gain was calculated again with some residual air along the X-ray path. Figure 2 shows a fit with the assumption that 90 mm air remained at the X-ray path for the energy region from 3,900 to 4,100 eV.

At energies below 3 keV, it was impossible to monitor X-rays in the air ambient. Using Beryl(1010) Johansson crystal, more than 100,000 photons/s are obtained at 2,400 eV with energy resolution

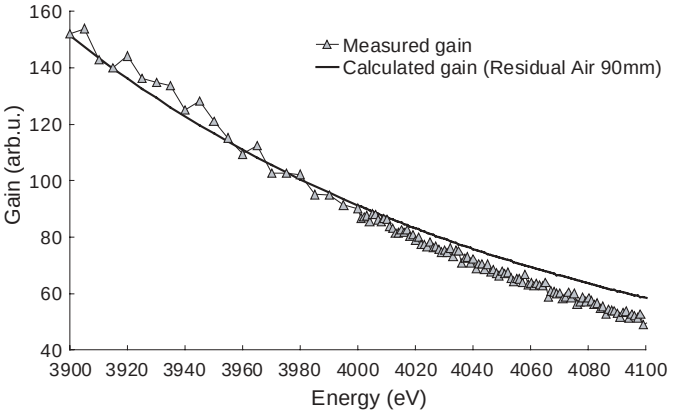

Fig. 2. Measured gain and calculated fit.

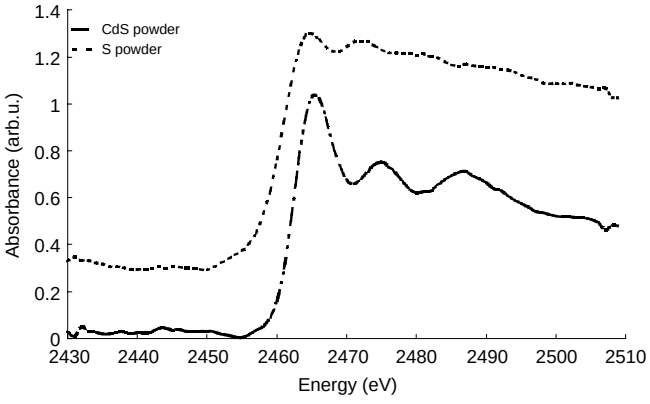

Fig. 3. XANES measurement of S and CdS.

better than 1 eV. Figure 3 shows sulfur powder and CdS XANES spectra measured with this spectrometer. At this energy range, the sample chamber needs to be replaced by helium, as well as the spectrometer chamber. Therefore a vacuum tight gas flow type proportional counter was used for the experiment since an ordinary detector caused discharge and counted no X-rays.

4. Conclusion

The soft X-ray capability (as low as to the S K-edge) of an in-house XAFS spectrometer is demonstrated. Sulfur in oil is turned to sulfur oxide (SOx), discharged to air and causes severe pollution. In addition, sulfur poisoning of catalysts has been a big problem for a long time and receives attention again since it plays an important role for the fuel cell development. Thus it is important study the chemical state of sulfur in materials, and it helps the effective removal of sulfur. Furthermore, many atoms' absorption edges (not only K, but also L and M) are at energies below 3.5 keV [5] and extent to much lower energy expands the usage of the in-house XAFS spectrometer.

Abstract

The electronic and optical properties of a series of PAMAM-dendrimer capped CdS quantum dots (QDs) have been investigated with UV-vis absorption (UV-abs), photoluminescence (PL), X-ray absorption near-edge structure (XANES) and X-ray excited optical luminescence (XEOL) techniques. The size-dependent electronic behavior of the QDs was observed in both the UV-abs and XANES (S K-edge) spectroscopy. Findings from the PL and XEOL studies provide complementary information to the UV- and X-ray absorption results and shed further light on the stability of the CdS QDs upon aging.

1. Introduction

It has been well recognized that the electronic properties of semiconductor quantum dots (QDs) are very sensitive to their local structure such as doping, capping and surface defects [1]. More recently, it became apparent that the wet-chemical synthetic method for QDs can be use to tune these properties by simply varying the experimental conditions. In this contribution, we show that by varying the concentration of the capping molecules, PAMAM dendrimer, the electronic and optical properties of the CdS QDs can be modified. The properties of the QDs thus prepared were examined by UV-vis absorption, photoluminescence (PL), X-ray excited optical luminescence (XEOL) and X-ray absorption fine structure (XAFS). The QDs investigated are generation 4 PAMAM-OH dendrimer-capped CdS with a dendrimer : CdS ratio of 1 : 24, 1 : 12 and 1 : 6.

2. Experimental

The details of the synthetic procedure have been reported elsewhere [2]. In addition, the 1 : 12 CdS QDs synthesized within a few days (henceforth denoted "as-prepared") and after six months (henceforth denoted "aged") were also studied to address the effect of aging on the properties of the QDs. The UV-vis spectra were obtained with standard instrumentation. X-ray studies were conducted at the double crystal monochromator (DCM) beam line of the Canadian Synchrotron Radiation Facility (CSRF) at the Synchrotron Radiation Center (SRC), University of Wisconsin-Madison. In the X-ray near edge structure (XANES) study, total electron yield (TEY) and X-ray fluorescence yield (FLY) were recorded simultaneously using specimen current and a multi-channel- plate detector, respectively. X-ray excited optical luminescence (XEOL) was recorded using a JY H-100 monochromator that is equipped with a Hamamatsu 943-02 photomultiplier (PMT).

3. Results and Discussion

Fig. 1(a) shows the UV-vis absorption spectra of a series of dendrimer capped CdS QDs synthesized by increasing the dendrimer/CdS ratio, i.e. 1 : 24, 1 : 12 and 1 : 6. In general, it is believed that the less the capping molecules, the bigger the QDs in that decreasing the amount of capping molecules (e.g. from 1 : 6 to 1 : 24) would facilitate the growth of the CdS [3]. The UV-vis absorption spectra of the 1 : 24, 1 : 12 and 1 : 6 CdS QD samples (increasing dendrimer to CdS ratio) clearly exhibit this trend. As seen in Fig. 1, the exciton peak that is closely related to the QD size slightly shifts to higher energy region when going from the 1 : 24 (340 nm) to 1 : 12 (332 nm) and then to the 1 : 6 sample (330 nm). According to a widely used empirical size-exciton energy relationship, the size of these QDs should be in the range of 1–3 nm [4]. The photoluminescence (PL) spectra shown in Fig. 1(b) are consistent with the observation of the UV-vis (absorption) spectra. The luminescence band of the 1 : 6 sample exhibits a blue shift in the PL relative to the 1 : 12 and the 1 : 24 sample. Furthermore, the PL band becomes considerably sharper in going from 1 : 24 to 1 : 12 and to 1 : 6, indicating that with increasing dendrimer/CdS ratio, the size of the QDs become mores uniform [5].

The local structure and the electronic behavior of the QDs were studied by S K-edge XANES as shown in Fig. 2. A couple of observations are noteworthy. First, the QDs synthesized using a larger dendrimers/CdS rato, particularly the 1 : 6 ratio, exhibit a large contribution of oxide that is most likely a sulfate species since the peak position matches that of $CaSO_4$. Second, the edge jump corresponding to the S^{2-} species shows a noticeable blue shift for the 1 : 6 sample (Fig. 2 inset).

As the UV-vis spectroscopy result indicates, the QDs with a larger dendrimers/CdS ratio are smaller. The XANES results support this notion in that the QDs with higher dendrimer/CdS

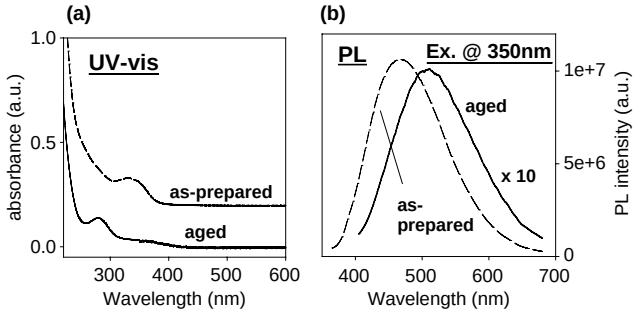

Fig. 3. UV-vis absorption spectra (a) and photoluminescence spectra (b) of a CdS QDs sample (1 : 12) measured within a few days (as-prepared) and after six months (aged).

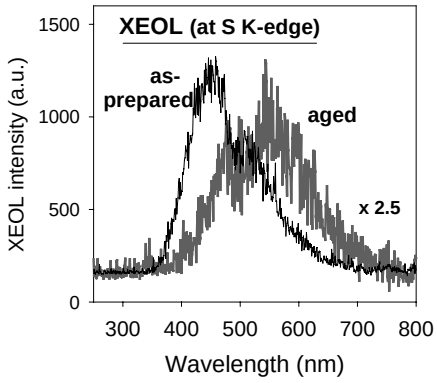

Fig. 4. X-ray excited optical luminescence (XEOL) spectra of the as-prepared and aged CdS QD sample (1 : 12) excited at S K-edge.

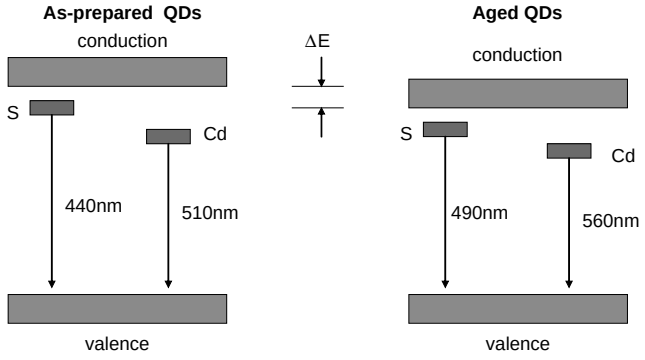

Fig. 5. A schematic illustration of the defect-involved luminescence mechanism of the as-prepared and aged dendrimer-capped CdS NPs.

ratio (1 : 6) display a more pronounced blue shift, which corresponds to a smaller size in terms of the quantum size effect. Moreover, a smaller QD has a larger contribution from the surface atoms, thus a more intense surface signal (surface sulfur oxidized to sulfate) is expected in the XANES. This explains the observation of a more intense sulfate peak in the XANES in that the higher the dendrimer to CdS ratio, the more intense the sulfate peak.

In a related study of the stability of the CdS QDs in the ambient, we selected the 1 : 12 sample with which UV-vis absorption and the PL spectra were collected a few days after (as-prepared) and six months after (aged). The results are shown in Fig. 3 where the absorption and PL spectra of the two samples show a dramatic difference. The absorption spectrum of the as-prepared sample exhibits an exciton band at ca. 332 nm whereas two bands were detected in the aged sample, one at ca. 370 nm and one at ca. 290 nm. Let us concentrate at the 370 nm band (the short wavelength band did not result in emission). According to classic quantum confinement theory [4], the first exciton peak determines the size of the NPs- the more blue/red-shifted the first exciton peak, the smaller/larger the QDs. The energy position of the first exciton peak shifts from 332 nm to 370 nm upon aging (a ∼40 nm shift). This clearly indicates an increase of the QDs size upon aging. The PL results are consistent with the absorption. In Fig. 3(b), the PL spectrum of the aged QDs clearly exhibits a red shift (∼50 nm) relative to the as-prepared sample. It is not too surprising since the PAMAM dendrimer interacts weakly with CdS relative to other capping molecules such as thiol [6], thus it cannot efficiently prevent the QDs from further aggregation upon aging. Another interesting observation is that the PL intensity decreases by a factor of 10 upon aging. This will be discussed below together with the XEOL results.

The X-ray excited optical luminescence (XEOL) excited at the S K-edge is shown in Fig. 4. As expected, the aged sample exhibits red-shifted (∼50 nm) XEOL bands relative to the as-prepared sample and the luminescence intensity of the aged QDs decreases (∼3 times) relative to the as-prepared sample. An inspection of the spectral shape reveals that both spectra exhibit two luminescence bands – bands at ca. 440 nm and 510 nm for the as-prepared sample and bands at ca. 490 nm and 560 nm for the aged sample.

Interestingly, the shorter-wavelength peak for the as-prepared sample is more intense than the other whereas in the aged sample, the longer-wavelength peak is more intense. It has been reported that in CdS QDs there are mainly two types of defects-related band-edge luminescence (i.e. radiation decay from defects near the conduction band to valence band) [7] – a short-wavelength emission attributed to S-related defect and a longer-wavelength emission attributed to Cd-related defect [8]. The two short-wavelength bands (440 nm for the as-prepared and 490 nm for the aged) observed in Fig. 4 reasonably match the reported S-defect emission (∼440 nm) and the longer-wavelength bands (510 nm, 560 nm) basically match the reported Cd-defect emission (∼580 nm) [8]. A schematic illustration of the attribution of these bands is shown in Fig. 5. It can be seen that from the as-prepared NPs to the aged sample, there is a band gap narrowing of ∼50 nm, or 0.2–0.3 eV. It indicates that after the six month, the NP size increases considerably, which is normal for the weakly capped NPs. Both Fig. 3 and Fig. 4 indicate that the aging also results in a decrease of the luminescence intensity of both S and

Cd-related emissions; moreover, the efficiency of the S-defect-related emission undergoes a more pronounced decrease.

4. Summary

We have reported the XEOL of dendrimer capped CdS quantum dots prepared under different conditions as well as the effect of aging. We found that in general, the higher the dendrimer to CdS ratio, the smaller the size as revealed from the optical studies. We also reported a dramatic change in the optical behaviour of these QDs upon aging. The detailed mechanism for the luminescence behavior of the CdS QDs upon aging remains unclear at the present. One possible reason is the change of the local environment of the S- and Cd-related defects in that in the S K-edge XANES (not shown), the aged CdS QDs exhibit a more intense sulfate resonance peak than the as-prepared QDs. Further experiments such as S and Cd K-edge EXAFS will provide new clues for the phenomenon.

Abstract

Chemical phase separation at processing temperatures is an important issue for integration of Zr and Hf silicates alloys into advanced CMOS devices. Chemical phase separation into ZrO_2 and SiO_2 has been detected by different spectroscopic techniques, including Fourier transform infra red, X-ray photoelectron, and X-ray absorption spectroscopy, as well as X-ray diffraction and high resolution transmission electron microscopy imaging. Comparisons between these techniques for Zr silicates identify an unambiguous approach to distinguishing between chemical phase separation with different degrees of micro- and nano-crystallinity. This is important since all modes of chemical separation degrade the dielectric properties required for high-K applications.

1. Introduction

One of the more significant limitations for the integration of transition metal silicate alloys such as $(ZrO_2)_x(SiO_2)_{1-x}$ and $(HfO_2)_x(SiO_2)_{1-x}$ as gate dielectrics into advanced Si devices is a chemical phase separation of these pseudo-binary alloys into SiO_2 and transition metal oxides, $Zr(Hf)O_2$ for Z(Hf) silicate alloys [1–3]. Studies of phase separation are important for device processing, since it results in significant decreases in effective dielectric constants, reducing the gate capacitance required for aggressive device scaling. This separation occurs in the same regime of temperatures as that required for integration of deposited dielectrics into device fabrication protocols [4, 5]. For example, chemical phase separation occurs in the 1000 °C temperature range required for dopant activation in conventional processing of source, drain, and polycrystalline gate electrodes in field effect transistors. It is therefore important to identify spectroscopic approaches that not only identify chemical phase separation accompanied by crystallization detectable by conventional diffraction techniques such as XRD, but also to detect chemical phase separation that occurs with amorphous, or nano-crystalline phases too small for detection by conventional diffraction methods.

2. Experimental Procedures

Zr silicate films 10 to 100 nm thick were deposited onto Si(100) substrates at 300 °C by a remote plasma process described in detail elsewhere [2]. The Zr : Si ratio in the deposited films was determined by the relative flow rates of the respective Zr and Si source gases. The alloy composition of the bulk films, reported as the Zr : Si : O ratio, was determined by Rutherford backscattering spectrometry (RBS). RBS results indicated that the $(ZrO_2)_x(SiO_2)_{1-x}$ alloy films were homogeneous, and fully-oxidized with an uncertainty in composition, $\delta x = \pm 0.03$ [1, 2]. These results were used to calibrate on-line AES results where a linear dependence was demonstrated between the ratio of the derivative spectrum peak-to-peak heights for Zr_{MVV} and O_{KVV} features and alloy composition as determined by RBS. Films were annealed *ex-situ* in an inert Ar ambient for one minute utilizing an AG minipulse 310 rapid thermal annealing (RTA) apparatus with an uncertainty in annealing temperature of ±15 °C.

FTIR absorption measurements, in the mid-IR (4000–400 cm^{-1}) and far-IR (700–50 cm^{-1}), were performed utilizing a Nicolet Magna-FTIR 750 spectrometer. XRD measurements were made using a Bruker X-ray diffractometer with a beryllium area detector centered at 2θ positions of 25° and 50°. XPS measurements of O 1s, C 1s, Zr 3d, and Si 2p core levels were made using a Riber LAS-3000 spectrometer with non-monochromatic Mg Kα radiation (1253.6 eV) and a pass energy of 20 eV. EXAFS and NEXAS measurements were made at the National Synchrotron Light Source (NSLS) at Brookhaven National Laboratory [6]. Absorption spectra for the O K_1 edge NEXAFS were recorded by measuring the photon energy dependence of primary photoelectron yield, and absorption data for the EXAFS and NEXAS studies using the Zr K_1 edge were obtained by monitoring X-ray fluorescence.

3. Experimental Results and Data Analysis

Figures 1(a) and (b) illustrate changes in FTIR spectra following the 900°C RTA. In films with 25% or less ZrO_2, chemical phase separation is detected as a reduction of absorption in a 970 cm^{-1} shoulder associated with terminal Si-O groups produced by network disruption. In films with more than 50%, ZrO_2, the changes are greater, and the emergence of SiO_2 like spectral features after the 900 °C anneal establishes the separation. This approach does not identify the morphology of the separated ZrO_2 phase.

Figures 2(a) and (b) are differentiated XPS spectra for the O 1s core level feature in as-deposited films and for films that have been annealed at 900 °C in Ar for one minute. The asymmetric line shapes in the as-deposited films are a manifestation of systematic changes in O-atom bonding coordination, which has been shown to change systematically from two (2) in SiO_2, to three (3) at the chemically-ordered silicate composition of $x = 0.5$ ($ZrSiO_4$), and then increase to four (4) in ZrO_2 [2]. The differentiated spectra for different samples which span the 50% concentration range, are markedly different, and clearly identify the emergence of two distinct spectral features at core level binding energies close to those of the end-member elemental oxides, SiO_2 and ZrO_2.

*e-mail: lucovsky@unity.ncsu.edu

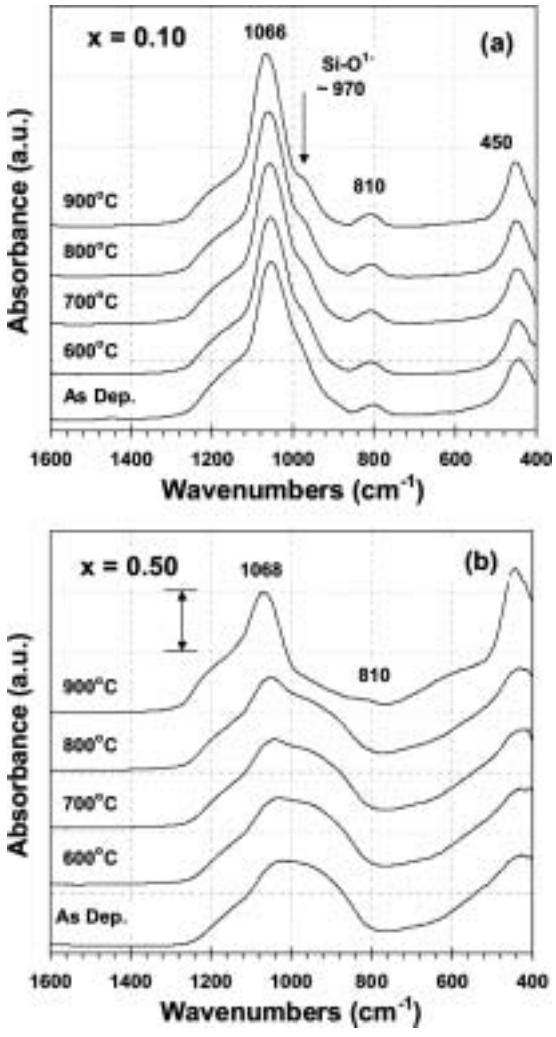

Fig. 1. FTIR spectral of Zr silicates alloys, 0.10 (top) and 0.5 (bottom) as function of temperature. Chemical phase separation is evident at 900 °C.

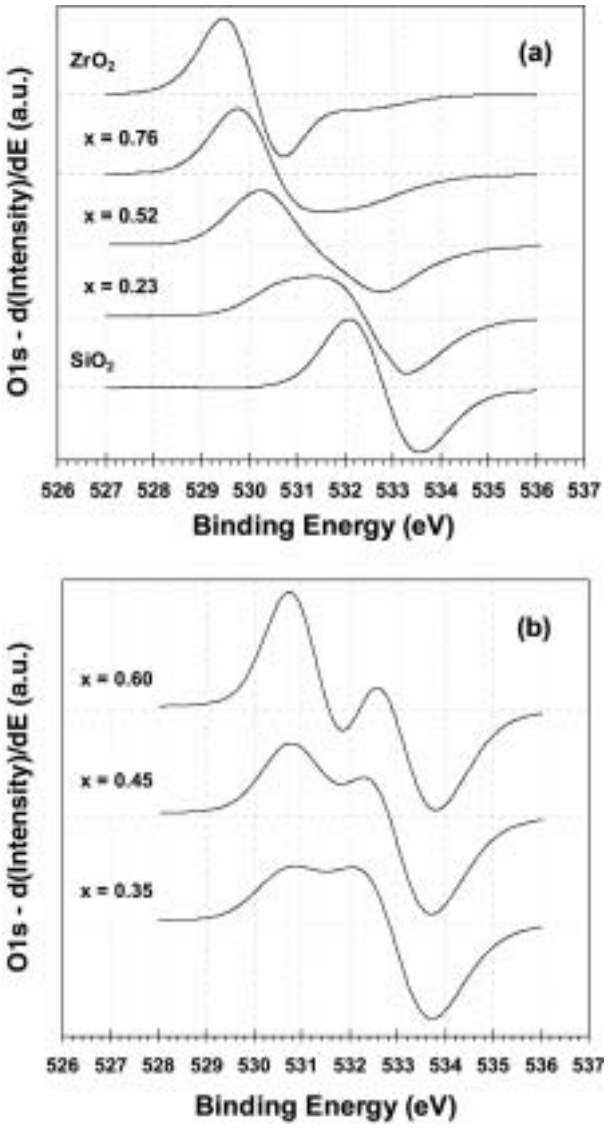

Fig. 2. Differentiated XPS spectra for the O 1s core level feature in as-deposited films and for films that have been annealed at 900 °C in Ar for one minute.

Finally, Figs. 3(a) and (b), and 4(a) and (b) compare respectively XRD and Fourier transformed EXAFS spectra for alloys Zr silicates with approximately 25% and 50% ZrO_2, including as-deposited and 900 °C annealed samples. The XRD spectra in Figs. 3(a) and (b) indicate the evolution of the X-ray scattering from as-deposited samples to those annealed at 900 °C. For the 25% alloy there is no evidence for the emergence of features at two-theta (2θ) values for any of the crystalline phases of ZrO_2. However, comparisons with SiO_2 XRDs confirm features associated with the alloy structure. These are more pronounced in the 50% alloy as a broad feature between about 26 and 34 degrees. In addition, the 50% alloy displays tetragonal crystalline features at 2θ values of ~28, 33 and 51 degrees.

Figures 4(a) and (b) indicate radial distributions functions obtained form Fourier transformed EXAFS spectra for 25% and 55% ZrO_2 alloys for as-deposited films and films annealed at 900 °C for one minute in Ar. The as-deposited films each show a feature associated with nearest-neighbor Zr-O bonding. The distance scale in the film has not been renormalized, and the real space spacing of this feature is ~0.22 nm. After annealing the RDFs show important qualitative and quantitative differences. A second shell feature in Fig. 4(a) assigned to Zr-Zr second neighbor distances emerges in the 25% ZrO_2 alloy, and its peak amplitude is about 40% of that of the Zr-O feature. In addition, there are also indications of third and fourth neighbor shells, but these are barely detectable above the background noise. In fact, the occurrence of stronger third and fourth shell features in the 55% sample helped to isolate these peaks. The RDF for the 55% ZrO_2 alloy is markedly different. The second shell, Zr-Zr feature is almost equal in magnitude to the Zr-O feature, and the third and fourth features are well above the background noise level. Based on these RDFs, the 50% alloy shows more long range order than the 25% alloy, and combined with the XRD results, the 55% alloy includes a tetragonal crystalline ZrO_2 phase after the 900 °C, anneal, but differences in long range order between the as-deposited and annealed 25% ZrO_2 alloy are too small for XRD detection.

A study of high resolution transmission electron micrographs clarifies this last point. The micrographs are included in Ref. [2]. The micrograph for the 25% alloy after 900 °C annealing displays dark and light patterns in the bright field image. The dark regions assigned to ZrO_2 on the basis of relative atomic masses, are approximately 3–5 nm in size, and are encapsulated by lighter regions assigned to the SiO_2 majority phase. This interpretation is consistent with the interpretation of FTIR and XPS data in Figs. 1 and 2. There is some evidence of crystalline organization in dark regions that are more than 5 nm distant from the Si substrate.

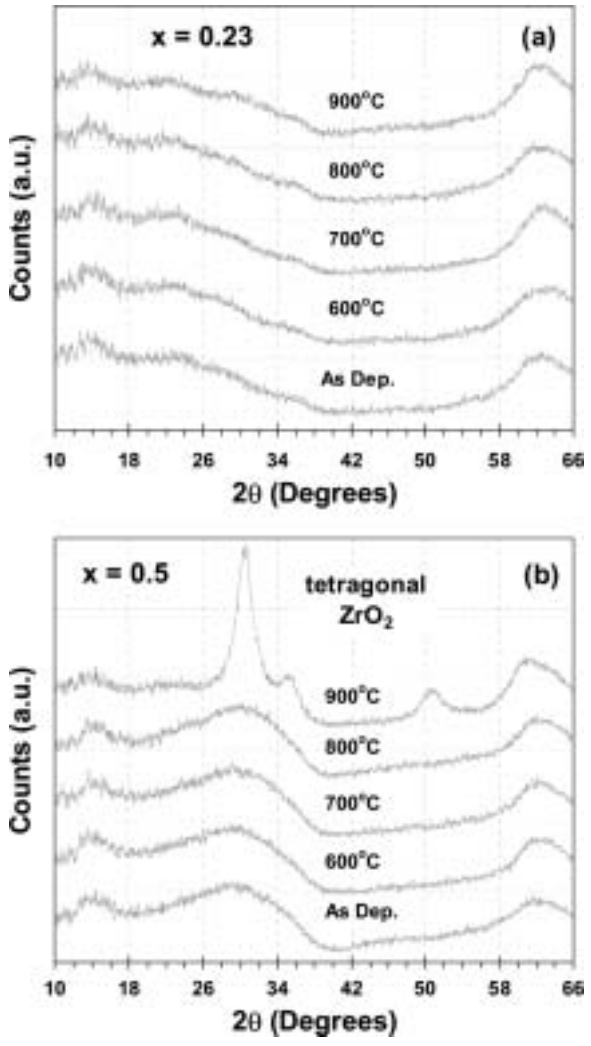

Fig. 3. XRD spectra for alloys Zr silicates with (a) 23% and (b) 50% ZrO_2 as-deposited through 900 °C annealing.

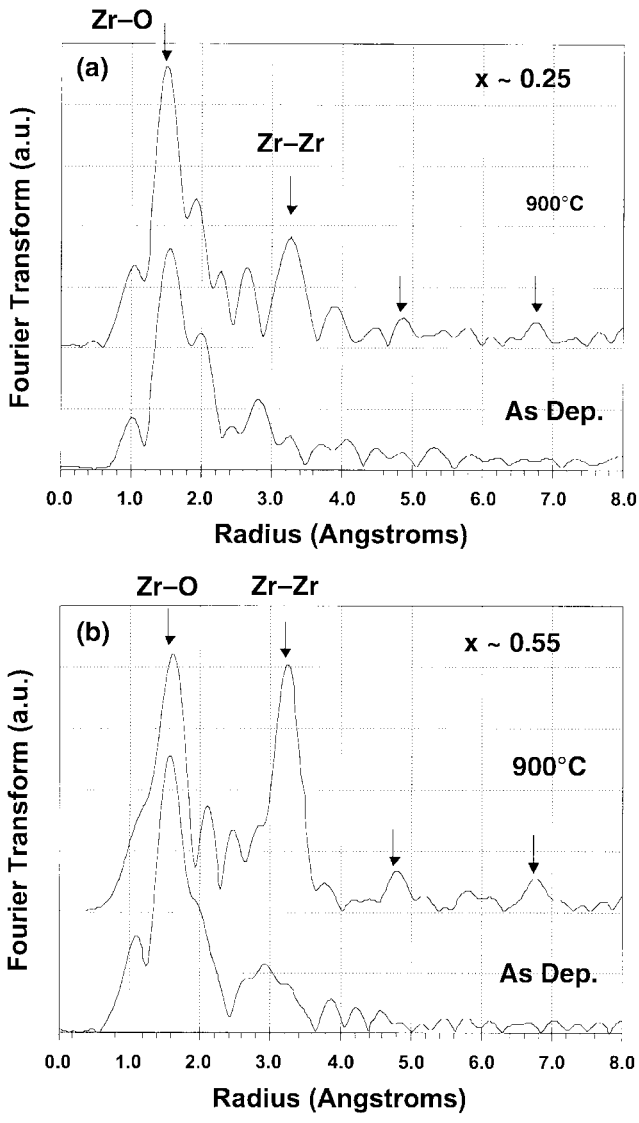

Fig. 4. Fourier transformed EXAFS spectra for alloys Zr silicates with (a) 25% and (b) 55% ZrO_2 as-deposited and after 900 °C annealing.

Combining the HRTEM and EXAFS, these regions are interpreted as being comprised of highly defective nano-crystals. In contrast, the HRTEM image for the 50% ZrO_2 alloy shows lattice planes indicative of micro-crystalline ZrO_2 that are again more distant that 3–5 nm from the Si-substrate. The 3–5 nm region devoid of micro- or nano-crystallite Si is assumed to occur because of compressive stress in the near interface region.

Studies of the O and Zr K_1 (1s) edges in Zr silicate alloys also show evidence for chemical phase separation after 900 °C annealing. These results are presented in Refs [7] and [8], and are complementary to the measurements discussed above. For example changes in the O K_1 edges in alloys with more than 50% ZrO_2 clearly indicate a crystalline ZrO_2 phase. In contrast, changes in the Zr K_1 edges indicate a change from Si to Zr second neighbors to a give Zr atom, i.e., phase separation, but with no direct evidence for crystallinity.

4. Summary

Zr silicate alloys films were prepared by remote plasma-enhanced chemical vapor deposition and compositions were obtained by RBS and AES. For Zr silicates with x between ~0.1 and 0.75, there are abrupt changes in the FTIR spectra between 400 cm^{-1} and 1100 cm^{-1} after rapid thermal annealing (RTA) for one minute in Ar at 900 °C, that indicate a chemical phase separation into SiO_2 and ZrO_2, but do not provide any information related to the crystallinity of the ZrO_2 product. Following the 900 °C RTA, changes in the O 1s XPS core level energies, and core level line shapes, and differentiated XPS signals as a function of alloy composition give unambiguous spectroscopic evidence for changes in O-atom bonding characteristic of 2-fold coordinated O-atoms in SiO_2, and continuous changing to 4-fold coordinated O in ZrO_2, but do not provide information relative to crystallinity. However, changes in the amplitudes of second-coordination shell Zr-Zr features compared to first-shell Zr-O features in Zr K_1 EXAFS RDFs before and after the RTA confirm differences in crystallite size as a function of alloy composition. Combined with HRTEM micrographs, these RDF differences are consistent with the grain sizes of ZrO_2 precipitates increasing from ~3 nm for 25% ZrO_2 alloys to >10 nm for 50% ZrO_2 alloys. XRD studies of silicate films with 25% ZrO_2 have shown relatively small changes in *amorphous-like* diffraction patterns after the 900 °C RTA, while alloys with 50% ZrO_2 indicate a tetragonal ZrO_2 phase after the anneal. Similar results have also been reported for Hf silicates, where the separation of homogeneous alloys can occur at temperatures approaching 1000 °C in SiO_2-rich alloy compositions [2].

In conclusion, combining FTIR and derivative XPS, with EXAFS RDFs, XRD and HRTEM imagining provides an

unambiguous and effective way to study chemical phase separation with *different degrees of crystallization*. This is of importance for semiconductor device processing since chemical phase separation at 900 °C in SiO_2-rich Zr and at 1000 °C in SiO_2-rich Hf silicates undetectable by XRD, can reduce gate dielectric capacitance, and therefore also reduce the current drive in FETs. Recently, SiO_2-rich Zr and Hf silicates with less than 40% $Zr(Hf)O_2$ have been shown to display reduced direct tunneling relative to their end member oxides [9]. If high-temperature processing produces a chemical phase separation with formation of nano-crystalline precipitates not detectable by XRD in these alloys, this will require the complementary characterizations for detection of chemical phase separation identified above: FTIR, XPS and EXAFS. Other issues yet to be resolved include properties of nitrided silicates, and defects at Si and poly-crystalline interfaces that give asymmetric behavior in N-/P-MOSFETs devices.

Abstract

Hard X-ray absorption spectroscopy is combined with scanning microtomography to reconstruct full near edge spectra of an elemental species at each point on an arbitrary virtual section through a sample. These spectra reveal the local concentration of different chemical compounds of the absorbing element inside the sample and give insight into the oxidation state and the local projected free density of states. The method is implemented by combining a quick scanning monochromator and data acquisition system with a scanning microprobe setup based on refractive X-ray lenses. The full XANES spectra reconstructed at each point of the tomographic slice allow one to detect slight variations in concentration of the chemical compounds, such as Cu and $Cu(I)_2O$.

X-ray absorption spectra reveal the local chemical environment of an element of interest. Its near edge spectra (XANES) can be used as a finger print for different chemical compounds, allowing one to determine their concentrations in a mixture. In many fields of science inhomogeneous samples are encountered, such as for example in physical chemistry (catalysts), materials science, biology, geology, and environmental science. In these samples, the composition of different chemical compounds can vary strongly as a function of position. A spatially averaged analysis often fails to reveal the information needed to understand the local chemical processes.

XANES microanalysis allows one to locally analyze inhomogeneous samples, provided the sample is thin enough in order to avoid averaging along the microbeam. This often requires difficult sample preparation that in addition is prone to change the chemical composition. One of the main strength of hard X-rays is their large penetration depth in matter that allows one to probe the volume of a specimen. In this article we have combined near edge spectroscopy with scanning microtomography to obtain full spectral information on an arbitrary virtual slice through an inhomogenious bulk sample. The method is illustrated for a sample taken from catalysis. Except for possible radiation damage, the method is non-destructive. A detailed description of the method is given in [1]. A complementary method, using full field imaging at different energies, is given in [2–4].

The experimental setup for this technique is shown in Fig. 1 and combines a fast scanning monochromator and data acquisition system developed at the University of Wuppertal [5–8] with a scanning microprobe setup based on beryllium parabolic refractive X-ray lenses [9, 10]. The hard X-rays from a synchrotron radiation source are monochromatized by a channel cut Si (111) double crystal monochromator and focused onto the sample position using a beryllium parabolic refractive lens. The

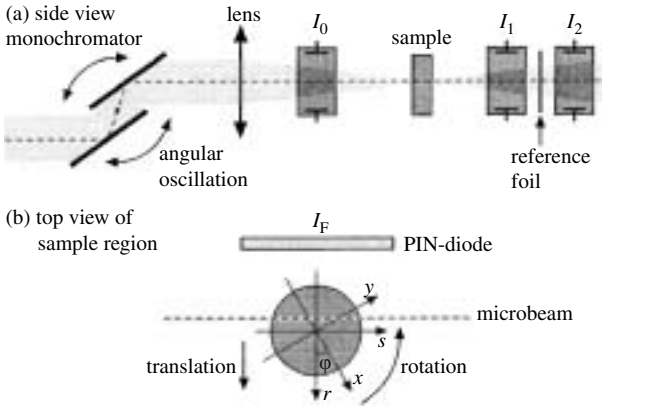

Fig. 1. (a) Side view of the setup for absorption spectroscopy tomography. (b) Top view of the sample region. The sample fixed coordinates (x, y) are rotated with respect to (r, s) by the angle ϕ. Both coordinate systems are translated with the sample. r denotes the position of the microbeam. The z coordinate perpendicular the slice is the same in both coordinate systems. resulting pencil beam has a lateral dimension in the micrometer range. As shown in Fig. 1(a), three ionization chambers measure the flux I_0 incident on the sample, I_1 transmitted by the sample, and I_2 transmitted by a reference foil, respectively. Simultaneously, a PIN-diode measures the fluorescence radiation I_F emitted by the sample (see Fig. 1(b)).

An absorption spectroscopy tomogram is recorded by scanning the sample through the microbeam in a two dimensional scan in r and ϕ as shown in Fig. 1(b). The translational scan in r corresponds to a single tomographic projection. After recording a projection, the sample is rotated in ϕ by an integer fraction of 360° and the next projection is recorded. This procedure is repeated until the sample has completed a full rotation. At each position of the scan, a full absorption spectrum is recorded. In order to record the full tomogram in a reasonable time, the time to record an absorption spectrum at a single position in the scan must be of the order of one second or shorter. This is possible with a QEXAFS monochromator and fast data acquisition system [5–8]. In the present experiment, the system recorded 10 full absorption spectra per second with 10^4 data points each, measuring simultaneously the signals I_0 through I_F described above.

The main advantage of this scanning technique is that it yields full absorption spectra at each point (r, ϕ) in the sinogram, both in absorption and fluorescence (cf. Fig. 2). In addition, all spectra are calibrated in energy. The method was first tested at the bending magnet beamline BM5 of the European Synchrotron Radiation

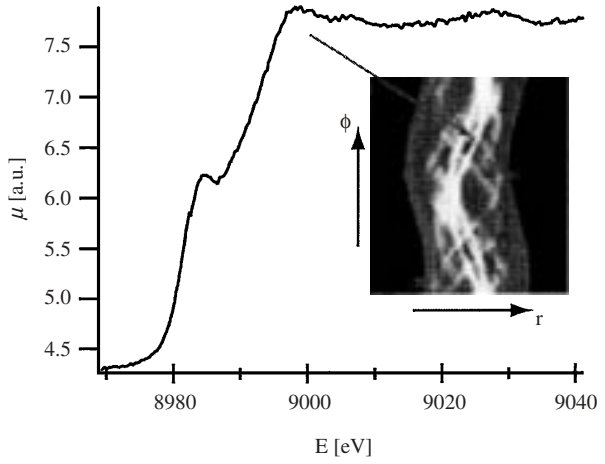

Fig. 2. (Color) XANES spectrum obtained at a single position (r, ϕ) in the tomographic scan. The position corresponds to the coordinates (r, ϕ) pointed to by the arrow in the inset that shows the absorption coefficient μ (at fixed energy $E = 9000\,\text{eV}$) as a function of r and ϕ, the so-called sinogram.

Facility (ESRF) in Grenoble, France. Although the feasibility of the method could be demonstrated at this beamline, recording larger tomograms requires the brilliance of a third generation insertion device. The experiments shown here were made at the undulator beamline 1-ID of the Advanced Photon Source (APS) in Argonne, Illinois. The sample is composed of a 30% CuO/ZnO catalyst that was twice reduced and re-oxidized by 4% H_2/He and 2% O_2/He at 200 °C–300 °C. After a final reduction the as grown Cu-particles on ZnO were re-oxidized at room temperature. The aim of the experiment was to analyze their structure and oxidation state in the volume. XANES tomograms were recorded both at the copper and zinc K-edge. At the copper K-edge, 101 projections with 90 translational steps of 10 μm each were recorded over 360°. The spectra recorded during the acquisition time of 1s at a given position are calibrated in energy using the spectra of the reference foil and summed up into a single spectrum. This is done for both the transmission and fluorescence channel. The negative logarithm of the transmission data yields the integral of the attenuation coefficient along the microbeam for each energy E.

Fig. 2 (inset) shows the transmission data at fixed energy for a full set of r and ϕ. This set constitutes the input data for transmission tomography. At each position (r, ϕ), a full XANES spectrum is available, a representative example of which is shown in Fig. 2.

Tomographic reconstruction yields the attenuation coefficient μ at each location (x, y) on the virtual slice. The attenuation coefficients below and above the K-edge of copper are depicted in Fig. 3(a) and (b), respectively. Fig. 3(c) shows the reconstructed spectra at the locations marked in Fig. 3(b) together with the reference spectra for metallic Cu, $Cu(I)_2O$, and Cu(II)O. At each location on the slice the reconstructed spectra can be fitted by these reference spectra (plus a constant stemming from other elements inside the sample). Two exemplary fits are shown as the red dashed curves in Fig. 3(c). In this way, the distribution of different copper compounds and of other elements (constant spectrum) can be obtained. The resulting distributions are shown in Fig. 3 of reference [1]. The quality of the fits to the spectra excludes significant concentrations of other compounds that have not a priori been taken into account. Copper is mainly contained in the present sample in metallic or monovalent osidation state. Slight variations in the relative concentrations of these constituents lead

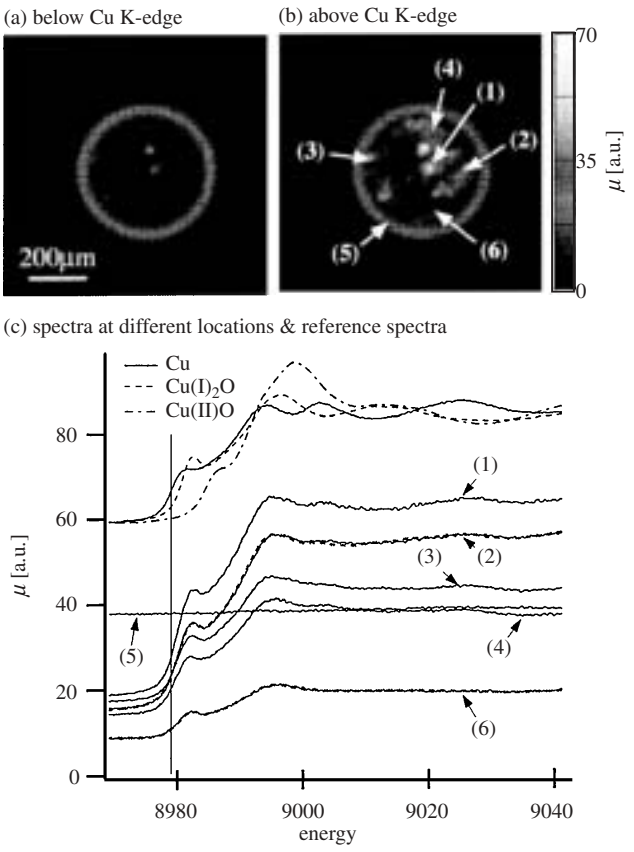

Fig. 3. (Color) reconstructed tomogram of a capillary filled with a CuO/ZnO catalyst (a) below ($E = 8970\,\text{eV}$) and (b) above the Cu K-edge ($E = 8995\,\text{eV}$). (c) Reconstructed XANES spectra at different locations marked in (b) and (offset) reference spectra of metallic Cu, $Cu(I)_2O$, and Cu(II)O. The dashed red curves in (c) represent two fits using the reference spectra. Reprinted with permission from [1]. Copyright 2003, American Institute of Physics.

to small changes in the near edge spectra. Faithful reconstruction of the relative concentrations requires full spectra, analyzing the residuals of the fits. For a detailed discussion see [1].

For more dilute samples, such as biological specimens, the fluorescence signal can be reconstructed. For fluorescence data the tomographic model is more complicated as self-attenuation effects need to be taken into account [11].

In the general case, absorption spectra of neighboring elements may overlap to produce a more complicated spectrum. This is the case for some of the spectra in the XANES tomogram recorded of the same sample at the zinc K-edge. Here, the Zn near edge spectra lie on top of the extended absorption fine structure of copper. Fig. 4 shows two spectra at locations marked by (1) and (2) in the reconstructed slice (lower right corner of Fig. 4). Spectrum (1) that is reconstructed at a location with high Cu concentration shows a slowly varying oscillation of Cu EXAFS being superimposed on the Zn XANES spectrum. Special care needs to be taken to separate these spectra from each other. Spectrum (2), on the other hand, comes from a pixel in the sample that contains only a small amount of Cu. For this pixel, a contribution of the Cu EXAFS to the spectrum is negligible.

The spatial resolution of the method is ultimately limited by the smallest spot size obtainable with hard X-ray optics [12–14]. The QEXAFS monochromator can be adjusted to cover the full EXAFS energy range [8]. In combination with achromatic X-ray optics, such as a Kirkpatrick-Baez total reflection mirror system [13, 15], the method can be extended to reconstruct full EXAFS spectra at each location on the reconstructed slice.

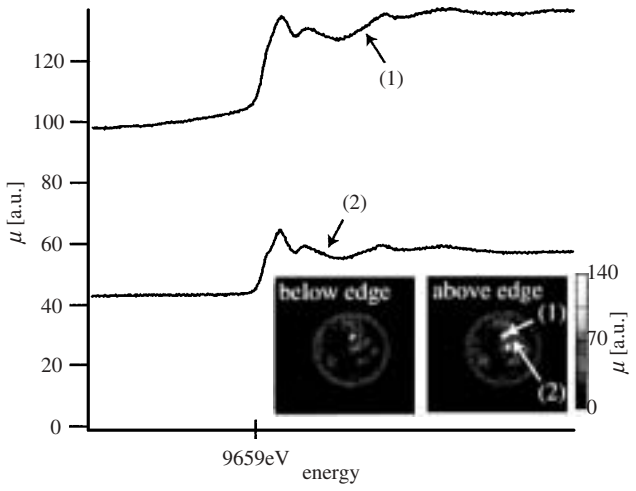

Fig. 4. (Color) XANES spectra (Zn K-edge) reconstructed at the locations marked by (1) and (2) in the tomographic slice shown in the inset. The tomographic reconstructions in the lower right corner show the absorption coefficient below and above the K-edge of Zn. Other than from Zn, the total attenuation in both spectra has contributions from Cu and other elements.

Abstract

X-ray microscopies using polarized X-rays allow for imaging magnetic microstructures down to a 20 nm lateral resolution with chemical sensitivity. Utilizing the pulsed time structure of synchrotron radiation a sub-ns time resolution can be implemented by performing stroboscopic pump-and-probe experiments. The temporal evolution of the magnetization in a 50 nm thin circular permalloy element with a diameter of 2 μm could be imaged with magnetic transmission X-ray microscopy. The magnetic pump pulse to the sample was generated electronically with a rise time of less than 100 ps up to 150 Oe by a microcoil. The probe pulse is the flash of the circularly polarized X-ray beam with a pulse width of about 70 ps at a frequency of 3 MHz. Images were recorded at varying delay times between pump and probe pulse up to 2000 ps. Fast detection schemes utilizing avalanche photo diodes are capable to pick individual bunches from the storage ring.

1. Introduction

The magnetism of systems with reduced dimensionality, as e.g. magnetic thin layers, multilayered films and laterally nanopatterned elements are subject to intensive experimental and theoretical studies. Magnetic thin film systems being composed of a large variety of elements to tailor a distinct functionality are key materials in current magnetic storage and sensor technologies. Laterally patterned magnetic elements in the sub-μm range can be prepared by adapting sophisticated techniques like e.g. e-beam lithographies which originally have been developed in semiconductor physics. Since the macroscopic behavior and the functionality of magnetic devices can be traced back to the magnetic microstructure, imaging magnetic domains on a nanometer scale is an outstanding challenge. In addition to the spatial imaging of static magnetic domain structures, where a huge variety of powerful techniques is available, recording the spin dynamics on a sub-second time scale is currently attracting rapidly increasing scientific interest. Precessional motion, the origin of damping and relaxation mechanisms, domain wall movements and coherent spin rotation and ultrafast switching processes are current scientific issues [1, 2, 3, 4, 5], which are being considered as new fast switching schemes in future magnetic storage and sensor technologies.

X-ray magnetic circular dichroism (XMCD) in core-level absorption, which detects basically the dependence of the X-ray absorption coefficient of circularly polarized radiation on the magnetization in a ferromagnetic species in the vicinity of an absorption edge, has become a powerful tool to investigate the magnetism of solids, surfaces and thin films. The magnetic contrast, which at the spin-orbit coupled $L_{2,3}$ edges in transition metals yields values up to 50% allows the combination of XMCD with imaging techniques to resolve the magnetic structure laterally. The first attempt reported in literature utilized a photoemission electron microscope (PEEM) [6].

Instead, magnetic transmission X-ray microscopy (MTXM) uses a high-resolution transmission X-ray microscope and the first results with a full-field microscope have been obtained at BESSY I in Berlin at the $L_{3,2}$ edges of Fe [7]. Currently, the full-field MTXM at the Advanced Light Source in Berkeley CA, where the presented data have been taken, has a lateral resolution down to 25 nm provided by Fresnel zone plates used as optical elements. Spin dynamics can be imaged with a stroboscopically pump and probe experiment where the magnetization is excited by short field pulses (pump) generated e.g. by small microcoils and probed by short (<70 ps) X-ray flashes of the synchtrotron source delayed with respect to the pump probe to obtain time spectra of the local laterally distributed magnetization.

In the following we describe the experimental setup for the pump-and-probe scheme and report on the observation of sub-ns magnetization dynamics in nanopatterned circular elements.

2. Experimental Details

The probe pulses are set by the time structure of the synchrotron. For the experiments described here the ALS was operating in the so-called two bunch mode, i.e. two electron bunches with a width of 70 ps are circulating in the storage ring at a frequency of about 3 MHz, i.e. the two bunches are separated in time by 328 ns and each of them contains a current up to 30 mA. In the corresponding multibunch mode some hundred bunches with each having a current up to 1–2 mA separated in time by only 2 ns are stored in the ring up to 8 h. Since the relaxation time of magnetization in small elements is of the order of tens of ns, the two-bunch mode operation is suited to study fast spin dynamics.

The pump pulses, i.e. fast magnetic field pulses exerted on the sample are generated by electronic pulses with a rise time less than 100 ps at a repetition rate matching the 3 MHz rate of the synchrotron. They are triggered by an ECL pulse given by the orbital clock of the storage ring and exhibit a time jitter of about 15 ps. Fed into a microcoil located adjacent to the magnetic element to be studied, these pulses provide a magnetic field pulse with its direction perpendicular the sample's surface. In order to study the temporal evolution of the magnetization the pump pulses are delayed relative to the probe pulse by a variable delay line in the range of −1000 ps and +3000 ps, whereby 0 ps defines the

*e-mail: peter.fischer@mf.mpg.de

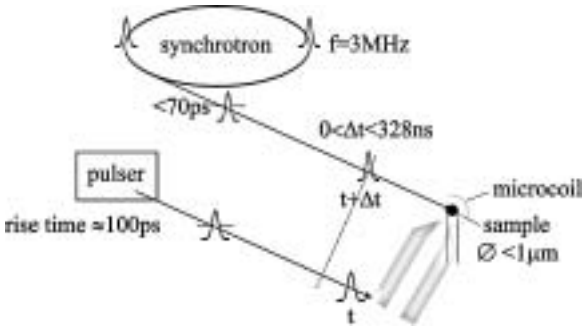

Fig. 1. Experimental setup for stroboscopic imaging with a pump-and-probe scheme at the ALS running in two-bunch mode.

coincidence of the pump and the probe pulse at the location of the sample's surface. An ultrafast photo diode (rise time 35 ps) and a fast avalanche photo diode (APD) (rise time 100 ps) situated close to the sample allow for accurate zeroing the delay time and in-situ monitoring of both pump and probe signals during the measurements. A schematic of the experimental setup is shown in Fig. 1.

The sample was a 50 nm thin and 2 μm diameter circular element of permalloy ($Ni_{81}Fe_{19}$). It has been prepared by e-beam lithography onto a 100 nm thin Si_3N_4 membrane with a transmission of 80% at a photon energy around 700 eV. Surrounding the sample a small 1 μm thin Cu microcoil with an inner diameter of 4 μm is prepared onto the same membrane. Fig. 2 shows a SEM image of the circular dot and the surrounding microcoil structure.

The relaxed, i.e. the static magnetization configuration in the circular microelement exhibits a vortex structure. The closed flux magnetization is described by the vorticity of the element, while in addition a singularity in the center with a pronounced out of plane magnetization is formed which could either point up or down (polarity). In Fig. 3 the schematic configuration of the magnetization in the circular element is displayed. Switching the magnetization of the element can reverse both the vorticity and polarity independently from each other [8].

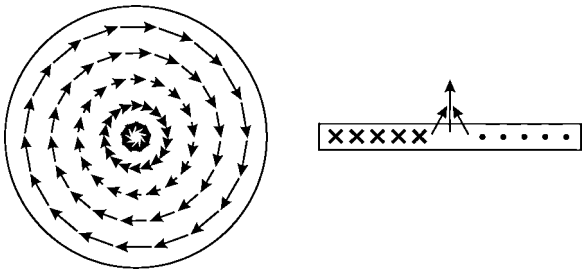

Fig. 3. Scheme of the relaxed static micromagnetic structure in a circular dot.

3. Results and Discussion

The temporal development of the magnetization is described by the Landau-Lifshitz equation $\frac{d\vec{J}_S}{dt} = \gamma[\vec{J}_S \times \vec{H}_{eff}] - \frac{\alpha}{J_S}[\vec{J}_S \times \vec{J}_S]$, accounting for both the precession of the magnetization in an external magnetic field $\boldsymbol{H}_{eff}$ with γ being the gyromagnetic ratio and the relaxation and damping of the system with α being a damping constant depending on the local geometry, anisotropy and morphology. So far a complete microscopic understanding of relaxation processes is lacking.

In Fig. 4 MTXM results with a circular PY element with diameter 2 μm are displayed. The sample is viewed at normal incidence to the photon beam and thus the static in-plane domain structure does not contribute to the magnetic contrast. The size of the vortec in the center is of the order of exchange lengths, which in permalloy amount to less than 10 nm and can thus be not resolved with MTXM. The field pulse applied normal to the sample plane creates a time-dependent z-component of the magnetization that can be recorded. Interesting features can be observed. The in plane magnetization of the elements performs a coherent switching that occurs on a time scale of less than 1 ns, since the white contrast seen observed at a delay time of 180 ps has reversed into a dark contrast at 980 ps. The inner part, i.e. the vortex of the element seems to be decoupled from that motion, since the white spot in the center remains up to 980 ps and is flipped rapidly at 1380 ps. A more complex temporal behaviour of the magnetization in the center is indicated by a shadowed dark region observed up to 380 ps. Since the applied magneticfield pulse has a duration of

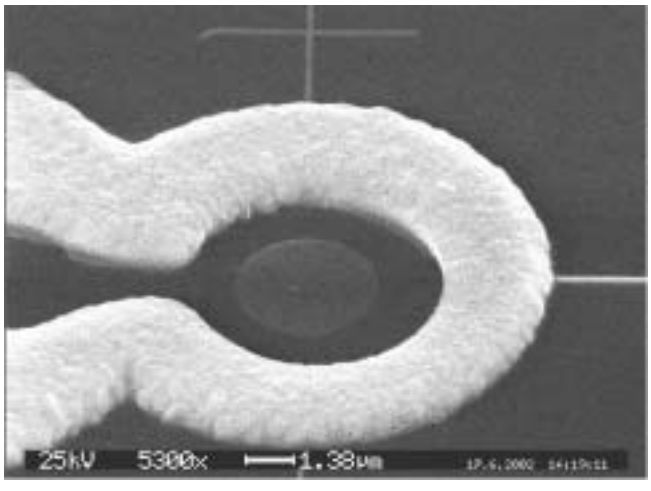

Fig. 2. Scanning electron microscopy of the sample studied. The circular dot and the surrounding microcoil are prepared by e-beam lithography onto a 100 nm Si_3N_4 membrane.

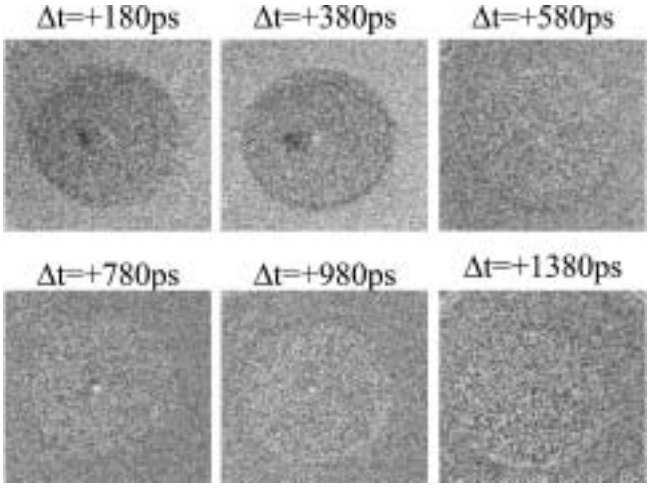

Fig. 4. Magnetic X-ray microscopy images of the temporal evolution of the magnetization in a circular dot at various delay times between pump and probe pulse.

500 ps this might be responsible for the observed feature where locally in-plane components of the magnetization could feel a torque due to the non static field pulse and are thus deviated from their symmetric position.

4. Outlook

Magnetic soft X-ray transmission microscopy allows the element-specific imaging of the magnetic domain structure of thin, multicomponent and nanostructured ferromagnetic systems. The inherent pulsed time structure of synchrotrons allows for the study of spin dynamics on a sub-ns scale with a stroboscopically pump-and-probe measurement.

Abstract

The K absorption pre-edge structure arises from excitations into the lowest unoccupied states that are partly formed by metal 3d orbitals. The pre-edge energy position, intensity and spectral shape can give valuable insight into the metal site symmetry and electronic configuration. The excited electronic states that form the absorption pre-edge subsequently decay radiatively. This fluorescence decay can be recorded using a crystal spectrometer that has a similar energy bandwidth as the incident beam. Plotting the fluorescence intensity versus incoming and outgoing energy yields three-dimensional plots that offer numerous possibilities for further analysis. In this paper we show that resonant inelastic X-ray scattering (RIXS) considerably facilitates separation of the K pre-edge structure from the strong dipole allowed transitions at higher incident energies. Previously unobserved spectral features could be revealed. The spectra along the energy transfer axis contain information on the electronic structure that is complementary to K-edge absorption spectroscopy.

1. Introduction

The electronic states that form an absorption spectrum are resonantly excited states that subsequently decay. The released energy can be carried either by an electron that is excited into the continuum (resonant Auger effect) or by a photon (resonant X-ray scattering or RXS). A review of the resonant Auger effect was published by Armen [1]. A large body of work already exists on resonant X-ray scattering that was reviewed comprehensively by Gel'mukhanov and Ågren as well as Kotani and Shin [2]. We will focus in this article on resonant inelastic X-ray scattering (RIXS) at the transition metal K absorption pre-edges where only few studies have been done up until now.

2. The RIXS plane

After resonant excitation of a 1s electron, the subsequent radiative decay with the highest probability is a 2p to 1s (Kα) transition. The 3p to 1s (Kβ) transitions are about a factor 8 weaker [3]. An expression for the RIXS spectrum $F(\Omega, \omega)$, where Ω and ω are, respectively, the incident and emitted photon energy, can be derived from the differential cross section that describes the inelastic X-ray scattering process [2]. It is giving by

$$F(\Omega,\omega) = \sum_f \left| \sum_i \frac{\langle f|T_2|i\rangle\langle i|T_1|g\rangle}{E_g - E_i + \Omega - i\frac{\Gamma_K}{2}} \right|^2 * \frac{\Gamma_L/2\pi}{(E_g - E_f + \Omega - \omega)^2 + \frac{\Gamma_L^2}{4}}. \quad (1)$$

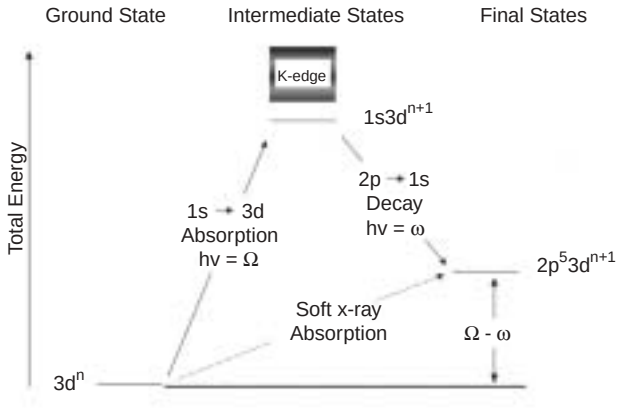

Fig. 1. Energy scheme for 1s2p RIXS in a transition metal ion. The vertical axis indicates the total energy of the electron configuration. For simplicity, atomic configurations are used and only 1s to 3d excitations are shown.

The intermediate state $|i\rangle$ is reached from the ground state $|g\rangle$ via a transition operator T_1. In a simplified picture using atomic configurations we can write $|g\rangle = 3d^n$ and $|i\rangle = 1s3d^{n+1}$, *i.e.* a 1s electron is resonantly excited into a 3d orbital (Figure 1). The intermediate states $|i\rangle$ in RIXS spectroscopy are the final states in conventional absorption spectroscopy. The spherical (SO_3) symmetry of the atomic 3d orbitals branches to the lower symmetry at the metal site. T_1 identifies with the quadrupole transition operator if the scattering atom is in centrosymmetric coordination (*e.g.* O_h symmetry). If the symmetry is reduced, *e.g.* to square pyramidal (C_{4v}) or tetrahedral (T_d), T_1 obtains some dipole contribution. In this case, the crystal field split 3d orbitals partly belong to the same irreducible representation of the point group as the metal 4p orbitals. The states can therefore mix and transitions from 1s to the 3d4p mixed states are dipole allowed [4]. The ratio of the dipole to the quadrupole contribution can be determined in single crystalline samples by analyzing the angular dependence of the absorption coefficient using linear polarized light [5] or by studying anomalous diffraction [6].

The final states are reached via a 2p or 3p to 1s dipole transition. The electron configurations of the RIXS final states are identical to the soft X-ray L-edge ($2p^53d^{n+1}$) and M-edge ($3p^53d^{n+1}$) absorption final states. However, the RIXS process is described by two transition matrix elements (cf. Equation (1)) that are connected coherently while an absorption spectrum arises from one transition (cf. Figure 1). Thus, the intensities in the fine structure of the spectra resulting from spin-orbit and electron-electron interactions as well as crystal field splittings might differ between K pre-edge RIXS and soft X-ray absorption.

The incident energy Ω as well as the emitted energy ω are varied in a RIXS experiment. The recorded intensity is proportional to $F(\Omega, \omega)$ and is thus plotted versus a two-dimensional grid. The overall spectra are best displayed in contour plots. In order to assign the total energy of an electronic state to the axes of the contour plots we will use the energy transfer or final state energy $\Omega - \omega$ as opposed to the emitted energy ω (Figure 1). The energy transfer axis relates to the excitation energy in L- and M-edge absorption spectroscopy, respectively. The lifetime broadenings Γ_K for the intermediate states and $\Gamma_f (f = \mathrm{L}, \mathrm{M})$ for the final states then apply in the Ω and $\Omega - \omega$ direction, respectively. Scans with constant emission energy (CEE) represent diagonal cuts through the $(\Omega, \Omega - \omega)$ RIXS plane. They are usually plotted versus the incident energy axis and then exhibit a line sharpening effect when compared to an absorption scan [7, 8].

The instrumental broadenings stretch in the diagonal (incident beam) and vertical (emitted beam) direction in the $(\Omega, \Omega - \omega)$ plane. Resonant 1s excitations into localized orbitals with a discrete energy occur along a diagonal line if we neglect many-electron transitions. Spectral features off of this diagonal line towards larger energy transfer are due to electron-electron interactions in the final state between the unpaired p-electron and the valence shell. Continuum excitations or excitations into delocalized final states with a broad energy band can be viewed as an infinite number of resonant excitations infinitely close to each other. In the $(\Omega, \Omega - \omega)$ plane they thus appear as a diagonal streak [9].

3. Experiment

The spectra were recorded at the BioCAT beamlime 18 ID at the Advanced Photon source. The total incident flux in the first harmonic of the undulator radiation was on the order of 10^{12} to 10^{13} photons/s depending on the incident energy monochromator crystal. For incident energies below 8 keV a cryogenically cooled Si(111) double crystal monochromator was employed. Above 8 keV (Ni K-edge) the Si(400) Bragg reflection was used. The fluorescence spectrometer features up to 8 analyzer crystal [10]. The following Bragg reflections were used: Ge(331) for V Kα, Ge(333) for Mn Kα, Ge(620) for Fe Kβ and Si(620) for Ni Kα. The total data acquisition time to record one RIXS plane was 2–4 hours. Careful radiation damage studies were performed for each sample. Radiation sensitive samples were measured in a He-flow cryostat in an exchange gas surrounding. The RIXS plane was constructed by recording CEE scans (2–30 seconds each in 'on-the-fly' mode) for different emission energies. The beam position on the sample was changed with every scan and the spectra were corrected for variations in sample concentrations.

4. Results

A series of Ni coordination complexes shows the pre-edge shift with Ni oxidation state (Figure 2). While the K pre-edge yields identical spectra for Ni(II) high-spin and low-spin we can clearly identify the different Ni species in the energy transfer direction. The 1s2p RIXS plane for NiF_2 ($3d^8$ in O_h symmetry) shows one K pre-edge resonance and a pronounced asymmetry towards the energy transfer direction due to (2p,3d) multiplet interactions. The high energy shoulder in the energy transfer direction has been used as a diagnostic of high-spin Ni(II) [11]. The K pre-edge is nearly invisible in the conventional absorption scan of the Ni(III)

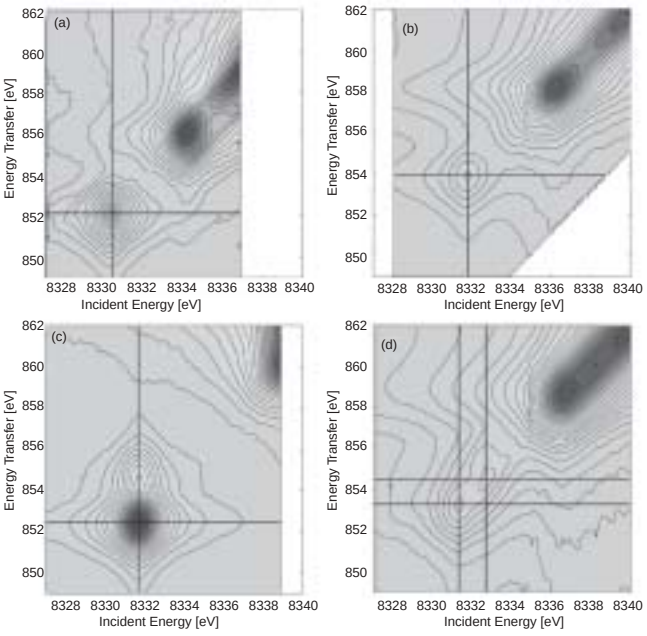

Fig. 2. $2p_{3/2}$ final states in the 1s2p RIXS contour plots for Ni coordination complexes: (a) Ni(I) in $[PhTt^{tBu}]NiCO$, Ni(II) (b) low-spin (ls) in $(Ph_4As)_2Ni(S_2C_2(CF_3)_2)_2$, Ni(II) (c) high-spin (hs) in NiF_2 and (d) Ni(III) low-spin in $[Ni(\eta^4\text{-DEMAMPA-DCB})]^-$. The vertical (constant incident energy) and horizontal (constant final state energy) lines indicate the lowest 1s to 3d resonances.

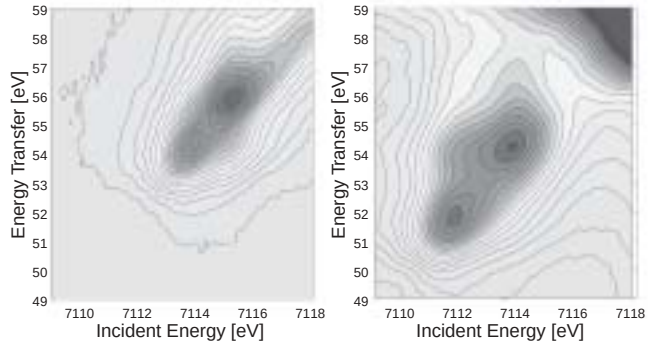

Fig. 3. 1s3p RIXS planes of Fe_2O_3 (left) and $Fe_{0.05}Mg_{0.95}O$ (right).

complex. Using the RIXS technique we can clearly resolve two strong resonances [12].

The 1s3p RIXS planes in Fe(II) ($Fe_{0.05}Mg_{0.95}O$) and Fe(III) (α-Fe_2O_3) in octahedral geometry show the pre-edge shift with oxidation state that we already observed for Ni. This is well documented in the literature (Figure 3) [13]. The crystal field splitting separates the two peaks for Fe(III) in Fe_2O_3 with $^5T_{2g}$ and ^5E_g symmetry. A theoretical analysis of the multiplet structure yields three 1s to 3d resonances for Fe(II) in $Fe_{0.05}Mg_{0.95}O$ with $^4T_1$, $^4T_2$ and $^4T_1$ terms [14]. A pronounced asymmetry relative to the diagonal towards larger energy transfer can be observed for the $Fe_{0.05}Mg_{0.950}O$ complex. This indicates strong (3p,3d) final state interactions. The RIXS spectra indicate that the center resonance with $^4T_2$ symmetry exhibits the strong final state interactions.

For a detailed analysis of the pre-edge features it is necessary to subtract the background due to the K main edge. We developed a procedure that fits horizontal cuts through the RIXS plane at constant energy transfer to Voigt line profiles [15]. The fit yields a background plane that can be subtracted from the experimental RIXS plane. An example is shown for MnO in Figure 4 where we also show ligand field multiplet calculations that reproduce

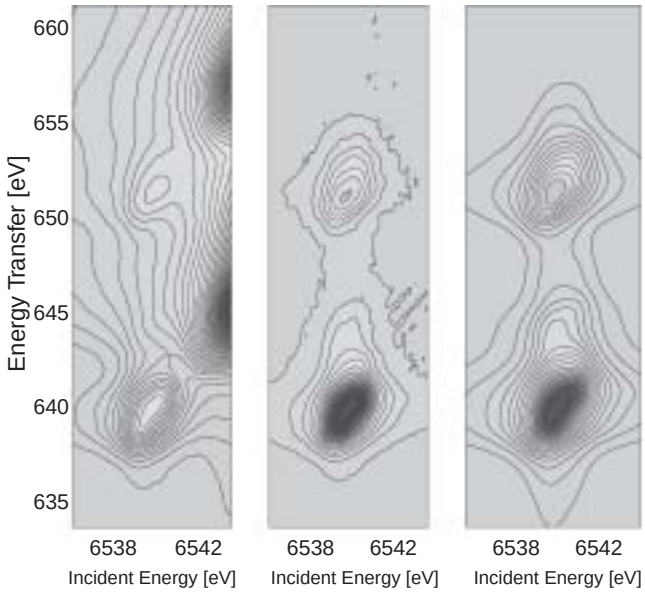

Fig. 4. 1s2p RIXS plane of MnO before (left) and after (center) subtraction of the K main edge together with ligand field multiplet calculations (10 Dq = 1.1 eV). The applied lifetime broadenings are $\Gamma_K = 1.1$ eV and $\Gamma_L = 0.5$ eV for the intermediate and final state, respectively, as well as 1.0 eV and 0.8 eV for the instrumental lifetime broadenings of the incident and the emitted X-rays. The features at 640 eV and 652 eV are the $2p_{3/2}$ and $2p_{1/2}$ final states, respectively.

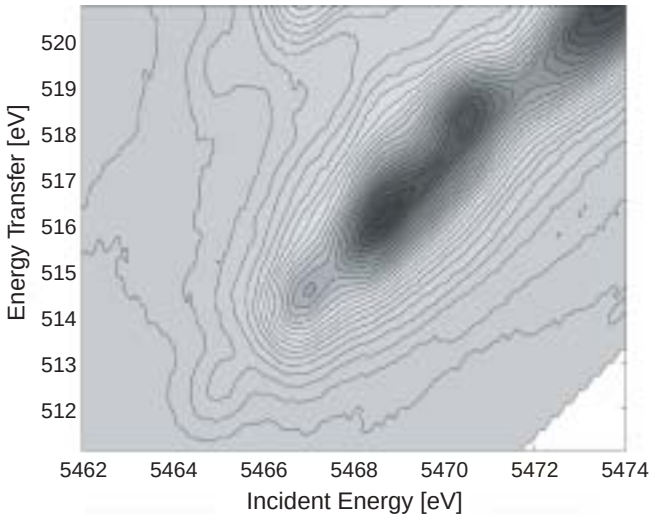

Fig. 5. $2p_{3/2}$ final states in the 1s2p RIXS plane of VF_4.

the experimental spectral shape after edge subtraction. The MnO $1s2p_{3/2}$ RIXS spectra can be fitted to two 1s resonances that are separated by the crystal field splitting similar to Fe_2O_3. This is consistent with 1s to 3d ligand field multiplet calculations for high-spin Mn(II) in O_h symmetry and thus indicates that quadrupole transitions contribute to the pre-edge intensity. The $2p_{3/2}$ final states exhibit a shoulder on the high energy transfer side that also appears in soft X-ray L-edge spectroscopy for high-spin Mn(II) compounds [16].

The K pre-edge of VF_4 presents a nice example for the interplay between crystal field and multiplet splittings. Both have approximately the same magnitude and result in four almost equally separated pre-edge structures (Figure 5) [17]. The two strong resonances at high incident energies appear to be further split. This could be indicative of the Jahn-Teller splitting in the t_{2g} orbitals.

5. Summary

RIXS spectroscopy enables to separate the K pre-edge from the main edge with a considerably higher accuracy than in conventional absorption spectroscopy. Previously unobserved spectral feature could be resolved. The energy transfer spectra contain information on the electronic structure that is complementary to the K pre-edge. Ligand field multiplet calculations can simulate the spectral features.

Abstract

We have established a high-precision depth-resolved X-ray magnetic circular dichroism (XMCD) technique, in which the probing depth of the partial electron yield XMCD spectra is controlled by changing the detection angle of the emitted electrons. The data quality has been significantly improved by using an imaging-type microchannel plate detector. We applied this new technique to Fe ultrathin films grown on Cu(100), and directly confirmed that the surface two layers of the 7 ML Fe film are ferromagnetically coupled, while the inner layers are in the spin density wave (SDW) state at 130 K. Then we separately extracted the XMCD spectra for the surface ferromagnetic (FM) and inner SDW layers. It was indicated that the SDW magnitude is almost the same as the magnetic moment of the surface FM layers, and that the orbital moment of the surface layers is larger than that of the SDW ones. Moreover, the extracted spectrum for the SDW layers exhibited a bulk-like feature, while the surface spectrum was similar to that from the 2 ML film, in which no bulk component should be included.

1. Introduction

Although the magnetic depth profile of ultrathin films has attracted much interest, it has been investigated mainly by measuring the total magnetization as a function of film thickness. Such a technique is not always reliable, since it is based on the assumption that the magnetic properties at surface, interface, and inner layers are unchanged regardless of the film thickness. Therefore, some attempts have been made to clarify the magnetic depth profile without changing the film thickness. Magnetization induced second harmonic generation (MSHG) [1–3] is one of the most powerful methods to investigate surface magnetism, since it is intrinsically surface sensitive. However, no magnetic information on the inner layers can be obtained. Spin-polarized appearance potential spectroscopy (SP-APS) also gives depth-resolved information [4, 5]. The interpretation of the spectrum is unclear, however, so that no quantitative information is deduced from the data.

Recently, X-ray magnetic circular dichroism (XMCD) measurements with depth resolution were achieved by utilizing the X-ray standing wave method [6]. This technique is quite effective, since the spin and orbital magnetic moments can be quantitatively determined from an XMCD spectrum by using the well-known sum rules [7, 8]. However, the samples which can be investigated with this technique are restricted, because a multilayer interference structure is necessary under the ultrathin film sample in order to generate standing waves. Moreover, the precise sample rotation as well as a high-quality multilayer structure is necessary to achieve high depth resolution. Recently, we have developed a much simpler depth-resolved XMCD technique, in which the probing depth is controlled by changing the electron detection angles determined by a slit placed in front of a microchannel plate (MCP) detector [9]. This novel technique allows us to investigate any thin film sample without modification in the sample preparation process. It takes a long data accumulation time, however, because one has to record the XMCD spectrum at each detection angle.

In the present study, we have significantly improved the depth-resolved XMCD technique by using an imaging type MCP detector. All the spectra with various probing depths are recorded simultaneously, so that the data accumulation time was drastically reduced with much higher data quality. We applied this technique to ultrathin Fe films grown on Cu(100), which exhibit peculiar magnetic structures [1, 4, 10–16].

2. Experiments

Experimental layouts for the previous [9] and present depth-resolved XMCD experiments are schematically depicted in Fig. 1. In the previous setup, we put a slit in front of the MCP detector to restrict the electron acceptance angle, and translated the sample to change the detection angle. Therefore, it was necessary to record the XMCD spectrum at each detection angle, θ_d, keeping various conditions such as sample cleanliness and photon energy scale unchanged during a series of measurements. Moreover, some complicated manipulation for the sample or detector is required if one wants to obtain both grazing and normal incidence XMCD spectra in order to investigate the magnetic anisotropy. In contrast, in the present setup, the emitted electrons are simultaneously collected at various θ_d, with a system consisting of a MCP, phosphor screen, and CCD camera. Moreover, we only have to rotate the sample in order to change the X-ray incidence angle. It should be emphasized that uniformity of detection efficiency over the whole detector is *not* necessary, because one can normalize the

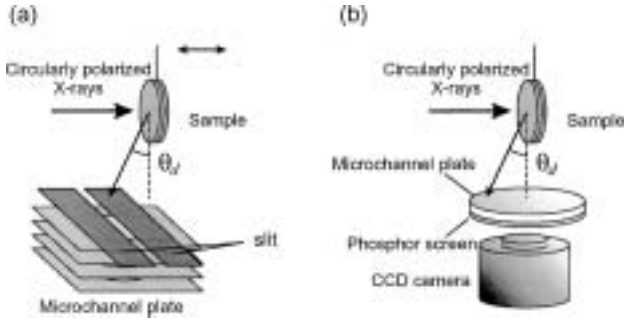

Fig. 1. Schematic layout for depth-resolved XMCD measurements with (a) a slit and (b) an imaging type detector.

*e-mail: ohta@chem.s.u-tokyo.ac.jp

obtained spectrum at each θ_d by using the absorption coefficients at the pre- and post-edge energies.

We adopted the partial electron yield mode with a retarding voltage of –500 V to enhance surface sensitivity. Accordingly, Fe LMM Auger electrons are mainly collected. Note here that the photoelectron and Auger electron diffraction effects are negligible, because the kinetic energy range for the collected electrons is so wide. The diffraction effects are further diminished by averaging over the azimuthal angles of the emitted electrons. Since the probing depth, λ_e, is not expected to be proportional to $\sin\theta_d$ in the case of partial electron yield detection mainly due to the inelastic scattering process, λ_e was experimentally determined for each θ_d by measuring the Fe-L edge jump as function of film thickness [9]. The estimated λ_e varies from 7.5 to 19.4 Å by changing θ_d in the range of 0–30° from the surface parallel direction.

All the experiments were performed in an ultrahigh-vacuum chamber placed at the soft X-ray station, BL-7A, in the Photon Factory [17]. Circularly polarized X-rays (circular polarization factor, $P_c \sim 0.85$) were obtained by collecting light emitted downward (-0.4 mrad) the orbit plane of the storage ring. The sample was magnetized by a current pulse through a yoke coil, and then the coil was retracted out during the measurements. A Cu(100) single crystal was cleaned by repeated cycles of Ar^+ bombardment (1.5 kV) and annealing to ~900 K. Fe was deposited at room temperature by electron bombardment heating of an iron rod, and the film thickness was monitored by *in situ* RHEED (reflection high-energy electron diffraction).

3. Results and discussion

Before describing the presents, let us summarize the earlier works concerning the ultrathin Fe/Cu(100) films [1, 4, 10–16]. As for the thermally deposited Fe films grown at room temperature, it has been believed that the Fe film exhibits ferromagnetic (FM) coupling below 4 ML (region I) and above 12 ML (region III), while it consists of the two-layer thick surface FM layers and inner antiferromagnetic ones in the case of 5–11 ML (region II). Recently, Qian *et al.* studied the magneto-optical Kerr effect (MOKE) as a function of film thickness and claimed that the inner layers of region II are in spin density wave (SDW) state with wave number $q = 2\pi/2.7d$ [16]. Here, d denotes the interlayer distance of the film. The ordering temperature for the inner layers in region II was reported to be ~200 K [11, 16].

Figure 2 shows Fe L-edge XMCD spectra for a 7 ML Fe film taken with various electron detection angles, θ_d. Since the film is known to have perpendicular magnetic anisotropy, all the spectra were taken at normal X-ray incidence. It is clearly seen that

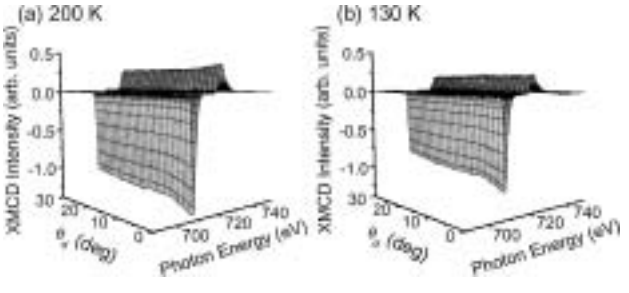

Fig. 2. Fe L-edge XMCD spectra for a 7 ML Fe film grown on Cu(100) taken with various electron detection angles, θ_d.

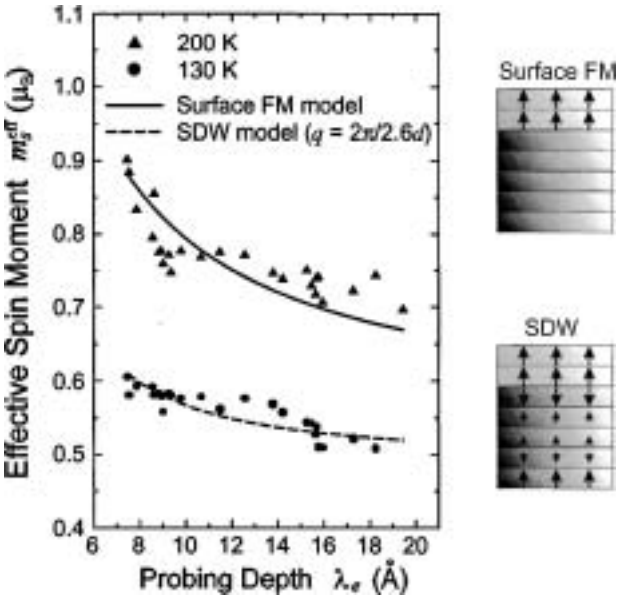

Fig. 3. Effective spin moment, $m_s^{\rm eff}$, as a function of probing depth, λ_e, together with the simulated curves assuming two-layer thick surface FM layers with the nonmagnetic inner layers (surface FM model) and the same with SDW inner layers with $q = 2\pi/2.6d$ (SDW model).

the XMCD intensity is reduced as θ_d increases both at 130 and 200 K. We can thus directly conclude that the magnetic moment is localized around the surface. Note here that the XMCD signals taken at 130 K were significantly smaller than those recorded at 200 K, suggesting some magnetic structure in the inner layers.

In order to further investigate the magnetic depth profile, effective spin magnetic moment, $m_s^{\rm eff} = m_s + 7m_T$, was estimated by applying the sum rules [7, 8] for each XMCD spectrum. The estimated moments are plotted in Fig. 3 as a function of λ_e, together with the simulated curves for the magnetic structures illustrated in the figure. In this simulation, we assumed an exponential decay for the emitted electrons, and neglected the self-absorption effect of the incident X-rays. The probing depth dependence at 200 K is well reproduced by the surface FM model, which consists of the two-layer thick surface FM layers and nonmagnetic inner layers. The reduction of the XMCD signals at 130 K can be explained by assuming that the inner layers are in the SDW state, where the first layer of the SDW state (third layer from the surface) is antiferromagnetically coupled with the surface FM layers. This behavior is in reasonable agreement with previous studies [11, 16] which indicated that the ordering temperature for the inner layers in ~200 K. We performed curve fitting analyses to determine the SDW wavenumber, yielding $q = 2\pi/2.6d$, which agrees well with our previous experiments [9] and the MOKE result [16].

Next, the layer-resolved spectra at 130 K were extracted in a similar manner described elsewhere [9]. We repeated the extraction procedure by changing q around $2\pi/2.6d$, finding again that $q = 2\pi/2.6d$ gives the smallest difference between the obtained data and simulation. The extracted XMCD spectra are depicted in Fig. 4. The XMCD spectrum for the first layer of the SDW has an opposite sign to that for the surface FM layers, this confirming the above-mentioned antiferromagnetic FM/SDW interface coupling. Moreover, it is suggested that the SDW amplitude is as large as the magnetic moment of the surface FM layers. Furthermore, we should note that the XMCD spectrum for the SDW layers has a small but significant structure just above

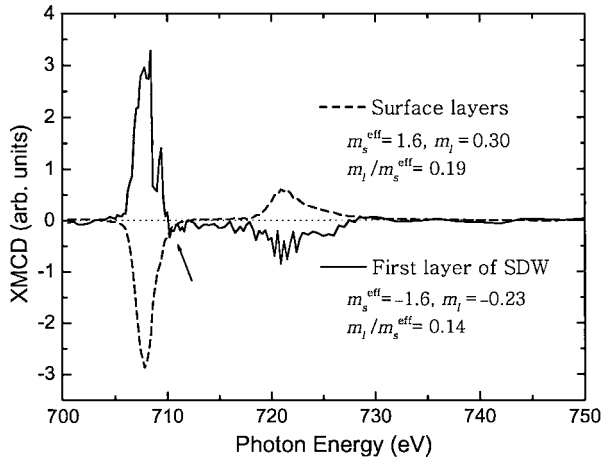

Fig. 4. Extracted Fe L-edge XMCD spectra for the surface FM (dashed line) and inner SDW (solid line) layers of the 7 ML film at 130 K. For the SDW layers, only the spectrum for the first layer (third layer from the surface) is given. A small structure above the L_{III} peak is indicated by an arrow in the XMCD spectrum for the SDW layers. The obtained effective spin moment (m_s^{eff}) and orbital one (m_l) are also indicated in the μ_B unit, together with their ratio.

the L_{III} peak with an opposite sign to the L_{III} peak (indicated by an arrow), while no such structure is found in the surface FM spectrum. Similar difference was reported for 2 and 40 ML Fe films grown on Pd(100) [18], where the opposite sign peak is observed only for the 40 ML film. They interpreted this as the difference in the diffuse magnetic moment [19] related to the empty s final states. No matter whether their interpretation is correct or not, the opposite sign peak can be attributed to a bulk-like feature, because the 2 ML spectrum should not include any bulk component. In fact, the opposite sign peak also appears in the bulk Fe spectrum [20]. We have thus succeeded in extracting the surface and bulk-like XMCD spectra separately from the single element film.

Finally we estimated the magnetic moments for the surface and inner layers by using the sum rules [7, 8] (see Fig. 4). The estimated magnetic moment of the surface FM layers is almost the same as that of the inner SDW ones, indicating again that the SDW amplitude is comparable to the magnetization of the surface FM layers. Moreover, the orbital moment of the surface layers is larger than that of the inner ones, which directly suggests the enhancement of the surface orbital moment.

4. Conclusions

We have significantly improved the depth-resolved XMCD technique by using an imaging type MCP detector. All the spectra with various probing depths are recorded simultaneously, so that the data accumulation time was drastically reduced with much higher data quality. We applied this technique to the Fe/Cu(100) films, and confirmed that the surface two layers of the 7 ML film are ferromagnetically coupled, while the inner layers are in the SDW state at 130. It was clearly indicated that the extracted XMCD spectrum for the surface FM layers is similar to the typical ultrathin film spectrum, while that for the inner layers has a bulk-like feature. The quantitative analyses suggested that the SDW amplitude is almost the same as the magnetization of the surface FM layers ($m_s^{eff} = 1.6\mu_B$), and that the orbital moment of the surface layers ($m_l = 0.30\mu_B$) might be larger than that of the SDW ones ($m_l = 0.23\mu_B$).

Abstract

We employed a combination of selective sequential extractions and bulk XAFS spectroscopy, and extracted spectral XAFS components and their concentrations by iterative transformation factor analysis (ITFA), in order to determine the Zn speciation in a smelter-contaminated, acidic soil. We compared the speciation by ITFA with one we performed earlier using principal component analysis and linear combination fit. ITFA identified 4 different species, two different franklinite-type phases (Zn-Fe spinels), sphalerite (Zn sulfide) and Zn oxalate, the latter forming as a precipitate during chemical extraction with oxalate solution. The second spinel-type phase could be extracted with the help of ITFA, although no appropriate reference sample was available. Spinel 1 and 2 have Zn-O distances of 1.96 and 1.99 Å, and Zn-Fe distances of 3.53 and 3.48 Å, respectively. The results from ITFA gave much better fits of experimental spectra and are better in line with elemental mapping and XAFS microspectroscopy. The major advantage of investigating XAFS data with ITFA is the possibility to derive all species even when part of the references are not available.

1. Introduction

Speciation of metals in contaminated soils is a prerequisite for predicting the environmental risks and to develop efficient and cost-effective remediation measures. While XAFS is the method of choice for providing molecular information on chemical forms, several coexisting species can be resolved only by the additional help of micro-spectroscopies, chemical and physical separation methods, and statistical methods [1–6]. Recently we have employed a combination of selective sequential extractions followed by XAFS spectroscopy, and have identified the spectral contributions by principal component analysis, target transforms and linear combination fits [7]. Another statistical method, ITFA, has been applied recently to derive the structure of two coexisting aqueous U(VI)-protocatechuic acid complexes [8]. This approach has the advantage that reference spectra of pure species can be substituted for by knowledge of the relative distribution of species in mixtures. That is, if the concentrations of at least some of the species are known from speciation modeling (or any other source like complementary spectroscopies), the spectra of the pure species can be calculated even when only spectra of species mixtures are available. The intention of the present paper was to investigate, whether this approach can be applied to decipher metal speciation in soils. As a model case, we investigated the Zn K-edge XAFS spectra collected from selective sequential extraction residuals of a contaminated soil [7].

2. Experimental

A topsoil sample was collected near the former zinc smelter in Palmerton, Pennsylvania [6]. This sample was ground, and subjected to increasingly aggressive extraction procedures [9]. After each of 6 extraction step, the removed zinc concentration was determined by atomic absorption spectrometry, and an XAFS spectrum was collected (fluorescence mode with Lytle detector at beamline X-11A, NSLS) [7]. The resulting 7 spectra (untreated soil sample and sample after each of 6 extraction steps) were investigated by ITFA [8, 10]. First, abstract Eigenvectors were derived from the set of XAFS spectra by principal component analysis. These Eigenvectors were used to estimate the number of species present (see below). Second, a Varimax rotation was applied to get qualitative concentrations of the factors. Third, additional information was used to derive real concentrations and real factors (i.e. the XAFS spectra of the pure species and their relative contributions) by iterative target transform.

3. Results and Discussion

Figure 1 (top) shows the first four Eigenvectors derived from XAFS spectra of the soil samples before and after 6 extraction steps. The amplitudes decline from vector 1 to 4. While vectors 1 to 3 still contain information similar to XAFS oscillations, vector 4 contains experimental noise only. Thus, the Eigenvectors suggest the presence of three species in all samples. From our previous investigations we knew that franklinite, sphalerite and zinc oxalate are the major Zn species of these samples [6, 7]. Therefore, by adding the spectra of these species to those of the soil samples, we would have expected to observe again three significant Eigenvectors only. However, Figure 1 (bottom) shows a fourth significant Eigenvector. Since we know the relative concentrations of three species in three of the spectra (the 3 reference spectra), we can now calculate the relative concentrations of all four species in the 10 samples by iterative target transform (Fig. 2). Finally, the real factors, i.e., the XAFS spectra of all four species, were derived (Fig. 3). Factor 2 is identical to the franklinite reference sample, factor 3 to the sphalerite sample, and factor 1 to the Zn oxalate reference. Factor 4 represents the fourth, unknown species. The spectral features (Fig. 3) and the fit results (Table I) suggest that factor 4 represents a second franklinite phase, which is distinguished from the franklinite reference by a larger Zn-O distance and a smaller Zn-Fe distance. The larger Zn-O distance may be due to Zn in both tetrahedral and octahedral coordination, which is not untypical for spinel structures. Furthermore, the difference in Zn-Fe distances may indicate different elemental composition, e.g. varying fractions of Zn, Fe and Mn in the structure.

In spite of their structural differences, the dissolution behavior of franklinite 1 and 2 is similar (Fig. 4). In the untreated soil sample, about 80% of the total zinc is in the two franklinite phases. During step 5, which is an oxalate solution step intended to dissolve weakly crystalline Fe oxides, a substantial amount of

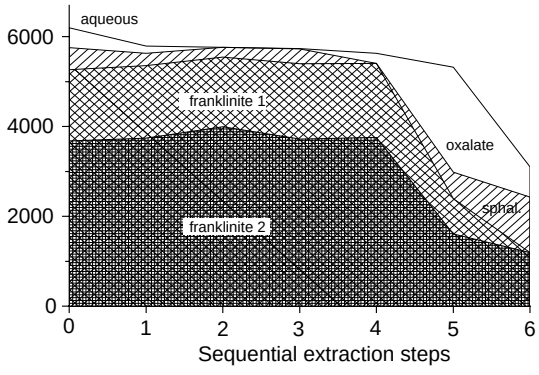

Fig. 4. Absolute species distribution (cumulative) of the untreated soil sample (step 0) and after each of the selective sequential extraction steps (1 to 6).

both franklinite phases is dissolved, but most of the dissolved Zn re-precipitates as Zn oxalate. The larger part of this Zn oxalate, and a smaller part of franklinite dissolves during step 6, a step intended to dissolve crystalline Fe oxides. None of these steps dissolves a significant amount of sphalerite, which hosts about 10% of total Zn (in the untreated sample). This is much less than the 30% derived by linear combination fits [7]. An amount of 10% is more consistent with the observations by XAFS microspectroscopy [6]. Furthermore, the reconstruction of the experimental spectra has significantly improved, giving another indication that the ITFA approach is superior to the approach employing principal component analysis, target transform and linear combination fits.

The problem of properly identifying aqueous and exchangeably sorbed Zn cations is evident from the fact, that ITFA assigns about 10% of Zn oxalate to the untreated soil sample. Step 1 employing a 1M NH_4NO_3 solution, removed 7% of Zn indicating that this amount is aqueous Zn^{2+} and/or Zn bound to cation exchange sites instead. The single O shell of aqueous Zn is a spectral feature also present in Zn oxalate, therefore making the discrimination by ITFA impossible.

In conclusion, we believe that ITFA has a great potential to improve the interpretation of XAFS of complex mixtures, since this statistical method depends less on a complete spectral database.

Abstract

The local environments around substitutional Cr^{3+} or Fe^{3+} ions in doped α-Al_2O_3 have been studied experimentally by dichroic X-ray absorption at the Cr and Fe K-edges in single crystals. A reliable method has been applied to remove diffraction peaks. This paper shows that the dichroic EXAFS analysis leads to the precise determination of the environment around impurity ions in α-Al_2O_3. The Cr or Fe coordination shell in doped α-Al_2O_3 is similar to the one of Cr in α-Cr_2O_3 or of Fe in α-Fe_2O_3. Aluminum or oxygen atoms at a farther distance are weakly affected by the presence of the impurity.

1. Introduction

Impurities in insulators modify the properties of the host crystal. Improvement in voltage holdoff capability can be obtained by doping plain alumina [1]. Laser light emission relies on the excited states of transition elements (Cr^{3+} for the first laser crystal) or rare earth (Eu^{3+}) in α-Al_2O_3 [2]. The color of allochromatic minerals results from minor impurities. Colorless corundum (α-Al_2O_3) becomes red ruby (α-$Al_2O_3:Cr^{3+}$) when few Cr^{3+} ions substitute for Al^{3+} ions. When few Fe^{3+} ions substitutes for Al^{3+} ions, α-$Al_2O_3:Fe^{3+}$ is yellow [3, 4]. Therefore, impurities play an essential role in the macroscopic properties of materials, in particular concerning the color or the dielectric behavior. The determination of the local structure around impurities is essential as a first step to understand the specific macroscopic properties of these materials.

The crystal structure of α-Al_2O_3 belongs to the space group $R\bar{3}2/c$ or D^6_{3d}, thus making it a uniaxial birefringent material [5]. The rhombohedral unit cell contains two Al_2O_3 formula. Aluminum ions are linked to six oxygen ions in a distorted octahedron. The six oxygen atoms are gathered into two groups of three atoms to comply with the C_3 symmetry. These two groups lie at two different distances from the central atom. The farther three oxygen atoms (O_2 type) compose the face shared by two joined octahedra. The nearest three oxygen atoms (O_1 type) are an edge shared by two joined octahedra. The ionic radius of the paramagnetic impurities is larger than the ionic radius of aluminum atoms ($r_{Cr^{3+}} = 0.615$ Å, $r_{Fe^{3+}} = 0.645$ Å and $r_{Al^{3+}} = 0.535$ Å in an octahedral site [6]). Since the Al-O bond in corundum is known to be ionocovalent [7], the relaxation is not exclusively geometric. The determination of the two precise metal oxygen bond lengths in the coordination shell is not obvious. X-ray absorption spectroscopy (XAS), in particular EXAFS, is a remarkable technique to probe the structural environment around a particular ion. However, the experimental determination of the distortion around transition metal impurities in α-Al_2O_3 powders is difficult to obtain from isotropic EXAFS spectra, since the differences between two fits of the experimental signal performed using either one averaged metal-oxygen distance or two different metal-oxygen distances leads to little improvement of the fit. Therefore, the analysis of the dichroic signal is needed to determine precisely the environment around impurities in corundum. This is done by using single crystals. Nevertheless, recording EXAFS on a single crystal is difficult due to the presence of diffraction peaks that strongly distort the experimental information [8]. We used a powerful method to remove diffraction peaks [14].

Our goal is to determine precisely the local environment around Cr^{3+} and Fe^{3+} in doped α-Al_2O_3. In the first part of this article, we show what kind of information is possible to reach using dichroic EXAFS. The dichroic EXAFS measurements, the process to remove diffraction peaks and the dichroic analysis of the spectra are described in the second part. Results are discussed and compared with *ab initio* energy minimization in the third part.

2. Dichroic EXAFS

Since the crystal structure belongs to the space group $R\bar{3}2/c$, the absorption cross section σ depends on the angle θ between the C_3 axis ([111] direction in the rhombohedral lattice) and the polarization $\hat{\epsilon}$ of X-rays [9] by $\sigma(\theta) = \sigma_0 + \sigma_1 \cos(2\theta)$. The isotropic cross section, analogous to the one of a powder, is given by $\sigma_0 - \frac{\sigma_1}{3}$. The dichroic cross section, given by the difference between $\sigma_{C_3 \| \hat{\epsilon}}$ and $\sigma_{C_3 \perp \hat{\epsilon}}$ is equal to $2\sigma_1$.

Since the six Al-O distances in the first coordination shell of α-Al_2O_3 are gathered into two groups lying at two different distances from the aluminum atom, and EPR measurements suggest that the chromium site in α-$Al_2O_3:Cr^{3+}$ is trigonal [10], we expect to determine the two metal-oxygen distances in the first coordination shell of the Cr and Fe impurities. In order to do that, the analysis of the dichroic EXAFS signal is essential. This is best seen in Fig. 1 where the calculated isotropic and dichroic EXAFS signals using the `feff8` code [11] have been represented for three different chromium environments described in the following and labeled cluster 1, cluster 2 and cluster 3. The three clusters contain 7 atoms (1 chromium atom and 6 oxygen atoms). The geometry in cluster 1 is given by *ab initio* density functional calculations [12]. It is built with three oxygen neighbors at 1.95 Å making an angle of 62.8 degrees with the C_3 axis and a further three at 2.00 Å with an angle of 48.4 degrees. In cluster 2, the chromium-oxygen bond angles are the same as for the preceding cluster and the bond distances for the six oxygen are set to the averaged value 1.975 Å. In cluster 3, the chromium atom is at the center of a pure oxygen octahedron (1.975 Å for the Cr-O bond lengths) and the dichroic EXAFS signal is zero (at least in the electric dipole approximation). One sees that dichroic EXAFS signals are much more sensitive to differences between chromium-oxygen bonds in the coordination shell than the isotropic signals. This proves that inequivalences

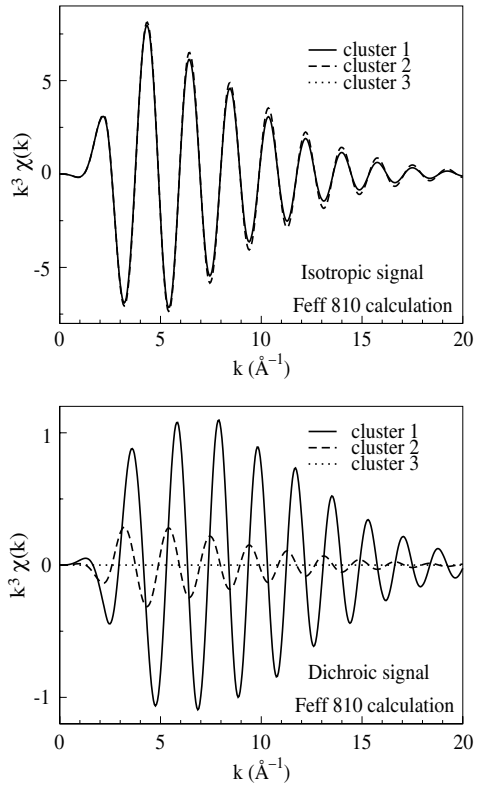

Fig. 1. Calculated isotropic (top) and dichroic (bottom) EXAFS signal of CrO_6 clusters. These clusters are made of 7 atoms (1 chromium atom and 6 oxygen atoms). Cluster 1 is given by density functional calculations (three oxygen atoms at 1.95 Å making an angle of 62.85 degrees with the C_3 axis and three other at 2.00 Å with the angle 48.36 degrees). In cluster 2, the Cr-O bond angles are the same as in cluster 1 and the bond distances for the six oxygen atoms are set to the averaged value 1.975 Å. Cluster 3 is a perfect octahedral cluster (1.975 Å for the Cr-O bond lengths).

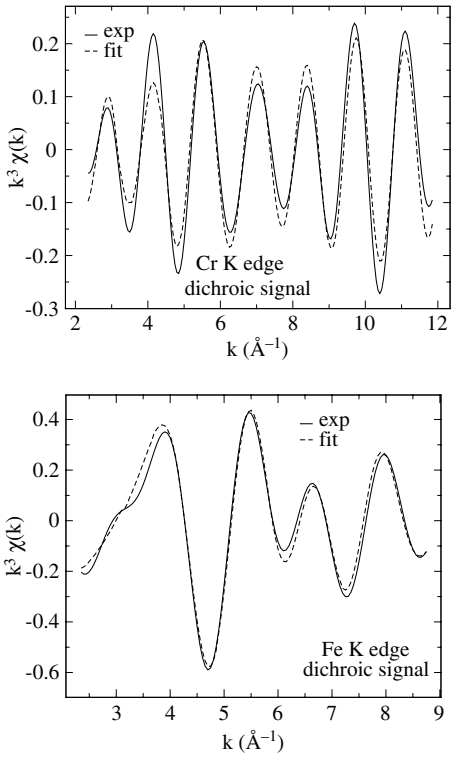

Fig. 2. Dichroic Fourier back-transformed experimental data $k^3\chi(k)$ (full line) and fit (dashed line) for Cr in α-$Al_2O_3:Cr^{3+}$ (top) and for Fe in α-Al_2O_3:Fe-Ti (bottom).

between oxygen atoms can reliably been addressed only through the EXAFS analysis of the dichroic signal.

3. Experimental details and results

Two types of single crystals synthesized by the Verneuil process are studied. They are a ruby ($Al_2O_3:Cr^{3+}$) containing 10000 ($\pm$500) wt ppm of chromium and a sapphire (Al_2O_3:Fe,Ti) containing 1500 ($\pm$50) wt ppm of iron and 750 ($\pm$30) wt ppm of titanium. The crystals are cut so that the C_3 axis is parallel to the surface. The chromium K-edge in α-Al_2O_3 and the iron K-edge in α-Al_2O_3:Fe-Ti have been measured on the ID12A beam line (European Synchrotron Radiation Facility, France) dedicated to polarization dependent spectroscopies [13]. In doing XAFS measurements of impurities in single crystals, one is faced with the problem of very intense diffraction peaks. These arise from either diffracted rays striking a fluorescence detector or from the occurrence of diffraction inside the crystal [8]. These diffraction rays may drag on and have devastating effects on the whole absorption spectrum, preventing any unambiguous EXAFS analysis [8]. A special technique called the rotating sample technique, proposed by J. Goulon, is applied to register the absorption spectra. This method, well described in [14] and [12], is used together with the filtering algorithm of [15] to obtain simultaneously both the isotropic absorption coefficient and the dichroic signal.

A standard procedure [16] is used to obtain the dichroic EXAFS signal $\chi_{dic}(k)$. Then, $\chi_{dic}(k)$ is analysed as a Fourier series of plane wavelets. The summation is over j shells and the signal for each shell is related to the back-scattering function $F_j(k)$, the total phase function $\Phi_{ij}(k)$, the electron mean free path $\lambda_j(k)$, the number N'_j, the bond distances r_j and the Debye-Waller factor σ_j:

$$\chi_{dic}(k) = -\frac{1}{k}\sum_j \frac{N'_j}{r_j^2} F_j(k) e^{-2\sigma_j^2 k^2} e^{-\frac{2r_j}{\lambda_j(k)}} \sin(2kr_j + \Phi_{ij}(k)) \quad (1)$$

where

$$N'_j = 3N_j\left[\frac{1}{N_j}\sum_i (\hat{\epsilon}_\parallel \cdot \hat{r}_j^i)^2 - \frac{1}{N_j}\sum_i (\hat{\epsilon}_\perp \cdot \hat{r}_j^i)^2\right] \quad (2)$$

with i runs over the jth shell.

Equation (1) is similar to the one of an isotropic signal except that the number N'_j is no longer a positive integer representing a number of atoms. In C_3 symmetry, the shell of neighbors are clustered in groups of three atoms, for which the angle θ_j between the bond $\hat{r}_j$ and the C_3 axis is constant. For such a shell, $N'_j = \frac{3}{2}(3\cos^2\theta_j - 1)$.

The dichroic Fourier back-transformed data $k^3\chi_{dic}(k)$ for Cr in α-$Al_2O_3:Cr^{3+}$ and for Fe in α-Al_2O_3:Fe-Ti are shown in Fig. 2. These experimental signals are fitted and results are displayed on Fig. 3.

4. Discussion and conclusion

Our ultimate purpose is the determination of the precise environment of a paramagnetic impurity present in a crystal of corundum. We found that the Cr-O distances in α-Al_2O_3 are 1.92 Å and 2.01 Å. The mean Cr-O distance (1.97 Å) is then in good agreement with the EXAFS measurements of Kizler *et al.* [17] (1.96 Å), and with optical measurements of Langer [18] (1.96 Å). For iron in α-Al_2O_3, we found that the two metal oxygen

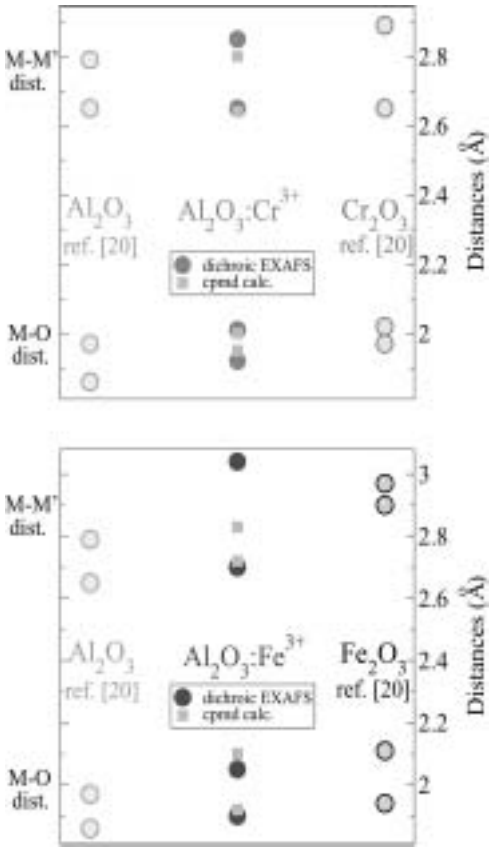

Fig. 3. Local environment around Cr in α-$Al_2O_3:Cr^{3+}$ (top) and around Fe in α-Al_2O_3 : Fe-Ti (bottom) from dichroic EXAFS (full circles) and *ab initio* calculations (squares). The results are compared with the structures of the Al_2O_3, Cr_2O_3 and Fe_2O_3 oxides (empty circles).

distances are 1.90 Å and 2.05 Å. It is then possible to have a description of the asymmetry of the impurity site by evaluating the parameter $\tau = 200\frac{d_{M-O_2}-d_{M-O_1}}{d_{M-O_2}+d_{M-O_1}}$ where d_{M-O_2} (resp. d_{M-O_1}) is the larger (resp. shorter) metal-oxygen distance in doped α-Al_2O_3. Despite similar Cr-O and Fe-O distances, the chromium and the iron site in doped α-Al_2O_3 are quite different ($\tau(Cr^{3+})$ = 4.58 and $\tau(Fe^{3+})$ = 7.59). In addition to the determination of the first neighbors distances, the analysis of the dichroic signal leads to the determination of the rather large second neighbors distances with a good reliability for α-$Al_2O_3:Cr^{3+}$. Indeed, the distribution of aluminum atoms in α-Al_2O_3 is strongly anisotropic and so yield a large contribution to the dichroic EXAFS signal. We found 2.65 Å and 2.85 Å for Cr-Al distances in α-$Al_2O_3:Cr^{3+}$. In the case of α-$Al_2O_3:Fe^{3+}$, the weak concentration of iron leads to a signal more difficult to analyze. We found 2.70 Å and 3.04 Å for Fe-Al distances in α-$Al_2O_3:Fe^{3+}$.

These bond lengths are in good agreement with results from *ab initio* energy minimization. Concerning metal-oxygen distances, they are 1.95 Å and 2.00 Å (Cr-O) and 1.92 Å and 2.10 Å (Fe-O). Concerning metal-aluminum distances, the are 2.64 Å and 2.80 Å (Cr-Al) and 2.72 Å and 2.83 Å (Fe-Al). The calculation permits us to have further structural information, in particular to know if the impurity ion is displaced, in respect to the position of the aluminum atom in α-Al_2O_3. Again, the result is different for the chromium or the iron impurity. The chromium atom is almost at the aluminum site, the oxygen atoms of its coordination shell move to accommodate for the larger ionic radius. Iron is repelled by the nearest aluminum neighbor along the C_3 axis. Its oxygen coordination shell is strongly relaxed, and further neighbors remain almost non displaced. That is in line with some previous EPR measurements where Fe is said to be moved by 0.04 Å ± 0.02 Å on the C_3 axis farther from the nearest aluminum neighbors [19].

It is possible now to picture the environment around the paramagnetic impurity in α-Al_2O_3. The local environment around the chromium ion in ruby is nearly the same as that in α-Cr_2O_3 [20]. The Cr-O bond lengths in ruby are closer to Cr-O bond lengths in α-Cr_2O_3 rather than to Al-O bond length in α-Al_2O_3 (see Fig. 3). However, Cr-Al (edge) distances are closer to Al-Al bond lengths in α-Al_2O_3 than to Cr-Cr bond lengths in α-Cr_2O_3. The case of iron in corundum is not exactly the same as that of chromium. The Fe-O bond lengths in blue sapphire are closer to the Fe-O bond lengths in α-Fe_2O_3 rather than to Al-O bond lengths in α-Al_2O_3. In both cases, the relaxation is local and does not affect atoms far from the chromium ion, within an error of about 1%.

Abstract

A facility at PNC-CAT in the Advanced Photon Source measures with sub-nanosecond time resolution both XAFS and diffraction on femtosecond laser-excited samples. XAFS measures with relatively high efficiency the time for the laser excitation to couple to the lattice, the sample temperature after reaching thermal equilibrium, any ablation of the sample with time, and, in many cases can distinguish between the amorphous and crystalline states. Preliminary measurements on 200 nm thick polycrystal Ge films indicate that the time for transferring the laser excitation to thermal heating of the lattice is less than 2 nanoseconds when the initial temperature is 560 K.

1. Introduction

Understanding the kinetics of how excitations of a sample by 200 femtosecond (fs) laser pulses regain a new thermal equilibrium state is a fundamental materials science question that is only in its infancy. The melting of Ge by this means is particularly interesting because of its complex behavior. For example, the density of the liquid is greater (by 4.7%) and has a larger number of nearest neighbors (6 vs. 4). Previous investigations have probed the melting kinetics with Bragg diffraction, which is insensitive to changes after long-range order disappears. X-ray Absorption Fine Structure (XAFS) spectroscopy, however, does not require long-range order, and can therefore monitor local structural changes from the solid to the disordered liquid phase.

We have developed time-resolved XAFS capability on the subnanosecond time-scale that can extend over microsecond time periods for investigating the excitation kinetics of samples using a Ti-sapphire laser producing 4 μJ pulses of 250 femtosecond duration and 800 nm wavelength. The apparatus performs pump-probe experiments with a laser pump and an X-ray probe. The laser fires pulses at the APS P0 clock rate (∼272 kHz), collecting data from a given X-ray pulse each time around the ring, which is about two orders of magnitude faster than other laser systems used in similar time-resolution XAFS experiments. This allows the collection of data at a rate similar to that of typical non-time-resolved experiments. Diffraction measurements can also be made concurrently with the same time resolution, though we present only XAFS measurements in this paper.

The PNC-CAT insertion device (ID) beamline at sector 20 of the Advanced Photon Source (APS) employing Undulator A [1] was used in this experiment. The X-ray source in the 1 + 22 bunch mode used for the measurements has 23 bunches spaced by an interval of 1/24th of the ring circumference, which is 3.683 microseconds/24 = 153.4 ns. There is a larger interval of 307 ns between the 23rd bunch and the first bunch that follows for the next cycle around the ring. The width of the X-ray pulse is the same width of the electron bunch. All bunches have the same time width of about 50 ps because they have the same charge with a current of about 4.5 mA. The pulse used was one with neighbors 153.4 ns on either side. In the top-off mode used in this experiment the pulse with the lowest charge is injected every two minutes with electrons to bring it back to its maximum charge. In this manner the average ring current is maintained essentially constant but a given pulse is increased about 10% every 46 minutes. A schematic of the timing electronics associated with the laser and X-ray beams is shown in Fig. 1.

2. Experiment

The requirements of the Ge sample we measured are: (a) the X-rays should just probe that portion of the Ge that is excited by the laser, and (b) the excitations should remain in the probed

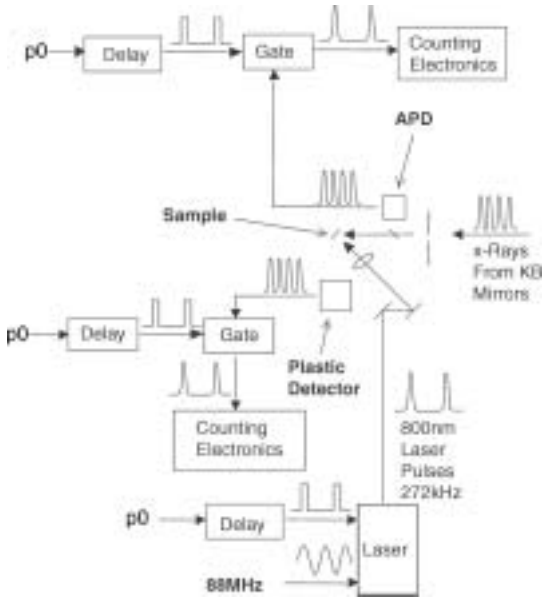

Fig. 1. Schematic of the timing electronics associated with the laser and X-ray beams. The P0 pulse is synchronized to the period of the APS ring period and is used to synchronize the laser pulse to a given X-ray pulse with a variable delay between the two. For a fixed time delay a standard XAFS scan is performed and this is repeated with steps in the time delay. The avalanche photodiode (APD) detects the I_0 of the X-ray pulse and the plastic detector detects the fluorescence signal from the sample induced by that same X-ray pulse.

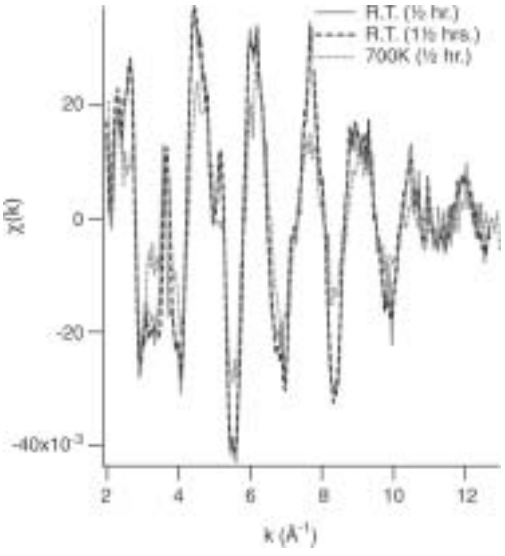

Fig. 2. EXAFS spectra measured from the $\Delta\mu x = 0.02$ thick Ge film after the indicated integration times for two different sample temperatures.

Fig. 3. A 2D scan of $\Delta\mu x$ of the sample with the focused X-ray beam. The dark area is about 50 μm in horizontal width and has about half the thickness of the surrounding region due to an accumulated ablation of the sample at a higher laser intensity than used in the measurements reported here.

region. These requirements were satisfied by a thin 200 nm thick Ge film (equal to the laser absorption length) evaporated on a (100) Si wafer covered on one face by a thermally grown 200 nm SiO_x film. During the evaporation the wafer was kept at 200 °C. After cooling to room temperature the wafer was treated with an anisotropic etch on the unoxidized face opposite from the one with the thin Ge film. The wafer was etched through to the oxide film forming a square pyramidal hole in the Si with the large opening in the unoxidized face and a small one 80 μm square in contact with the oxide film. The SiO_x film with its Ge film sample was thus freed from the Si backing in this 80 μm square, isolated from the Si wafer, and freely supported.

Figure 2 shows the EXAFS spectra obtained from a 10 μm focus X-ray beam on the 200 nm thick ($\Delta\mu x = 0.02$) polycrystal Ge film at room temperature (RT) and one heated to 700 K by the partially unfocused laser in a He environment to prevent oxidation. The temperature of the film was measured by determining the vibration amplitude of the Ge-Ge bond by EXAFS. The increased vibrations cause the amplitude of the EXAFS oscillations to decrease with increasing wavenumber k as seen for the 700 K plot. The high quality of the data is illustrated by comparing the average of 3 RT scans with one of them. The fully focused laser beam of 50 μm diameter gives an unattenuated energy per pulse of 200 mJ/cm^2 and produces a periodic time dependence in the temperature of the sample with the 3.68 μs period of the APS ring. At this power density the sample is ablated and to prevent this the power density was attenuated to 10 mJ/cm^2. Increasing the laser pulse energy density to more than 20 mJ/cm^2 caused ablation of the sample. The thickness of the Ge sample was chosen so that the laser would fully penetrate and excite it. Since the penetration depth of the X-rays is about 50 times that of the laser light the thin film assures that the X-rays sample a uniformly excited sample.

By measuring the XAFS signal one can determine, in addition to the Ge-Ge bond vibration amplitude, other features of the sample directly. Its thickness can be determined by the edge step in absorption or fluorescence signal allowing the determination of any ablation of the sample as shown in Fig. 3. Since the laser initially excites only the electrons in the sample, the time dependence of the transfer of this excitation to the lattice can be directly monitored by XAFS. Finally, the near-edge portion of the XAFS (the XANES) contains electronic information about the material and, for example, is sensitive to the shielding between the core hole and photoelectron that can be modified by the laser pulse in a semiconductor since the excited carrier density can be initially that of a metal. In addition, the excitation of the electron-hole carriers introduces a change in the absorption distribution at the edge which may be visible during the lifetime of the excited carriers. Moreover, the shape of the XANES can distinguish between the crystalline and amorphous state because its high-energy side has a shoulder in the crystal not present in the amorphous state (Fig. 4). XAFS can monitor the time dependence of these phenomena in the crystalline, amorphous and liquid state. Good XAFS spectra at a given delay time between the laser pump and the X-ray probe were accumulated in about 15–30 minutes. Careful tests were made that verified that both the 50 μm laser pump and 10 μm X-ray probe were overlapping and centered on the same point of the sample.

Figure 5 shows the magnitude of the Fourier transforms of the XAFS signal as a function of nominal time delay (t) between the

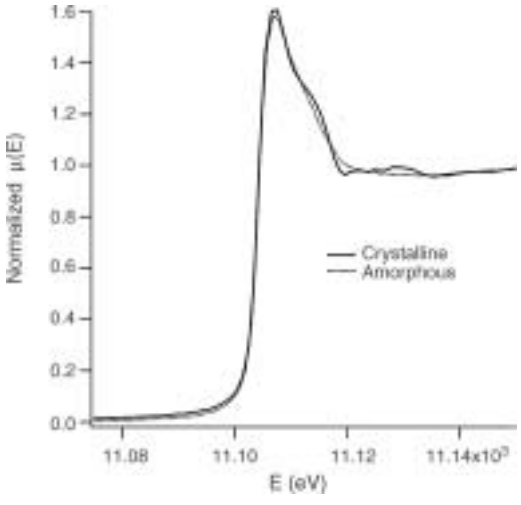

Fig. 4. The XANES of the Ge sample showing the difference between the initial amorphous state and the laser annealed polycrystal state employed in the measurements reported here.

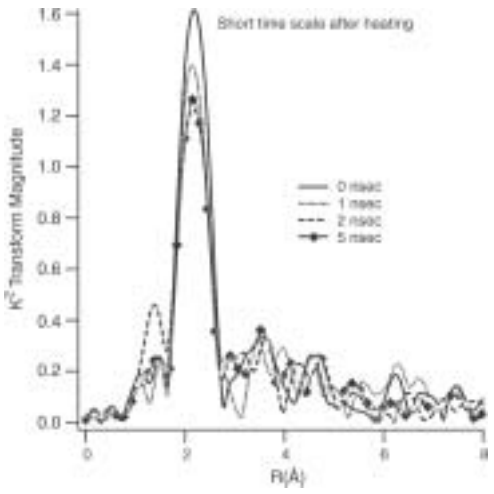

Fig. 5. The fourier transform magnitude of the EXAFS of the sample as a function of the nominal delay time between the laser and the X-ray pulses. The zero has not been carefully calibrated and could be off by 1 ns but the time differences are precise to 0.2 ns. The decrease of the magnitude indicates that the sample lattice has been heated to a new equilibrium temperature from 560 K to 740 K by the 200 fs laser pulse in less than 2 ns.

laser and X-ray pulses. The time delay differences are precise to 0.2 ns but the zero calibration may be off as much as about 1 ns. Note that the sample is hot enough at all times so that the thermal disorder is large enough so as to obscure all shells beyond the first shell. The temperature at nominal zero is 560 K. The magnitude of the first shell is the same as that found for times several ns before $t = 0$, indicating that the nominal zero in time is probably somewhat earlier than the true one. However, there is a definite heating at $t = 1$ ns and further heating at $t = 2$ ns as shown by the decreases in the height of the first shell. For the later time of 5 ns no further significant heating is apparent corresponding to a maximum temperature of 740 K. Measurements at longer delay times show that after the rapid heating the sample monotonically cools during the 3.6 µs between pulses to 560 K. Further measurements with a finer time difference are required to obtain a more accurate determination of the details of the rapid increase of the vibrations of the Ge-Ge bond induced by the laser excitation, but our present data indicates that it occurs in less than 2 ns.

3. Discussion

Since the direct gap is 1.1 eV in Ge, the 1.5 eV photons from a laser pulse initially couple most strongly to the valence electrons exciting them into the conduction band producing about 0.04 electron-hole pairs per Ge atom in the region irradiated by the laser. This electron-hole (e-p) cloud is confined between the SiO_x and He interfaces by the larger band gap of the oxide and the larger work function at the Ge/He interface and does not escape from the irradiated region with its much smaller thickness than laser beam diameter. The question to be answered is how and how fast the excitation equilibrates. Other measurement techniques have been employed to this question but ours is the first to apply XAFS. XAFS by measuring the Ge-Ge bond vibration amplitude can directly determine when the lattice has reached its thermal equilibrium, in contrast to the many other techniques applied to the problem.

We will discuss here only the one other technique that directly measured an aspect of the Ge-Ge bond, namely, the Raman effect [2]. Single crystals of Ge were employed as samples. Pump and variably delayed probe pulses were derived from a synchronously pumped R590 dye laser. The pulse duration was 4 ps, and both beams were focused to 50 µm diameter on the sample surface. The anti-stokes lines for the LO and TO phonon were monitored and the excitation of these modes decayed in the same time of 8 ps at RT. In this case neither the e-p cloud nor the phonons were confined in the irradiated region, but were free to propagate into the interior of the sample. An estimate of the time for excited phonons to escape from the probed region of 200 nm, using an average phonon speed for Ge of 5000 m/s, is 40 ps, not too different from the measured decay time. In addition, a simple calculation shows that the e-p cloud will escape from the probed region in times less than the resolution of the experiment. Assuming a conservative estimate of the average excitation energy of the electrons and holes above the gap of 0.1 eV the velocity of such particles is about 1.8×10^5 m/s and their escape time is about 1 ps, less than the laser pulse width. Thus the majority of the excited e-p pairs have escaped before the TO/LO excited phonons have decayed, further questioning whether the measured decay time of the phonons is significantly distorted by the escaping e-p pairs. By measuring changes in reflectivity on Ge films with pump-probe fast laser experiments [3] it has been determined that the e-p cloud has lifetimes of about 70 ps when it is confined within the probed region, so only a small fraction of the e-p pairs interacted with the probed sample in the Raman experiment. Moreover, the Raman measurement only addresses the lifetime of the TO/LO modes and does not assure that after their de-excitation the lattice is fully equilibrated. Thus, the measurement does not respond to most of the e-p pairs and does not track how the e-p pairs transfer their full energy to the TO/LO modes nor to the lattice. Our XAFS experiment, with the better than 0.1 ns time resolution we hope to attain, has the potential to determine the time for the e-p cloud to fully reach thermal equlibrium in the Ge sample.

4. Summary and Conclusion

XAFS can monitor many of the parameters of thin films. These are its temperature, its thickness, its local structure, and in many cases its structural phase. With self-supported thin films, sub-nanosecond time resolution, and femtosecond laser pulses at the period of the APS ring the kinetics of the transfer of the initial excitation to a thermal equilibrium condition can be followed by 30 minute XAFS scans on the PNC-CAT facility. Preliminary measurements with such a facility at PNC-CAT indicate that thermal equilibrium occurs for a 200 nm Ge film in a time scale less than 2 ns after excitation when the sample is initially at 560 K.

Abstract

We report preliminary observations of tissue images and micro-XAFS using X-ray microscopy techniques. Tissue specimens from hemocromatosis liver and knockout mice kidney were the subjects of the investigation. The X-ray microprobe experiments were conducted with a micro beam from an undulator beamline equipped with a set of K-B mirrors. Micro-beam XAFS studies at selected pixels of interest from the metal images were conducted. These techniques, together with optical and IR imaging provide a powerful tool for tissue analysis using synchrotron radiation. Preliminary Fe and Cu K-edge XAFS results from these experiments are reported and discussed.

1. Introduction

The X-ray micro beam technology at the insertion device beamlines of third generation light sources has evolved to become a powerful tool for microanalysis. The use of zone plate and KB mirrors optics can now provide routinely X-ray beams with sub-micron and micron spatial resolution, respectively, allowing for the collection of element images, which in turn can be used to facilitate micro-XANES and micro-XAFS analysis of hot spots or spots of interest, pixel by pixel. In this paper, we report preliminary results of a study of human hemochromatosis liver and mice kidney tissues at the Fe and Cu K-edge, respectively. We find that it is entirely feasible to use an X-ray micro-beam for the analysis of tissues.

Hemochromatosis is a disease in which the body absorbs excessive iron from the diet. Excess iron in the liver eventually leads to cirrhosis of the liver and hepatocellular carcinoma. It is the most common genetic disease in Canada (1 in 327 documented in a large population screening in London, Ontario, Canada) [1, 2]. Hemochromatosis is an autosomal recessive condition in which a defective gene has been inherited from each parent. Over 90% of patients have a mutated HFE gene. The exact role of the HFE protein in the pathogenesis of hemochromatosis is not completely understood [3]. It is useful to have chemical information about the distribution and chemical identity of Fe in liver tissues. We will present preliminary Fe K-edge micro-XAFS results of normal and hemochromatosis tissues.

In another tissue analysis, we are interested in testing a hypothesis in which it is thought that diabetes induced renal damage is mediated by the alternation of metallothionein (MT) and transition metal, especially Cu, in the kidney. The strategy is to investigate kidney tissues of transgenic mice with MT over-expression, MT knockout (KO) and wild type (WT) mice. Some Cu K-edge results for the knockout and the wild type (normal) mice tissues will be presented.

2. Experimental

Human biopsy liver tissues are obtained from Dr. Adam's clinic. Three specimens were examined in this study, a hemochromotosis liver tissue showing cirrhosis (henceforth labeled A4), a hemochromatosis liver cancer tissue (henceforth labeled A7) and a normal liver tissue (henceforth labeled B6). These tissues were prepared as thin slices of 10 microns on a substrate by standard procedures and were protected with a thin layer (∼5 micron) of paraffin. Both silicon wafer and high purity fused silica glass slides have been used as substrates, which show no detectable Fe and Cu impurities. The optical images (not shown) of the normal liver tissue (B6), the cirrhosis tissue (A4) and the cancer tissue (A7) show that the normal tissue is very uniform while the hemochromatosis cirrhosis tissue exhibits clusters of heavy iron accumulation. However, in the cancer tissue, the iron accumulation becomes less apparent. In another study, mice kidney tissues were from a KO and a WT mouse. There was no apparent difference in the morphology between the two tissues in their optical image.

The experiments were conducted at the microprobe station of the Pacific Northwest Consortium – Collaborative Access Team (PNC - CAT) ID line at the Advanced Photon Source (APS), Argonne National Laboratory [4]. APS operates at 7 GeV with an injection current of 100 mA (often in a top-off mode). The photon beam from the undulator was monchromatized with a cryogenically cooled Si (111) double crystal monochromator and

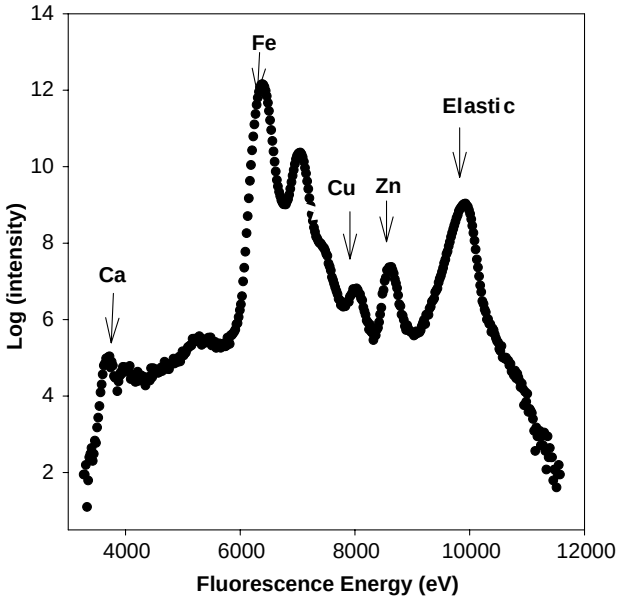

Fig. 1. Cu K-edge micro XAFS at a hot spot of the KO mouse kidney tissue compared with Zn K-edge XAFS of Zn metallothionein.

*e-mail: tsham@uwo.ca

focused with a set of KB mirror at the specimen with a spot of ∼5 micron (horizontal) × 7 micron (vertical). Specimens were placed at the sample holder at ∼45° with respect to the beam and to a liquid nitrogen-cooled, 13-element Ge solid-state detector. The sample holder can be scanned in x and y direction in micron steps with sub-micron precision.

The beam size was optimized and calibrated with a thin Pt wire prior to the mounting of the specimen by adjusting the horizontal and vertical KB mirrors. The specimen was then placed on the holder and at the focal point of a high-resolution video camera so that the position of the X-ray beam can be tracked optically. The monochromator was tuned to energies above the Fe K-edge in the liver study and the Fe K α fluorescence X-rays were monitored with the 13-element detector. Fig. 1 shows the fluorescence spectra of the A4 sample at an excitation-energy of 9.8 keV. It is apparent form Fig. 1 that there is a significant amount of Fe while Ca, Cu and Zn are also noticeable.

Element maps of metals of interest were then obtained by setting an energy window to collect fluorescence photons characteristic of Fe, Ca, Cu and Zn while scanning a region of the specimen (typically several hundreds of microns) pixel by pixel. Micro XAFS was then obtained at selected spots of interest from the element map.

3. Results and Discussion

A comparison of the Fe K-edge XAFS for the two hot spots in two different areas of the A4 specimen is shown in Fig. 2. The two XAFS in Fig. 2 exhibit a slightly different pattern as can be seen in the near edge region (inset). A Fourier transform of the EXAFS of the two hot spots are shown in Fig. 3, which shows a slightly different Fe-ligand bond length (by 0.1 Å) in the first shell. It must be noted that although this analysis is semi-quantitative at best with data collected from a limited number of scans, it does show that the local environment of Fe at these two hot spots is different. This result suggests that the technique is chemically sensitive and feasible for hemochromatosis Fe analysis. Similar maps and XAFS have also been obtained for the B6 and the A7 liver specimens. A comparison of the Fe K-edge XAFS (normalized) from two or more selected spots from each specimen indicates

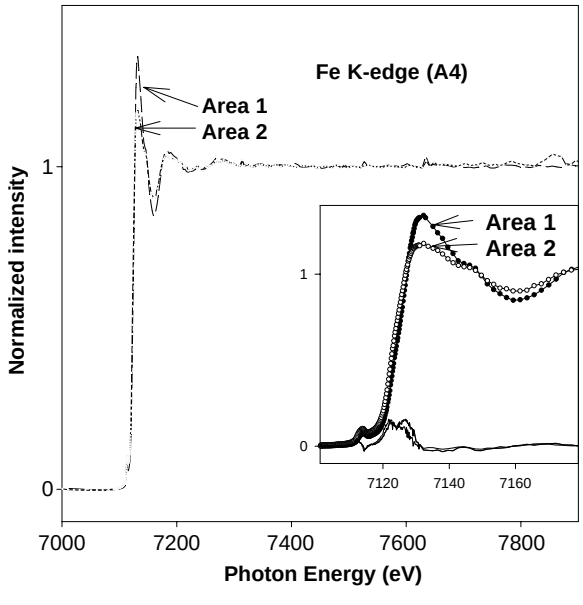

Fig. 2. Comparison of the XANES region of Fig. 6 with that of ferritin.

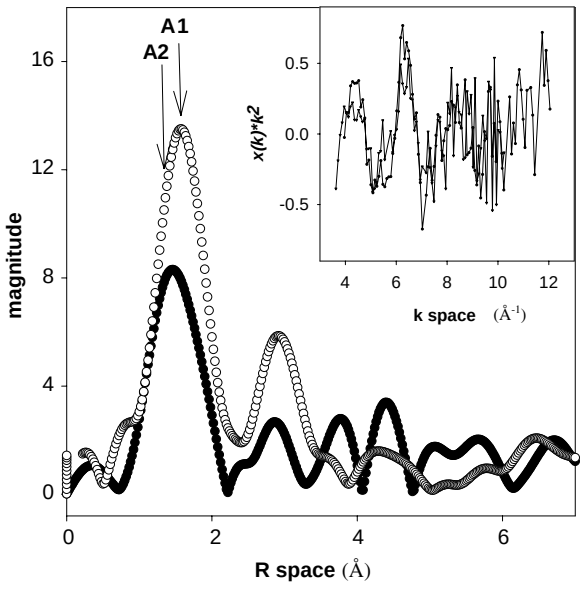

Fig. 3. Comparison of the Fe XAFS of a A4 hot spot with two standards: human ferritin and trans-ferrin (in diluted solution).

that there are excessive amount of Fe in A4 (largest edge jump), the cirrhosis specimen, relative to the normal tissue and that Fe in the cancer tissue (A7) is reduced considerably (by a factor of 10 judging by the relative edge jump) relative to A4, consistent with the optical images.

Fig. 4 shows the micro XAFS of Fe in a spot of A4 together with two standards: Ferritin (human) and Holo-tranferrin (human). It appears that the Fe XAFS in the hemichromatosis liver resembles that of ferritin, not a surprising result. Close examination of the Fe K-edge XANES of various spots of the specimens reveals some differences, which are shown in Fig. 5. The intensity of the 1s to p transition at the edge appears to decrease in the A4 specimen, which contains excessive Fe in the hot spots.

Finally, we also want to report a preliminary observation of Cu in the kidney specimens of the knockout and the wild type mice. There is a hypothesis that in the KO mice, the Cu is expected to be metallothionein and its concentration is expected to be smaller than that in the WT mice. Fig. 6 shows a typical Cu K-edge XAFS spectrum compared with that of a Zn metallothionein (Cu metallothionein is not very stable) [5]. It is expected that if Cu is in the metallothionein environment, its EXFAS may resemble that

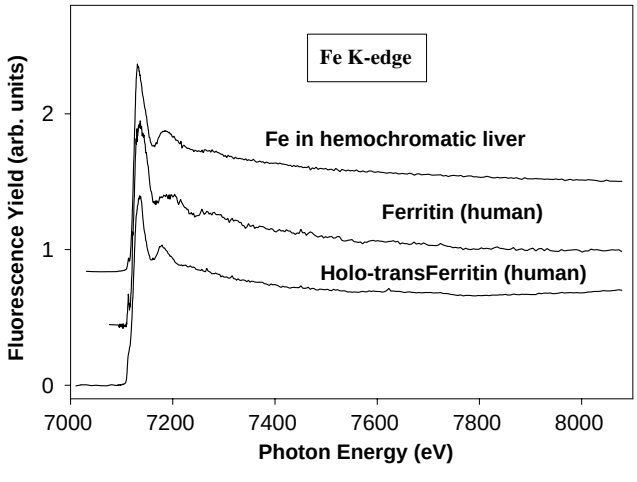

Fig. 4. Fourier transform of the EXAFS (inset) for the two hot spots shown in Fig. 2.

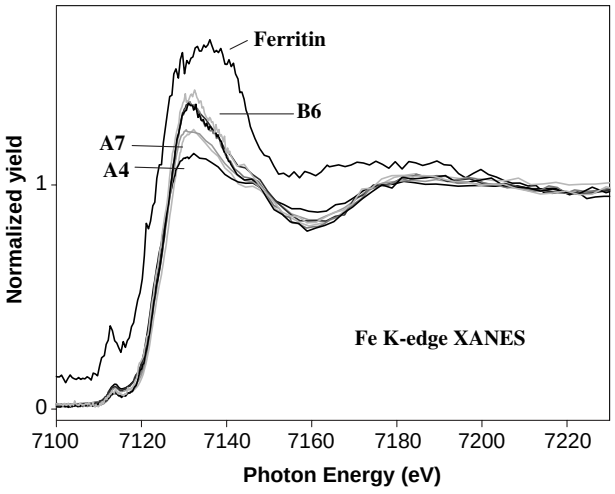

Fig. 5. Fe K-edge XAFS for the two hot spots. The XANES region and the corresponding first derivative are shown in the inset.

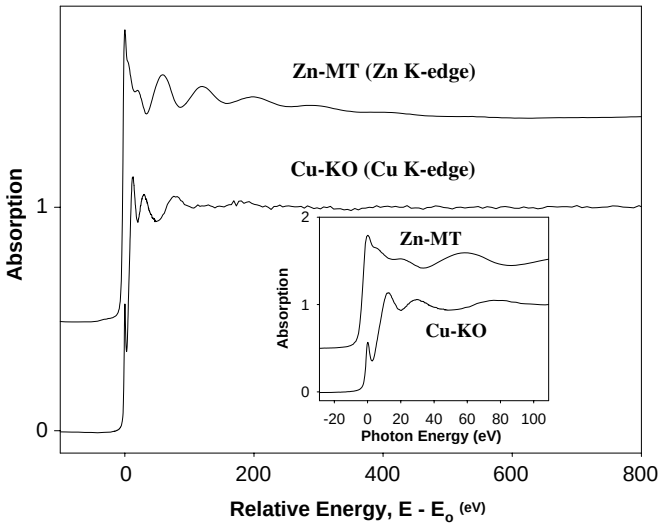

Fig. 6. X-ray fluorescence from metallic elements in the tissue excited with 9.8 keV photon.

of the Zn metallothionein. It is interesting then to find that Cu in these tissues exhibits XAFS very different from that of Zn metallothionein, suggesting a change in coordination. Further studies are needed. In addition, we also find that there is noticeably more Cu in the KO kidney than in the WT, while they both show the same XAFS, in contrast to the conventional wisdom.

4. Summary and Conclusion

We have reported some preliminary results of the microanalysis of metals in hemochromatosis liver and mice kidney tissues using a micro X-ray beam. The results clearly show that the microbeam technique can indeed be applied to yield useful information about the distribution and local environment of metal of interest in these tissues. This preliminary study allows us to embark on a systematic study of these tissues using X-ray microbeams.

Abstract

The light-modulation method was applied to XAFS spectroscopy as a useful tool for the electronic and structural studies of light-excited states. Visible light for electronic excitation was modulated by an optical chopper and concomitant change in the X-ray absorbance was extracted by a lock-in amplifier. It is essential to reduce noises arising from several sources, especially those generated by the X-ray monochromator. Light-induced changes were measured successfully by the present approach with high S/N ratios for the Fe and Co K-edge XANES and EXAFS spectra of spin transition compounds. It is also possible to construct the pure EXAFS $k^3\chi(k)$ for the light-induced state from the light-modulated EXAFS difference spectrum. Detailed experiments including the signal amplitude and phase shift information revealed that the two components with different rate constants can be discriminated by changing the modulation frequency. The light-modulated XAFS method is found to be applicable to the systems with the excited-state ratio less than several percents. It has the following advantages; (1) simple experimental set-up, which requires only a visible-light source, an optical chopper, a lock-in amplifier, and a conventional XAFS beamline, and (2) free from the ground-state components because the light-induced absorbance difference is directly detected.

1. Introduction

Structural and electronic changes upon photoexcitation have attracted much attention and various methods have been developed to study the subject. X-ray absorption fine structure (XAFS) spectroscopy is one of the most useful tools to obtain direct information on local structures and electronic properties, especially for the materials without long-range ordering. However, it is much behind other methods for the study of short-lived photoexcited states.

There are two serious inherent problems in application of XAFS spectroscopy to photoexcited states. One is a large difference between visible light and X-rays in their absorption coefficients, and another is that the X-ray absorption edge energy is almost the same for ground and photoexcited states. By these reasons, conventional XAFS measurements of short-lived photoexcited species under continuous light irradiation often give a spectrum that is hardly distinguishable from the ground state, and extraction of information of the photoexcited state is very difficult. Several techniques have been developed for the studies of photoexcited states [1–6], which allows a 14-ns time resolution at the fastest. They are indeed powerful, but very elaborate and time consuming even with highly developed techniques and facilities. Further, the contribution of the remaining ground state species cannot be avoided.

The photo-modulation method, or the phase-sensitive detection method, is one of the popular methods to detect small spectral changes [7]. It is widely used in UV and visible spectroscopies, in which light is modulated periodically, making the signal follow the modulation to be detected by a lock-in amplifier, and only the synchronising component being extracted. It enables to detect weak signals hidden in a strong background without any subtraction of spectra. The purpose of the present study is to apply the photo-modulation method to XAFS spectroscopy as one of the useful tools for the study of photo-induced metastable states. It was performed by modulating the visible excitation light and detecting the concomitant X-ray absorbance change. We call this method the 'light-modulation' method hereafter to distinguish the pumping visible light from the probing X-rays.

2. Experimental

Experimental set-up for the fluorescent X-ray yield mode is shown in Fig. 1. Transmission experiments can also be performed with a similar set-up. Visible light was modulated using an optical chopper and introduced onto a sample through a PET window of the cryostat, together with incident X-rays I_0. The fluorescent X-rays were detected by a Lytle detector [8], whose intensity would be modulated in accordance with the change in the X-ray absorbance caused by modulated-light irradiation. Fluorescent X-ray signals, I_f, were divided into two after pre-amplifying with a picoammeter, one as the normal I_f and another for extraction and amplification of the modulating component, using a lock-in amplifier. Finally, I_0, I_f, and the output signal of the lock-in amplifier, I_{mod}, were collected with a counter/timer.

Because of the large difference between the absorption coefficients of X-rays and visible light, the light-modulated XAFS signal intensity becomes very small. Thus, much effort was paid

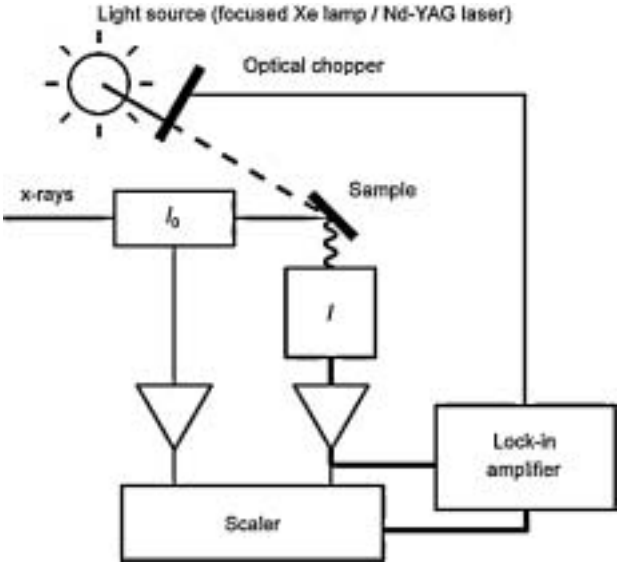

Fig. 1. Set-up for the light-modulated XAFS measurement.

*e-mail: ohta@chem.s.u-tokyo.ac.jp

to keep the noise level as low as possible. The Lytle detector was set in a soundproof box on a heavy base with vibration insulators made of silicone rubber and connected to the picoammeter with a low-noise cable to avoid vibration and electric noises, respectively. It was also essential to avoid signal fluctuations at each step of energy scanning caused by the monochromator. For this purpose, the signal counter was controlled by an external timer circuit to wait until the signal became stable. This elongated the measurement time, but improved the spectrum quality dramatically.

Light-induced spin transition compounds, $[Fe(pic)_3Cl_2]\cdot C_2H_5OH$ [9, 10], **1**, and $K_{0.4}Co_{1.3}[Fe(CN)_6]\cdot 4.2H_2O$ [11, 12], **2** were prepared according to the literatures. They both show spin transitions from low-spin (LS) to high-spin (HS) states at Fe and Co ions, respectively, which is induced by heat or light at low temperatures and accompanied by large changes of local geometric and electronic structures. Though the relaxation details have not been fully clarified yet, one of the Co-W analogue of **2** shows a first-order relaxation at X-ray-induced spin transition [13], while **1** shows a very complicated relaxation behaviour due to strong intermolecular interactions and the decay constant was estimated to be of seconds or subseconds at the applied temperatures [14, 15]. The samples were used as powders dispersed on Scotch tapes. Fe and Co K-edge XAFS experiments were carried out at Beamlines 9A [16] and 12C [17] in KEK-PF, using double-crystal Si(111) monochromators detuned by ~40%. The incident and transmitted X-rays were detected by ion chambers filled with N_2 and the fluorescent X-rays by a Lytle detector filled with Ar. Two types of the Lytle detectors, conventional and fast ones [8, 18], were used in the experiments. Data acquisition times were 2 s and 8 s for the conventional XANES and EXAFS measurement, respectively, and 20 s for the light-modulated spectra at the longest.

3. Results and discussion

Figure 2(a) shows the Fe K-edge XANES spectra of **1** at 30 K with and without white-light irradiation by a Xe lamp. Continuous light irradiation gave a similar spectrum (Fig. 2(a), solid line) to that of the pure HS phase at 300 K. It is reproduced as a linear combination of pure HS and LS spectra measured at 300 K and 30 K, respectively [9, 10], with the HS ratio of 0.88, assuming that the temperature dependence of XANES is negligible. Figure 2(b) shows the spectrum obtained by the light-modulation method. It is in good agreement with the difference spectra in Fig. 2(a), together with the EXAFS difference spectra in Fig. 3(a). Nd-laser irradiation at 532 nm gave an identical result. It was revealed that the light-modulated XAFS spectrum is detectable using our experimental set-up not only for the XANES but also for the EXAFS regions where only a small change is expected.

Figure 3(b) shows the EXAFS $k^3\chi(k)$ spectrum of the purely light-induced phase constructed from the difference spectrum in Fig. 3(a) using the HS/LS ratio obtained from the absorption difference at 7121 eV. It is roughly in good agreement up to $k \sim 6\,\text{Å}^{-1}$ with the HS spectrum at room temperature, indicating the structural similarity of the light-induced and high-temperature phases of **1**. Although the quantitative measurements should be achieved in the future, present result is very encouraging.

Figures 4(a) and (b) show the frequency dependence of the light-modulated XANES difference spectra $\Delta I_f/I_0$ at 30 K and 60 K, respectively. The signal intensity decreases monotonically upon faster modulation at 30 K, while at 60 K it is the strongest at

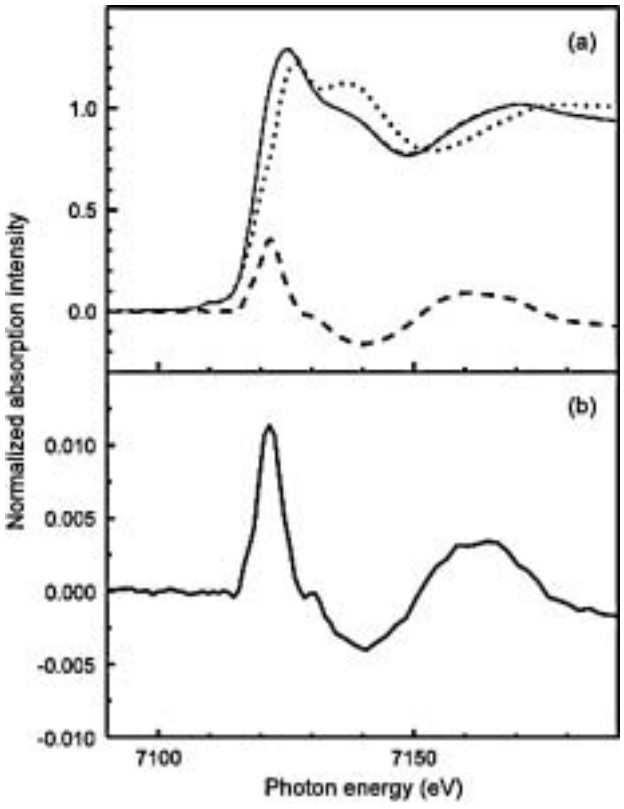

Fig. 2. Fe-K XANES spectra of **1** at 30 K (a) with and without Xe-lamp irradiation at 30 K (solid and dotted lines), and their difference (dashed line). (b) Fe-K XANES difference spectrum obtained by the light-modulated XAFS method with a modulation frequency of 10 Hz.

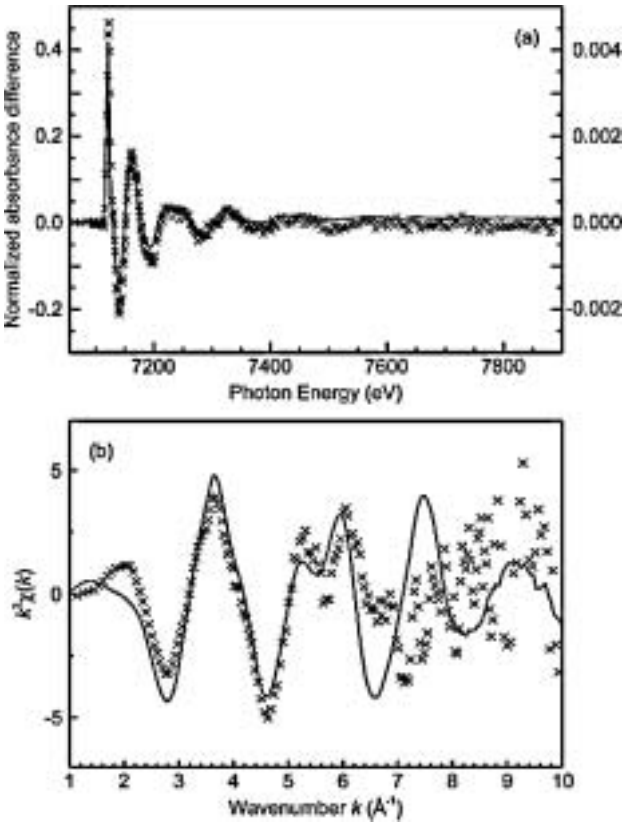

Fig. 3. (a) Fe-K EXAFS difference spectra of **1** at 30 K obtained by subtraction (solid line, left axis) and by the light-modulation method with a modulation frequency of 10 Hz (cross symbols, right axis). (b) Fe-K EXAFS $k^3\chi(k)$ of the room-temperature HS state (solid line) and EXAFS spectrum of the purely light-induced state at 30 K constructed from the light-modulated EXAFS spectrum in (a) (cross symbols).

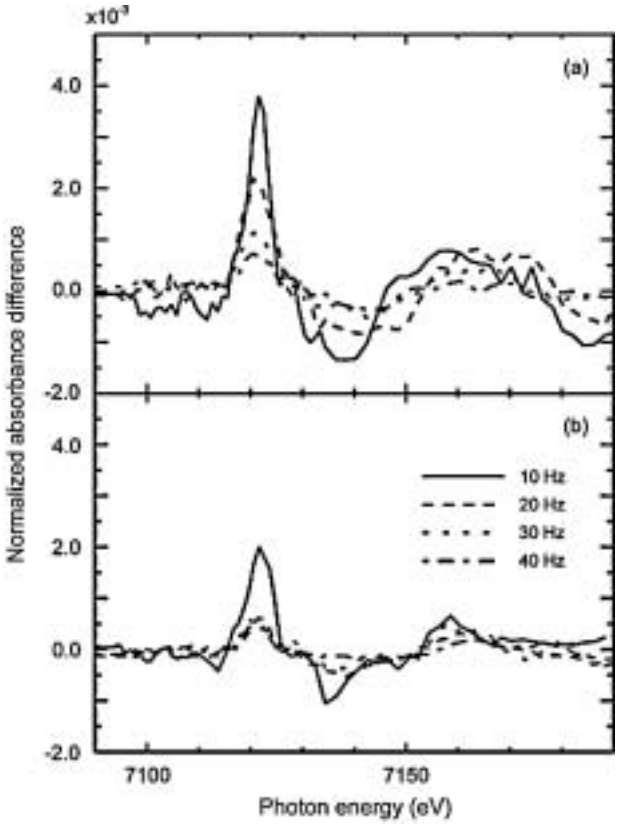

Fig. 4. Modulation-frequency dependence of Fe-K XANES spectra of **1** (a) at 30 K and (b) at 60 K. The fast-type Lytle detector was used with a phase shift of 180°.

10 Hz, becomes weaker at 20 Hz, and stays the same at higher modulation frequencies. The behaviour at 30 K is understood simply as a consequence of relatively slow relaxation to follow fast light modulation. On the other hand, thermally-induced transition is not negligible at 60 K, which results in a drastic decrease of the signal at 10 Hz. The temperature might also affect the photo-excited state and change the probability to transfer to the high spin state. This causes a different behaviour at higher frequencies from that at 30 K. It should be emphasized that the dependence of the modulation frequency enables us to discriminate the contributions with different time scales, light- and thermally-induced transitions in the present case. This is one of the advantages of the light-modulated XAFS method.

The detection limit of the light-modulation XAFS method would be the order of 10 ppm change of the edge jump, which corresponds the 10 μV change in a 1 V signal, as investigated using a prussian blue analogue, **2**. Spectrum subtraction gave an inaccurate result for such a small change, while the light-modulation method gave the same shape as that was expected from the temperature dependence of the XANES spectra of **2**. This demonstrates the superiority of the light-modulation method to the conventional subtraction method. The limiting factors are the high noise level in the experimental hall and the finite response rate of the ion-chamber detectors. However, we believe that the further development of the detectors would solve these problems, although noises coming from the X-ray beam itself cannot be avoided.

4. Conclusions

Present study demonstrates the applicability of the light-modulated XAFS spectroscopy as a method to study short-lived photoexcited states. Using two spin-transition compounds, changes caused by light-irradiation were detected successfully for both XANES and EXAFS, as a consequence of elimination of various noises. The modulation frequency change enables to study the relaxation process and to distinguish two components with different relaxation rates. The light-modulation XAFS method has the following advantages; (1) simple experimental set-up, which requires only a visible-light source, an optical chopper, a lock-in amplifier, and a conventional XAFS beamline, and (2) free from the ground-state components because the light-induced absorbance difference is directly detected. Although the current performance is enough for qualitative studies, more technical improvement is required for quantitative discussions such as the relaxation kinetics and detailed EXAFS analysis of light-induced structural changes.

Acknowledgements

The authors are grateful to Dr S. Emura (Osaka University) and Professor I. Watanabe (Osaka Women University) for fruitful discussions. Experimental support from Professor M. Nomura, Drs T. Obina and A. Koyama (KEK-PF), and Drs T. Uruga and H. Tanida (JASRI/SPring-8) are highly appreciated. The authors also thank Professors K. Hashimoto (The University of Tokyo) and O. Sato (KAST) for sample preparations, and Professor H. Okamoto (IMS) and Dr M. Suzuki (JASRI/SPring-8) for their help in instrumentation. The present work was performed under the approvals of the Photon Factory Program Advisory Committee (2000P019, 2001G319). One of the authors (K. O.) also appreciates the JSPS Research Fellowships for Young Scientists.

Abstract

X-ray reflection is a well-known method for structural studies of multilayers. By measuring the specular reflectivity, the thicknesses, electron densities and interface roughness can be determined. On the other hand, the off-specular or diffuse scattering carries information about the lateral morphology and roughness of the interface. In particular, correlations of the interface roughness give rise to Resonant Diffuse Scattering (RDS). In this paper, we will show that RDS can be combined with the anomalous effect in order to obtain interfacial chemical information. Additionally we describe an experimental procedure that allows us to record anomalous RDS spectra exhibiting fine structures analogous to those observed in the well-known DAFS spectroscopy. Diffraction from Ni/Mo multilayers grown by ion beam sputtering are used to illustrate the method.

1. Introduction

Nowadays, much interest is devoted to multilayer systems due to their unique physical properties that make them attractive for optical, mechanical or electronic (magnetic recording, semiconductor devices) applications. These properties depend strongly on the structure of the stacking and more specifically on the interface between constituents (roughness, intermixing, etc...). Among others, X-ray reflectivity is a useful method for characterizing multilayers because it is sensitive to the refractive index and thus to the electronic density variations across the interfaces. This sensitivity to electronic density is enhanced in off-specular or Diffuse Scattering (DS) reflectivity experiments. In particular, the existence of Bragg DS peaks (Resonant DS: RDS) is explained by conformal roughness [1], e.g. when interfaces are strongly correlated to each other. In this contribution we will show that it is feasible to combine RDS and the anomalous effect using an experimental procedure analogous to the now well-established DAFS (Diffraction Anomalous Fine Structure) spectroscopy [2]. Such a method allows us to extract interfacial structural information at the atomic scale.

2. Experimental

The present study is focussed on a $[Ni_{22}/Mo_{12}]_{40}$ multilayer deposited on a Si (001) substrate using a direct ion beam sputtering method (primary Ar beam energy: 300 eV) which has been previously described [3]. The bilayer period Λ is 7.14 nm and the total thickness is 285.7 nm. High angle X-ray diffraction and high resolution transmission electron microscopy both give evidence [4] of a strong crystalline texture within the constituent layers, with the fcc Ni (111) planes being parallel to the bcc Mo (110) ones. The experiments were carried out at the Laboratoire pour l'Utilisation du Rayonnement Electromagnétique (LURE) at Orsay on the DCI storage ring at the H10 beam line. Its optical characteristics are described in ref. [5]. The specular reflectivity scan recorded at 8.1 keV, shown in Fig. 1, confirms the overall good quality of the multilayer since at least 8 Bragg peaks are observable within the investigated angular range. Fig. 2 shows the rocking curve, or ω scan, around the fourth Bragg peak. In that case, a single specular peak is seen as well as Yoneda wings on each side of the diffuse scattering intensity. However, when the grazing angle slightly shifts from the Bragg condition, a peak is still observable on the $\omega - 2\theta$ scan (insert in Fig. 1, fixed offset angle $\omega - \theta = -0.66°$). Such a rather intense Bragg diffuse scattering (the intensity ratio at the Bragg peak is around 13%)

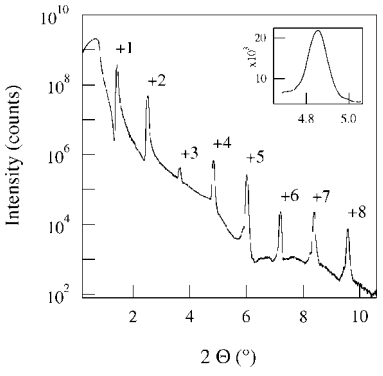

Fig. 1. Reflectivity profile for the $[Ni_{22}/Mo_{12}]_{40}$ multilayer sample recorded at 8.1 keV. Numbers indicate Bragg order. Insert: $\omega - 2\theta$ scan showing the RDS around the fourth Bragg order at the same photon energy (offset angle $\omega - \theta = -0.66°$).

‡ e-mail: Anny.S.Michel@univ-poitiers.fr

makes it possible to perform a DAFS-like experiment on RDS peaks. The presence of such RDS peaks attests the existence of a conformal roughness (lateral) within the multilayer since for small angles the variation of the q_z component of the scattering vector $\boldsymbol{q}$ is practically negligible so that an ω scan is equivalent to a q_x scan.

However one must take into account that the refractive index varies with the incident energy. Indeed, during a DAFS scan, one has to keep q and the angle $\psi = (\boldsymbol{q}, q_z)$ constant. It needs corrections for refraction that are given, according to the Snell-Descartes laws, by:

$$\cos(\omega) = \cos(\theta_c(\lambda))\cos(\omega_{int});$$
$$\cos(2\theta - \omega) = \cos(\theta_c(\lambda))\cos(2\theta_{int} - \omega_{int}) \quad (1)$$

where the index *int* is for angles internal to the sample, $\theta_c(\lambda)$ is the critical angle for total reflection determined from the specular reflectivity scan at the wavelength λ. These corrections have been included into the acquisition software procedures.

3. Data acquisition procedures

The raw RDS DAFS spectrum recorded at the Ni-K edge is shown in Fig. 3 where fine structures are clearly observed. However, the analysis needs to include the fluorescence effect, the contribution of which may become very important at low angles. The detector used to record these data is a Peltier cooled Si photodiode with an energy resolution which is rather poor (700 eV). Therefore each data point may include a fluorescent contribution that varies from point to point beyond the edge. The whole Multi Channel Analyzer (MCA) energy spectrum was recorded in the energy range 6–11 keV for each point of the incident energy and a fitting procedure was used to separate the different contributions to the spectrum. For each incident energy point, the MCA spectrum was fitted with Gaussian lines that account for the K_α and K_β fluorescent and elastic contributions (the ones of interest). During the fitting procedure the positions, intensities and widths of the K_α and elastic Gaussians are free to vary, while the position and intensity of the K_β line were fixed. Indeed the intensity ratio of the K_β and K_α lines can be calculated by taking into account the angle and energy dependant re-absorption of the fluorescence. A straightforward calculation gives:

$$\frac{I_\beta}{I_\alpha} = K\frac{\mu_E \sin(\varpi_e) + \mu_\alpha \sin(\varpi_i)}{\mu_E \sin(\varpi_e) + \mu_\beta \sin(\varpi_i)}\left[\frac{1 - e^{-\left(\frac{\mu_E}{\sin(\varpi_e)} + \frac{\mu_\beta}{\sin(\varpi_i)}\right)e_t}}{1 - e^{-\left(\frac{\mu_E}{\sin(\varpi_e)} + \frac{\mu_\alpha}{\sin(\varpi_i)}\right)e_t}}\right] \quad (2)$$

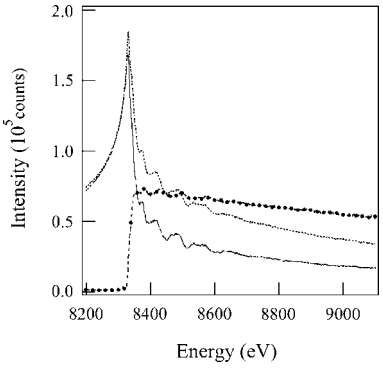

Fig. 3. Raw SCA DAFS (full line), pure elastic (dotted line) RDS DAFS and fluoresence (dashed line with diamonds) spectra at the Ni-K edge.

where $\varpi_i = \omega$ and $\varpi_e = 2\theta - \omega$ are the incident and exit angles, μ_E the absorption coefficient of the incident beam calculated according to the sample composition (μ_α is at E_{K_α}, μ_β at E_{K_β}), e_t its total thickness while K denotes the emission ratio K_β/K_α ($K = 0.1126$ for Ni). The pure elastic and fluorescence spectra retrieved using this fitting procedure are displayed in Fig. 3. This procedure works fairly well because the fluorescence is found to be nil below the Ni-K edge, while the elastic peak intensity is close to the intensity measured using a Single Channel Analyzer (SCA). It is obviously no longer the case beyond the edge since the SCA integrates a part of the fluorescence because of the too low energy resolution of the photodiode, whereas fitting the MCA gives good discrimination. Therefore the procedure proposed herein allows us to reconstruct a pure elastic DAFS spectrum which can be used to obtain the fine structure oscillations after making the necessary absorption correction.

4. Oscillatory component of the spectrum

The theory underlying RDS anomalous fine structure spectroscopy presented here is not yet established. However, the variation of q_z being very small for small angles, as a first approximation we can consider we are in specular reflectivity regime. In the kinematical limit, it has been shown [6] that the specular intensity scattered from Ni and Mo layers can be expressed as:

$$I(E) \propto |\rho_{Ni} f_{Ni}(E) - \rho_{Mo} f_{Mo}(E)|^2 \quad (3)$$

where ρ denotes the density and f the scattering factor for an atom. For the resonant Ni atoms, f_{Ni} can be split into a smooth and an oscillatory component:

$$f_{Ni}(E) = Z_{Ni} + f'_{Ni}(E) + i f''_{Ni}(E) + f''_{Ni}(E)\tilde{\chi}_{Ni}(E);$$
$$\tilde{\chi}_{Ni}(E) = \chi'_{Ni}(E) + i\chi''_{Ni}(E) \quad (4)$$

where Z is the atomic number, f' and f'' the real and imaginary parts of the bare atom anomalous corrections. $\chi(E)$ is the fine structure of interest of which the imaginary part is the EXAFS. Following Luo *et al.* [6], this oscillatory term can be expressed as:

$$\frac{I(E) - I_0(E)}{I_0(E)} = \frac{2\rho_{Ni} f''_{Ni}(E)\kappa_1}{\kappa_1^2 + \kappa_2^2}(\chi'_{Ni}(E) + \varepsilon\chi''_{Ni}(E)) \quad (5)$$

with $\kappa_1 = [\rho_{Ni}(Z_{Ni} + f'_{Ni}(E)) - \rho_{Mo}(Z_{Mo} + f'_{Mo}(E))$, $\kappa_2 = [(\rho_{Ni} f''_{Ni}(E)) + (\rho_{Mo} f''_{Mo}(E))]$ and $\varepsilon = \kappa_2/\kappa_1$. In Eq. (5), $I(E)$ is the measured intensity and $I_0(E)$ the smooth component of the intensity spectrum extracted from the experimental data using the method described in Ref. [7].

After normalization according to Eq. (5) and transformation in k-space, we obtain the oscillatory component $\chi(k) = (\chi'_{Ni}(k) + \varepsilon\chi''_{Ni}(k))$ of the RDS signal shown in Fig. 4. These results demonstrate that the oscillations above the edge are significant and representative of the absorption and scattering processes, even if this spectrum becomes noisy at high k values. It remains to isolate $\chi'_{Ni}(E)$ and $\chi''_{Ni}(E)$ that are related through Kramers-Kronig relations to obtain structural information using the EXAFS standard method for data analysis. Being out of the scope of the present contribution, these results will be presented in a forthcoming paper.

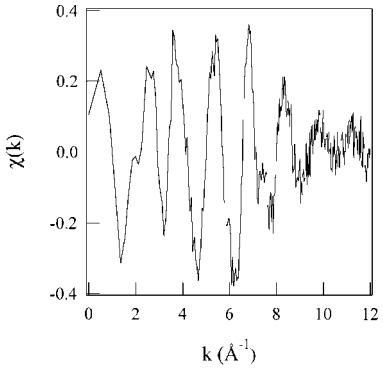

Fig. 4. Fine structure $\chi(k)$ of the elastic RDS DAFS spectrum of Fig. 3.

5. Conclusion

In this paper we have demonstrated that it is possible to perform DAFS-like experiments on Resonant Diffuse Scattering peaks. The feasibility of this new spectroscopy was illustrated with the example of a textured Ni/Mo multilayer sample. We have established a method for data acquisition that includes the reflectivity particularities of the off-specular diffraction. We also propose a method to remove the fluorescence using a fit of the whole detector spectrum at each point of the incident beam energy scan. It should be noted that such a method can be also used to obtain EXAFS spectra related to data recorded in the fluorescence mode.

Abstract

In this work liquid and solid cadmium has been investigated in a wide pressure and temperature range in order to provide new information about structure and transitions occurring in this metal. X-ray absorption, single-energy temperature scans and energy scanning X-ray diffraction data were collected in a 25–600 °C temperature and 0–5.8 GPa pressure range, exploiting the setup available at the ESRF-BM29 beam-line. Clear changes in the absorption spectra (measured at cadmium K-edge) and in the diffraction patterns, associated with the solid-liquid transition, allowed us to obtain an accurate measurement of the melting curve as a function of pressure. The structural data are compared with the few available calculations and X-ray scattering data on molten Cd at ambient pressure. High pressure data on liquid cadmium are reported for the first time and are essential to shed some light on the changes of the local structure induced by pressure.

1. Introduction

The divalent hexagonal closed packed (hcp) structured metal, cadmium, shows pressure dependences of several physical properties. Recently, it has been the subject of intense theoretical [1, 2, 3, 4] and experimental investigations [5, 6, 7, 8] mainly because it crystallizes in the hcp structure with an unusually large c/a axial ratio. This anomaly, common also to solid Zn, is usually related to the occurrence of an electronic topological transition (ETT) at high pressures and the existence of the ETT and its possible correlation with the observed anomalies is a debate still open. The structural change of this metal under pressure is itself of fundamental crystallographic interest. On the other hand, only a few measurements are available for what concerns the high-temperature behavior under pressure and even the melting curve. In the recent past, X-ray absorption spectroscopy (XAS) has been successfully used to investigate structural properties of liquid metals [9, 10] and in this context is able to give very accurate information. In particular the change in the shape of the XAS spectra at selected high-contrast energy points combined with energy scanning X-ray diffraction (ESXD), as a function of temperature at fixed pressure, is an excellent probe for locating phase transitions as shown by the recent extended use of single-energy X-ray absorption technique (SEXAD) [11]. This work presents experimental measurements of the melting curve, looking at the effect of pressure on the cadmium melting point. Moreover XAS data analysis results on solid and liquid cadmium are shown. First neighbor distance values and accurate reconstruction of pair distribution function of cadmium in its liquid phase as function of pressure are presented.

2. Experimental

The experiments on solid and liquid cadmium were performed at the BM29 beam-line at the European Synchrotron Radiation Facility (Grenoble). Using an especially developed set-up [12], measurements were performed combining ESXD and XAS techniques for several temperatures up to the cadmium melting point at selected pressures. In particular, high resolution ESXD patterns were recorded by using a multi-channel detector collimator [13]. The conditions of high pressure (0.1–5.8 GPa) and high temperature have been obtained using a large volume Paris-Edinburgh (PE) press, having a 10 mm boron/epoxy toroidal gasket. The high toxicity of Cd metal together with the extreme experimental conditions of the measurements posed severe constraints. In fact the sample was prepared starting from micrometric powders of high-purity cadmium which were mixed with appropriate quantities of boron nitride and manipulated in a glove box under Ar atmosphere. Diffraction patterns of fine silicon powder mixed with the sample, were used as pressure markers. The powder obtained was pressed into a cylindrical shape of about 1.6 mm^3, insert into a graphite heater and then loaded in the toroidal gasket. The beamline was protected to avoid Cd contamination during the measurements, sealing the large volume PE press with a shield of kapton foil. The *in-situ* purification and characterization of the samples was preliminary performed increasing the temperature of the sample up to 500 °C and after comparing the XAS spectrum with a reference. The temperature was controlled by using a K type thermocouple inserted through the gasket.

3. Results and discussion

Low-noise K-edge XAS spectra of solid and liquid Cd were analyzed using multiple scattering (MS) calculations (GNXAS) [14, 15, 16]. Structural refinement is based on a fitting procedure that minimizes the difference between a model absorption signal and the experimental X-ray absorption raw data. Particular attention was paid to the modelling of the atomic background taking into account corrections associated with $[1s4p_{3/2}]$ and $[1s4p_{1/2}]$ double-electron excitation channels. The structural signal was calculated using an MS n-body expansion $\gamma^{(n)}$. In Fig. 1 we present the results of the fitting procedure of solid Cd at $T = 25$ °C and $P = 0.0$ GPa. Multiple-scattering two body $\gamma^{(2)}$ signals related to the first five neighbor shells around the Cd photoabsorbing site were calculated. The model and the experimental $k\chi(k)$ signals (lower part of figure) are in excellent agreement. The fitting procedure gives an average first-neighbor distance of 2.998 ± 0.005 Å in good agreement with the well known value for the lattice parameter $a = 2.97794$ Å at ambient pressure and $T = 25$ °C [17].

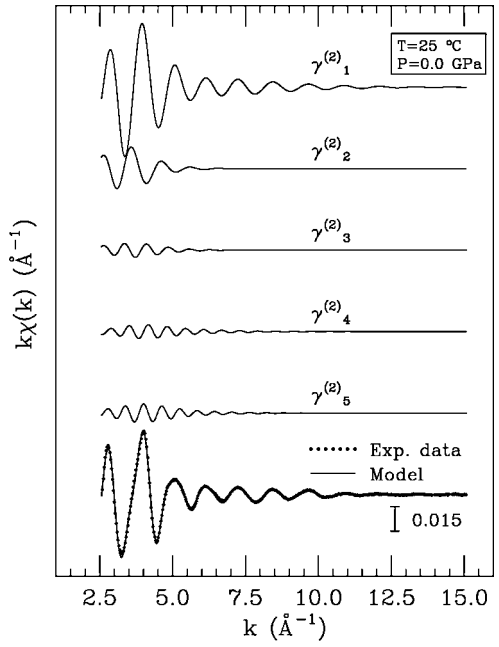

Fig. 1. Solid Cd EXAFS $k\chi(k)$ experimental data (Exp. data) at $T = 25\,^{\circ}$C and $P = 0.0$ GPa, compared with the best-fit multiple scattering $k\chi(k)$ signals. Individual two-body contributions associated with the first five neighbor shells are reported in the upper part of the figure, from top to bottom.

Our study has also been extended to the liquid phase of cadmium. The sensitivity of XAS to the local structure makes it possible to investigate the occurrence of phase transitions. In fact, we identified the solid-liquid phase transition of Cd, recording a series of precise measurements of the absorption coefficient at a single wavelength as a function of temperature at constant pressure, starting from 0.7 GPa up to 5.8 GPa. In Fig. 2 the single-energy scans performed at selected energy $E = 26.7145$ keV are shown. We chose this energy point because it appears more sensitive to the changes in the electronic density of unoccupied states occurring during the solid-liquid transition (see Fig. 3). The melting temperatures were determined looking at of the maximum

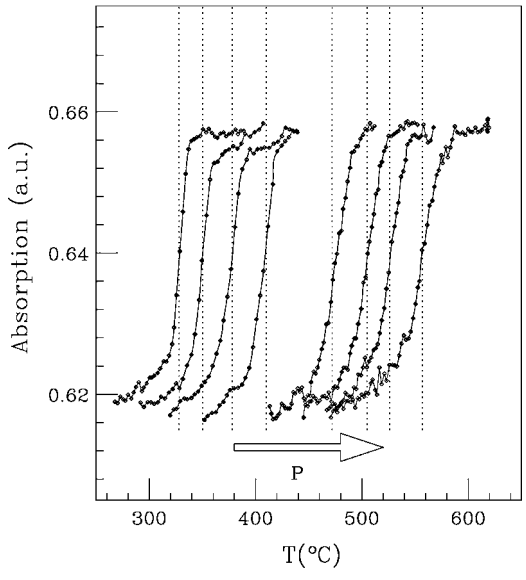

Fig. 2. Single-energy measurements as function of pressure. The pressure increases from left to right (0.7, 0.9, 1.3, 1.7, 3.0, 3.8, 4.6, 5.2 GPa respectively). The dotted lines define the temperatures of the melting-points.

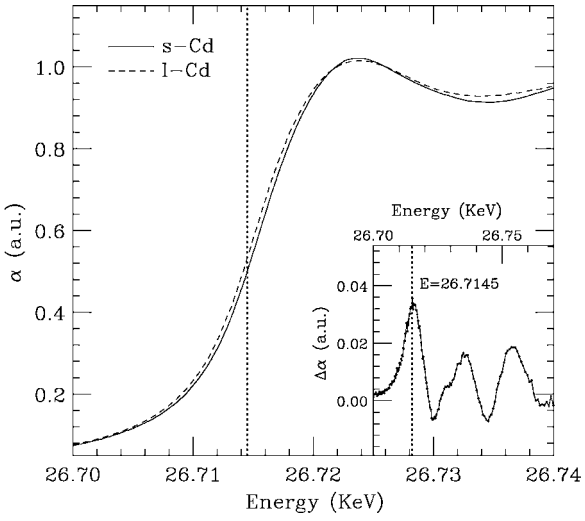

Fig. 3. XAS spectra of liquid (1-Cd) and solid cadmium (s-Cd) at $T = 440\,^{\circ}$C. In the inset we show the differences between the two spectra. We chose the SEXAD point $E = 26.7145$ keV as it corresponds to maximum variation of absorption during the solid-liquid phase transition.

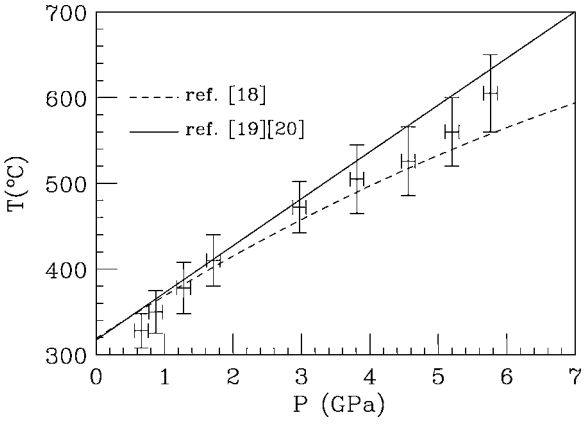

Fig. 4. Solid-liquid transition points determined by using SEXAD technique at constant pressures vs. melting curves previously determined [18, 19, 20].

of the derivative of SEXAD scans as a function of temperature and the results obtained are compared in Fig. 4 with previous data [18, 19, 20]. The results of our measurements lie in the region between the melting curves previously determined and are, substantially, in good agreement with existing determinations of the solid-liquid phase transition line. During the occurrence of the Cd liquid phase, we also recorded low-noise XAS spectra at the Cd K-edge. The XAS data analysis was performed following a scheme already applied in several molten systems [21, 22] using as a model an existing $g(r)$ previously determined [23] by XRD. The refinement of the short-range structure was carried out using an appropriate decomposition of the $g(r)$ model refining only the shape of the short-range peak. In fact, XAS technique is quite sensitive to the short-range distance but essentially blind to the long-range order. In Fig. 5, we report the refinement of $g(r)$ after the fitting procedure of the liquid Cd XAS spectrum at $T = 440\,^{\circ}$C and $P = 1.7$ GPa compared with the $g(r)$ model. In the inset we show the best fit of the liquid Cd at temperature and pressure cited above. The pair distribution function reconstructed after the refinement process, presents a shift toward larger distance of about 0.1 Å well outside our error bars. We found similar results from the data analysis of the whole set of liquid Cd XAS spectra at the various pressures.

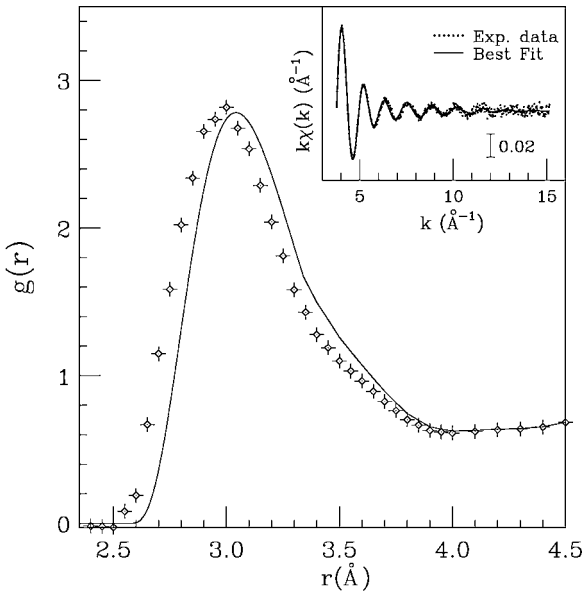

Fig. 5. Comparison between the pair distribution function of liquid Cd (solid line) at $T = 440\,^{\circ}\mathrm{C}$ and $P = 1.7\,\mathrm{GPa}$ determined by EXAFS and $g(r)$ from XRD (symbols) [23]. Inset: best fit (solid line) Cd K-edge EXAFS signal compared with experimental data of liquid Cd (dots).

4. Conclusions

Low-noise Cd K-edge EXAFS measurements of Cd in its solid and liquid phases were performed at BM29 beamline (ESRF). The cadmium melting curve was investigated using single-energy X-ray absorption temperature scan technique and X-ray diffraction, allowing to identify the melting temperatures at various fixed pressures. EXAFS data of solid Cd have been analyzed finding results in substantial agreement with previous diffraction studies. A detailed investigation of liquid Cd at various temperatures and pressures, has also been carried out using XAS technique. XAS data of liquid Cd have been analyzed using a pair distribution function derived from XRD measurements [23] as a starting point. The $g(r)$ obtained was compared with XRD results showing a shift of the foot of reconstructed $g(r)$ toward larger distances of about 0.1 Å. This result shows that XAS represent a powerful tool for investigating short-range structure, enhancing its complementarity with standard diffraction technique. Experiments were performed at the ESRF-BM29 beamline during allocated beamtime (HE-1407 project).

Abstract

RbI and RbBr local atomic structure has been accurately investigated by using X-ray absorption spectroscopy (XAS) in a wide range of temperatures, covering the solid and the liquid phase. In the RbI case, the study has been extended also at high pressure up to 3.5 GPa. Rb, Br and I K-edge XAS spectra has been collected and analyzed using the GNXAS package. Multiple scattering and atomic background contributions have been taken into account, providing a very accurate determination of the first shell structural parameters. The experimental partial $g_{+-}(r)$ of the $RbBr_{1-x}I_x$ ionic alloy are also reported for the solid and the liquid phases, showing the characteristic bimodal distribution in pseudobinary alloys. These results can be very useful for testing the validity of theoretical ionic potentials employed in computer simulations.

1. Introduction

Structure and dynamics of alkali halides at high temperature have been widely studied using both theoretical and experimental means [1]. Standard experimental techniques which detect directly the structure factor $S(k)$, like neutron and X-ray scattering, have been successfully employed to investigate these systems. The radial distribution function $g_2(r)$ can be easily obtained from the $S(k)$ using the general relation

$$S(k) = 1 + \frac{4\pi\rho}{k}\int_0^\infty (g_2(r) - 1)\sin(kr)\,\mathrm{d}r. \quad (1)$$

Quite recently X-ray absorption spectroscopy (XAS) has offered a valid complement to the traditional diffraction techniques. Novel experimental devices [2] and data analysis procedures [3, 4] have been developed which have made possible to collect low noise XAS spectra of several liquid ionic compounds and to obtain very accurate structural information [5, 6, 7]. A relation similar to (1) holds for the EXAFS signal in the two body approximation

$$\chi(k) = \int_0^\infty 4\pi r^2 \rho g_2(r)\gamma^{(2)}(r,k)\,\mathrm{d}r, \quad (2)$$

where $\gamma^{(2)}(r,k)$ is the single scattering EXAFS signal, associated with the presence of a single atom at distance r from the photoabsorber, ρ is the number density [3, 4].

From (2) it follows that also $\chi(k)$ can be manipulated to reconstruct the radial distribution function $g_2(r)$. Therefore, in spite of several intrinsic differences in the nature of the $S(k)$ and the total EXAFS signal $\chi(k)$, both of them contain a similar structural information. However, the sensitivity of the XAS technique is limited only to few Å around the selected photoabsorber. In fact the amplitude of $\gamma^{(2)}(r,k)$ decreases exponentially to zero, due to the short photoelectrons mean free path. Nevertheless this is sufficient to define with excellent precision the first $g_2(r)$ peak. On the other hand the $S(k)$ contains a complete information about the short and long range order, but the structural details of the first shell are limited by the low values of k accessible in the standard diffraction experiments ($k_{max} \sim 8$ Å^{-1} for a Cu X-ray tube). Only very recently [8] the high real-space resolution measurements performed by means of synchrotron radiation, have made accessible the high k region up to 45 Å^{-1}.

These complementary characteristics suggest the possibility to combine EXAFS and XRD in the study of high disordered systems, like molten ionic compounds and alloys. In particular, EXAFS can be useful to increase the precision of $g(r)$ obtained in XRD experiments or produced by numerical simulations (MD, MC), refining their first peak. A simple but powerful method [3, 4] proposed by A. Filipponi and implemented in the GNXAS package [9, 10], makes this combination possible.

The need of employing the XAS technique becomes crucial especially in the investigation of more complex systems like the pseudobinary ionic alloys [11]. These salts are characterized by the presence of two different atomic species in the first coordination shell, which cause a bimodal bond length distribution behavior, not detectable by the standard diffraction techniques. Diffraction can provide only a weighted average of these distributions (Vegard's law), while EXAFS is able to discriminate between them and makes possible to reconstruct accurately the first peak of the two partial $g_{+-}(r)$. In the next sections we show an example of the advantages offered by the XAS technique in the investigation of the local order in ionic compounds and alloys. Reconstructed $g_{\text{Rb-Br}}(r)$ and $g_{\text{Rb-I}}(r)$ of solid and liquid RbBr, RbI and $RbBr_{1-x}I_x$ are presented, which are related to the first shell single scattering EXAFS signals.

2. Experimental and data analysis

The measurements have been realized at the European Synchrotron Radiation Facility (ESRF), at the BM29 XAS-ESXRD beamline [12]. The high purity samples have been finely grounded in a mortar, mixed in a C inert matrix and put into an high vacuum furnace [2] designed for high temperature XAS experiments. The $RbBr_{1-x}I_x$ alloys have been obtained by melting the two starting compounds into suitable quartz ampules under vacuum. The high pressure RbI experiment has been realized by means of a "Paris-Edinburgh" press. In the latter case, the samples have been mixed with a BN matrix and placed inside a 10 mm boron gasket. The XAS spectra have been collected both at the Rb K-edge and at the anions K-edge. The XRD set up [13] has allowed us to verify the melting of the samples and to detect the peaks position of the calibrant in the high pressure experiment. The data analysis has been performed using the GNXAS package, taking into account the contribution of the double electron excitations and the multiple scattering related to the triangular configurations

present in the cubic ionic lattices. Although the amplitude of the EXAFS signals is low in ionic compounds, the structural data obtained with the GNXAS analysis are particularly accurate, due to the double (and also triple) K-edge simultaneous fitting [11]. The fitting procedure of the XAS spectra, has been realized varying three structural parameters, namely, the first neighbor average distance (R), its variance (σ^2) and the skewness (β). Both in the solid and in the liquid case the first $g_{+-}(r)$ peak has been reconstructed using an asymmetric function dependent on the latter structural parameters, which express the probability of finding an atom at distance r from the photoabsorber:

$$p(r) = \frac{2}{\sigma|\beta|\Gamma(4\beta^{-2})}\left(\frac{4}{\beta^2}+\frac{2(r-R)}{\sigma\beta}\right)^{4\beta^{-2}-1} \cdot\exp\left[-\left(\frac{4}{\beta^2}+\frac{2(r-R)}{\sigma\beta}\right)\right], \quad (3)$$

where $\Gamma(x)$ is the Euler's Gamma function. In the liquid cases a "tail" [3] obtained by elaborating available numerical simulations [14, 15] has been added to the first peak.

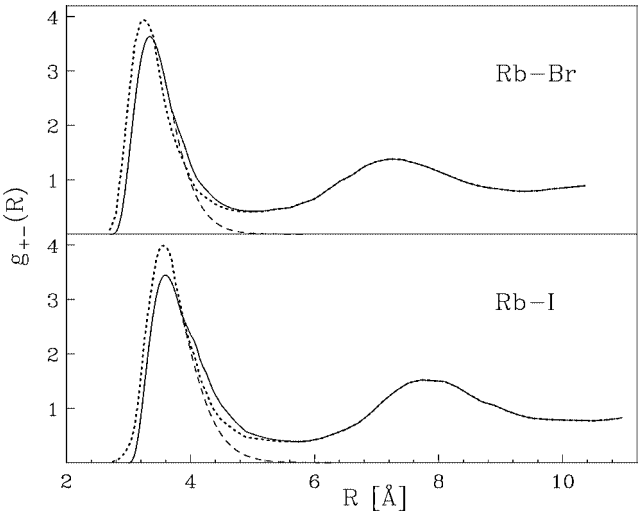

Fig. 2. Partial radial distribution of liquid RbBr ($T \sim 1000$ K) and RbI ($T \sim 950$ K) calculated respectively by MD [14] and MC [15] (dotted lines). EXAFS-refined curves are shown as solid lines. The first peaks calculated by GNXAS are drawn as dashed lines.

3. Solid and liquid RbBr, RbI and RbBrI

The first shell structural parameters in solid RbBr and RbI are shown in figure 1. Increasing the temperature, the first neighbor distance detected by EXAFS is found to be larger than the one obtained with XRD [16]. This is due to the positive orthogonal contribution of the thermal vibrations respect to the bonding direction, which are detectable only by EXAFS. Both the variance and the skewness increase monotonically with the temperature, indicating clearly that the thermal disorder and the asymmetry of the bond length distribution increase. Our data agree with previous low temperature [17] and room temperature [18] measurements. Moreover, in accord with the Lindemann criterion [19], the values of the thermal lattice vibrations just below the melting point ($T_m^{\mathrm{RbBr}} = 966$ K, $T_m^{\mathrm{RbI}} = 920$ K) are roughly 1/10 of the bond length.

In figure 2 the partial $g_{+-}(r)$ of RbBr and RbI are calculated respectively by Molecular Dynamics [14] and Monte Carlo [15] numerical methods. The EXAFS analysis allows us to refine the first shell peak of the $g_{+-}(r)$ (dashed lines) introducing the experimental structural parameters into the formula (3). It is evident that the simulations (dotted lines) overestimate the penetration of the first neighbors toward the central ion located at $R = 0$ Å. This points out the need of choosing more repulsive potentials in the simulations.

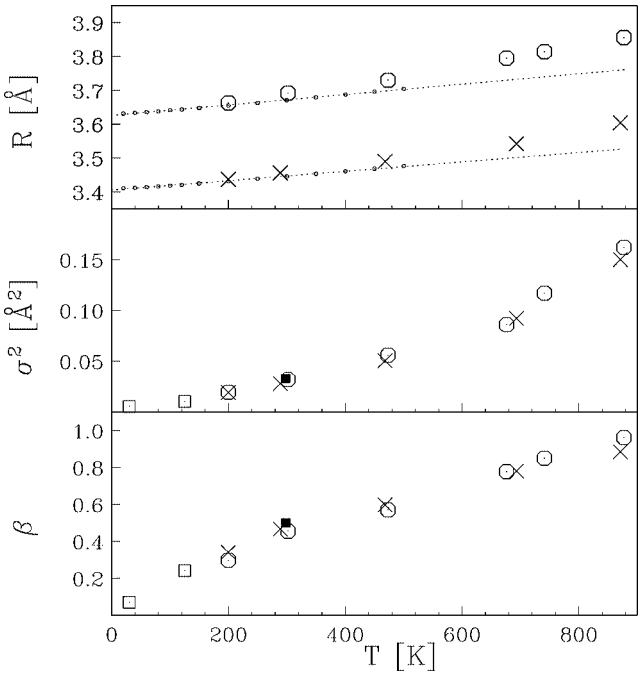

Fig. 1. Structural first shell parameters of solid RbBr (crosses) and RbI (circles) obtained from the EXAFS analysis. *Upper panel*: XRD data from [16] (small circles), fitted linearly (dotted lines). *Central and lower panel*: EXAFS data from [17] (empty squares), [18] (black squares).

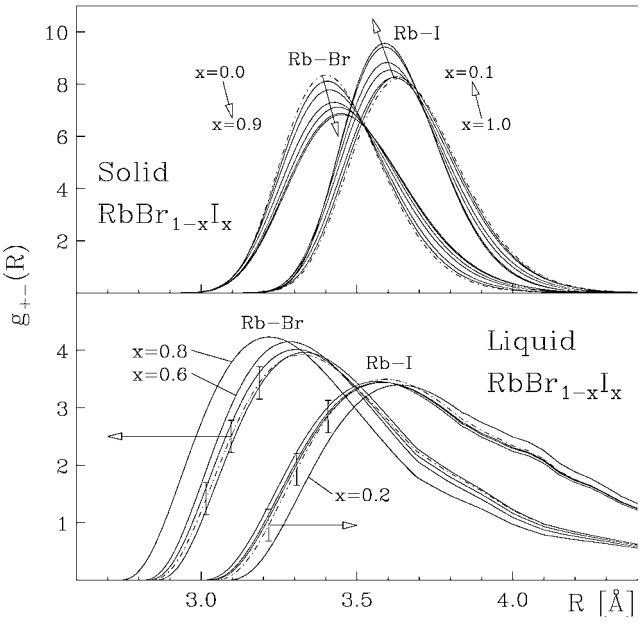

Fig. 3. Bimodal behavior of the first neighbor distance distribution in the $RbBr_{1-x}I_x$ alloy varying the concentration of I^- (equal to x) and Br^- (equal to $1-x$) anions. The dot-dashed lines indicate the RbBr ($x = 0$) and RbI ($x = 1$) compounds. The arrows indicate the trend of the $g_{\mathrm{Rb\text{-}Br}}(r)$ increasing x, and the trend of the $g_{\mathrm{Rb\text{-}I}}(r)$ increasing $1-x$. *Upper panel*: $x = 0.0, 0.1, 0.2, 0.4, 0.6, 0.8, 0.9, 1.0$. *Lower panel*: $x = 0.0, 0.2, 0.4, 0.6, 0.8, 1.0$; the error bars are applied to the $x = 0.0, 1.0$ cases.

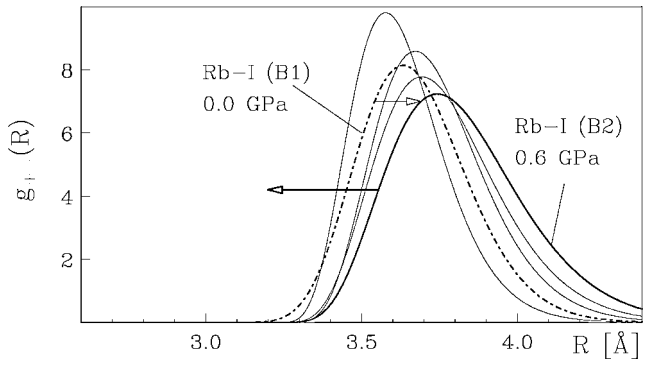

Fig. 4. RbI high pressure phase transition at room temperature. Dot-dashed line: $g_{\text{Rb-I}}(r)$ of RbI with the NaCl-type lattice (B1) at ambient pressure. Solid lines: $g_{\text{Rb-I}}(r)$ of RbI with the CsCl-type lattice (B2) at higher pressures (0.6, 1.5, 2.2, 3.5 GPa). The arrow indicate: the B1-B2 transition (right arrow), the B2 peak trend increasing the pressure (left arrow).

In figure 3 the two partial radial distributions $g_{+-}(r)$ of the $RbBr_{1-x}I_x$ alloy are shown at various concentrations x [11]. They clearly remain distinct varying the stoichiometry of the alloy (bimodal behavior) both in the solid (RT) and in the liquid phase. In the liquid case varying x both the $g_{+-}(r)$ distributions can be considered constant inside the experimental uncertainty (errors bars in figure 3). Nevertheless at the extreme concentrations, an evident shift in the $g_{+-}(r)$ positions is detectable. This effect suggest that the small Br^{-1} anions tend to approach the Rb^+ cations at (at $x = 0.8$), while the larger I^- anions behave in the opposite manner (at $x = 0.2$). This phenomenon, still not completely understood, could be caused by an effective charge screening [11]. In fact the high concentration of Br^- around the Rb^+ ions, can reduce the positive charge of the cations allowing the elongation of the Rb-I bonds. On the other hand, the high concentration of I^- at greater distances from the cations, could compress the Rb-Br distances. In the solid alloy the presence of the lattice constraints prevents this anomalous behavior at extreme concentrations preserving the homogeneous distribution of charge. Nevertheless the overall effect induced by the structural disorder on the lattice potential, is able to partially overcome the natural values of R and σ^2 (dot-dashed lines in figure 3). In fact a gradual increase of bond length and variance is present in $g_{\text{Rb-Br}}(r)$ increasing x. An opposite trend is followed by the $g_{\text{Rb-I}}(r)$ increasing $1 - x$. The intensity of this gradual evolution of the partial radial distributions, depends on the chemical characteristics of the bonds and on the lattice "rigidity" which define the topological rigidity parameter a^{**} [20, 21], with $a^{**} \sim 0.65$ in the $RbBr_{1-x}I_x$.

4. Solid RbI at high pressure

The well known RbI solid structural phase transition at low pressure $P_c = 0.4$ GPa [22, 23] is shown in figure 4, where the reconstructed $g_{\text{Rb-I}}(r)$ are calculated at the pressures of 0.0, 0.6, 1.5, 2.2, 3.5 GPa. The transition at P_c is detectable observing the change in shape and position of the first peak of the $g_{\text{Rb-I}}(r)$, due to the variation of the coordination number and the structural parameters (R, σ^2 and β) presented in table I. In fact upon the transition the lattice goes from the B1/NaCl-type structure (6 neighbors) to the B2/CsCl-type structure (8 neighbors), with a sudden increase of the number density ($\rho_{(0\,\text{GPa})} \simeq 0.020\,\text{atoms/Å}^3$, $\rho_{(0.6\,\text{GPa})} \simeq 0.023\,\text{atoms/Å}^3$) associated with an evident volume compression ($V_{(0.6\,\text{GPa})}/V_{(0\,\text{GPa})} \simeq 0.82$).

Table I. *First shell structural parameters in RbI upon pressurization at room temperature. N is the coordination number.*

pressure	N	R[Å]	σ^2 [Å^2]	β	phase
0.0 GPa	6	3.692(5)	0.033(1)	0.46(5)	B1
0.6 GPa	8	3.849(5)	0.054(1)	0.72(5)	B2
1.5 GPa	8	3.789(5)	0.044(1)	0.72(5)	B2
2.2 GPa	8	3.756(5)	0.035(1)	0.72(5)	B2
3.5 GPa	8	3.646(5)	0.025(1)	0.72(5)	B2

5. Conclusions

The XAS technique is a powerful tool to investigate the local order in high disordered matter. Here a method to reconstruct the $g_{+-}(r)$, starting from the EXAFS structural data has been proposed, which allows us to combine our results with the usual information provided by XRD or by theoretical simulations (MD, MC). Although a good understanding of structural disorder in solid ionic alloys has been reached during the last decade, further experimental and theoretical efforts have to be devoted to comprehend details and causes of the effects observed in liquid ionic alloys.

Abstract

The real and imaginary parts of the anisotropy of the iron atomic scattering factor are experimentally determined as functions of the X-ray energy near the iron K-edge in the FeS_2 (pyrite) crystal. The anisotropy is a result of a deformation of electronic states induced by local asymmetry of atomic environment of iron atoms in this cubic crystal and provides a quantitative measure of that deformation. Some Bragg reflections, otherwise forbidden by screw-axis or glide-plane symmetry operations, are caused by this anisotropy and their structure factors are proportional to the anisotropy. The energy spectra and azimuthal angle dependence of the anisotropy-induced "forbidden"' reflections is studied and the phase of the anisotropy is determined from an interference of the "forbidden" reflections with different multiple-wave reflections. The energy dependence of the real and imaginary parts of anisotropy is shown to be in good agreement with theoretical curves calculated within two different approaches (the full multiple scattering method employing cluster muffin-tin potential and the pseudopotential *ab initio* calculations). It is found that the anisotropy is much more sensitive to atomic environment and to the theoretical parameters than the average absorption coefficient.

1. Introduction

Only recently it was recognized that the resonant X-rays diffraction can be applied for rather sophisticated studies of magnetic and electronic structure of crystals [1, 2, 3, 4]. In most cases, the contribution of the magnetic and electronic structure effects are rather small in comparison with conventional X-ray scattering. However, this contribution is anisotropic and it is strongly enhanced in the resonant region near absorption edges of atoms, that is, it depends on frequency and polarizations of diffracting beams, on the anisotropy of atomic environment, and on the orientation of the magnetic and orbital moments. Owing to this anisotropy, one can use a very helpful tool to observe those small effects, the so-called "forbidden" reflections. Those reflections are forbidden due to some symmetry operations, like glide-planes and/or screw axes, but they can be excited just because of the anisotropy of X-ray suseptibility induced by magnetic ordering and/or by deformed electronic states of atoms.

The physical reason for these reflections is that the atomic scattering amplitudes (called usually the atomic scattering factors (ASF)) and the corresponding structure factors become tensor in XAFS regions. In other words, ASF depends on the polarizations and wave vectors of the initial and diffracted waves. Using different incident directions and different polarizations one can measure all the tensor components of the structure factors and obtain this way detailed information about the deformed electronic states and magnetic ordering.

In the absence of the magnetic ordering, the deformations of the electron wave functions are induced only by the asymmetrical configuration of neighboring atoms. The "forbidden" reflections of this type were first predicted and observed by Templeton and Templeton [5, 6] and a phenomenological theory of the resonant diffraction was developed in the dipole-dipole approximation [7, 8]. Since that time the "forbidden" reflections were observed in many crystals and several papers in this Proceedings are devoed to this phenomenon [9, 10].

However, similar to conventional reflections, the information available from "forbidden" reflections is restricted by the so-called *phase problem*: one can usually measure only intensity of a reflection whereas the information about its phase is lost. The phase is sensitive to the distortions of atomic wave functions and therefore it would be important to measure it. One method to do this is the interference between the "forbidden" reflections and the multiple-wave contribution from nonforbidden reflections. This interference appears for some orientations when the crystal is rotated around the reciprocal lattice vector of the "forbidden" reflection. The intensity of the "forbidden" reflection changes drastically in the region of the interference and depends on the relative phase of the "forbidden" and non-forbidden reflections. Supposing the phases of non-forbidden reflections known, one can measure this way the unknown phase of the "forbidden" reflection. Up to now there are only two works on the phase of the "forbidden" reflections: the preliminary studies of the phase of the anisotropy as a function of the X-ray energy near the iron absorption edge in FeS_2 [11] and the measurement of the phase of the 006 reflection in Ge for a fixed X-ray energy [12].

In this paper, a study of the real and imaginary parts of the Fe atomic factor in the pyrite, FeS_2, is presented. Section 2 describes the multiple-wave method used for the experimental solution of the phase problem. Then, in sections 3 and 4, different theoretical approaches are discussed and the comparison between theoretical and experimental spectra is presented in section 3.

2. Experimental

In the pyrite crystals, four equivalent Fe atoms are at positions with threefold symmetry $\bar{3}$ but the orientations of the corresponding threefold axes are different. Just this difference is responsible for

*dmitrien@ns.crys.ras.ru

the forbidden reflections and their structure factor is proprotional to the anisotropy $f_{||} - f_{\perp}$ where $f_{||}$ and $f_{\perp}$ are the eigenvalues of the tensor atomic factor f corresponding to directions parallel and perpendicular to the threefold axis.

Experimentally, one can probe only the reflection intensity for different polarizations of the incident and reflected beams. The intensity is proportional to the absolute value of the structure factors so that the phase is lost. In the case of the forbidden reflections, the structure factor F_H is proportional to the anisotropy of the atomic scattering factors of resonant atoms, and it would be very important to have access to the phase of the anisotropy.

The well known solution of this phase problem consists in exploring the interference between the reflection with unknown phase and a multiple-wave reflection with the known phase (see a survey in [13]). In the vicinity of the multiple-wave reflection, the intensity of the forbidden reflection contains a term proportional to $F_{\boldsymbol{H}} F^*_{\boldsymbol{H}-G} F^*_{\boldsymbol{G}}$ where $F_{\boldsymbol{G}}$ and $F_{\boldsymbol{H}-G}$ are the known structure factors of non-forbidden reflections $\boldsymbol{G}$ and $\boldsymbol{H} - G$. From the measured value of this term it is possible to calculate the phase of $F_{\boldsymbol{H}}$ and hence the real and imaginary part of $f_{||} - f_{\perp}$.

The theory of this effect was developed for FeS_2 in Ref. [15] where the best geometries for the observation were found. In the present work, the intensity of the 001, 003, and 011 forbidden reflection were measured at the Tsukuba Photon Factory and the real and imaginary parts of $f_{||} - f_{\perp}$ were found for the photon energies from 7105 to 7165 eV.

3. Muffin-tin (MT) calculations

The calculations of Fe K-edge anomalous atomic scattering factor (ASF) and intensities of the "forbidden" reflections for the FeS_2 crystal are performed by the one-electron multiple scattering Green's function method [14, 16]. The standard expression for the anomalous contribution into X-ray atomic scattering amplitude [24], determined in dipole-dipole approximation, is employed. The computer code was developed earlier at Rostov State University by A. A. Novakovich. A cluster muffintin (MT) approximation for the crystalline potential is used. The cluster MT potential is constructed by the same method which was successfully employed earlier for the XANES calculations [17, 18, 19, 20]. According to this method the atomic electron densities are calculated by the Herman-Skillman code [21] using the spin-independent local $X\alpha$-potential with the α-parameter determined by K. Shwartz [22].

The electron configurations of all the atoms, excluding the scattering one, are considered to be the same as those of free atoms. Taking into account that the scattering atom is excited at the intermediate stage of the anomalous X-ray scattering process we consider the electron configuration of this atom to contain 1s hole and additional screening 3d-shell charge. The incomplete screening model is used in the present calculations just as in the XANES calculations [17, 18, 19, 20], and the screening charge is assumed to be equal to 0.8 electrons. The atomic potentials used for the virtual photoelectron Green's function computations are considered to be spin independent and are determined through the free atom electron densities, calculated by the Hermann-Skillman code. A decreased value of the α parameter ($\alpha = 0.6$) is used for calculating these potentials [17, 18, 19, 20]. The MT zero level is chosen at -0.5 Ry relatively to the vacuum zero. As in the case of the XANES calculations, we consider the potential to be equal to MT-zero everywhere outside atomic spheres. The potential inside each atomic sphere is considered to be a sum of the corresponding free atom potential and a fixed energy shift ΔE, which is an adjusting parameter, determined so as to achieve the best agreement with the experiment. We consider the shifts to be acceptable if they do not exceed 0.5 Ry. The radii of the atomic MT spheres are chosen so as to exclude a discontinuity at the boundaries of the neighboring atomic spheres. In the case of the pyrite we obtain: $R_{Fe} = 1.263$ Å, $R_S = 1.11$ Å.

To include the processes of the photoelectron–hole pair decay, caused by many-electron effects, we calculate the Green's function for a complex valued energy parameter E. The imaginary part of E determining the energy-dependent width $\Gamma(E)$ of the electron-hole excitation state is a sum of the 1s hole width $\Gamma_h = 1$ eV [23] and the photoelectron one. The latter is considered to be equal to zero near the conduction band bottom and to increase rapidly with the photoelectron energy growth.

4. Full potential (FP) calculations

We performed the Full Potential (FP) calculations by using the method developed by Taillerfumier *et al*. [25, 26]. This method is a reciprocal-space scheme initially dedicated to the calculation of X-ray Absorption Near-Edge Structure at K or L edge. Since the theory is detailed in Ref. [25], only its main aspects are recalled here. The method uses norm-conserving Troullier-Martins [27] pseudopotentials. The pseudo-wave functions are expanded in a plane wave basis set. The scheme allows the reconstruction of the *all electron* wave functions by using the projector augmented wave method of Blöchl [28]. The method incorporates a recursive algorithm [29], that permits to transform an Hermitian matrix (here the pseudo-Hamiltonian) into a symmetric tridiagonal form, and to write the absorption cross section, σ, as a continued fraction [30]:

$$\sigma(\omega) = -4\pi\alpha\hbar\omega \times \mathcal{J}m \cfrac{\langle\tilde{\varphi}_{\boldsymbol{R}_0}|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle}{a - E - \mathrm{i}\gamma - \cfrac{b}{a - E - \mathrm{i}\gamma - \cfrac{b}{a - E - \mathrm{i}\gamma - \cfrac{b}{\ddots}}}}. \quad (1)$$

In Eq. (1), α is the fine structure constant, $\hbar\omega$ is the photon energy of the incident beam, the energy E is equal to $\hbar\omega + E_i$ where E_i is the energy of the initial state (core state), and γ is a broadening parameter similar to $\Gamma/2$ used as above in the MT calculations. The $\{a_i\}$ and $\{b_i\}$ are two sets of real coefficients, corresponding to the diagonal and subdiagonal matrix elements of the pseudo-Hamiltonian in its tridiagonal representation, respectively. The pseudo-wave function $|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle$ is non-zero only within a spherical core region (smaller than the usual muffin-tin sphere) centered on the absorbing atomic site $\boldsymbol{R}$. In the electric dipole approximation, $|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle$ is defined by a sum over the ($\ell = 1$) components of the product of Blöchl's projector functions [28] and transition matrix elements between the initial core state and the *all electron* valence atomic wave functions:

$$|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle = \sum_n \sum_m \sum_{,\pm} |\tilde{p}_{\boldsymbol{R}_{0,n,,m}}\rangle\langle\phi_{\boldsymbol{R}_{0,n,,m}}|\hat{\varepsilon}\cdot\boldsymbol{r}|\phi^c\rangle. \quad (2)$$

In Eq. (2), $\hat{\varepsilon}$ is the polarisation of the photon beam, and the sum over n is used if there is more than one Blöchl's projector function per angular momentum channel.

The FP method was used to calculate the imaginary part of the anomalous scattering factor, f'', since it is proportional

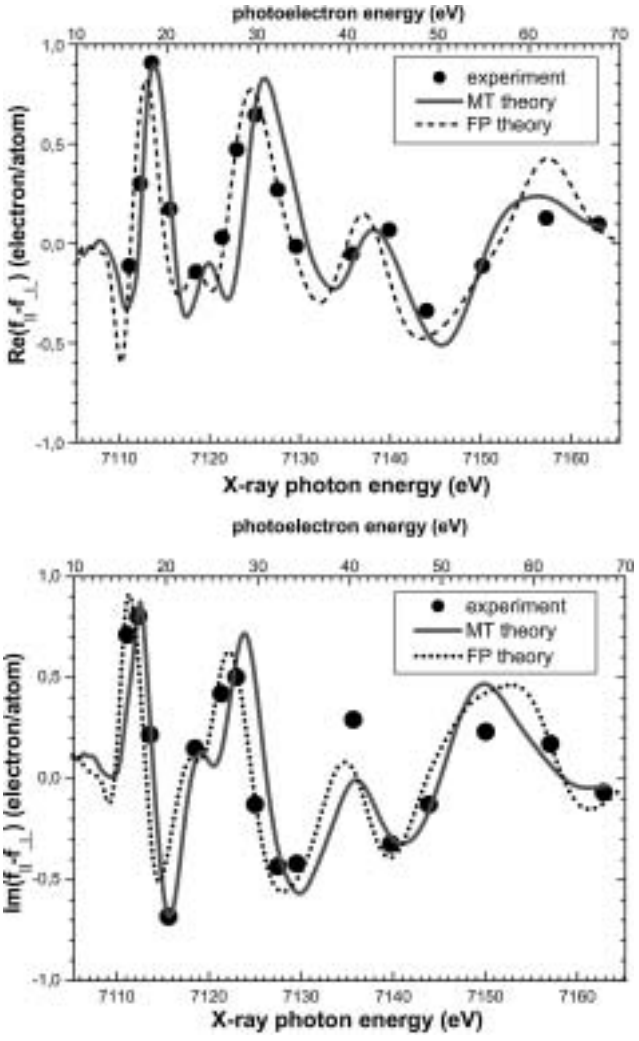

Fig. 1. Experimental (circles) values of the real (top) and imaginary (bottom) parts of the anisotropy $f_{||} - f_{\perp}$ of the iron atomic factor compared with the MT and FP calculated values as functions of the photon energy near the Fe K-edge.

to $\omega\sigma(\omega)$. Then the real part, f', was obtained by a Kramers-Kronig transform. The calculations were carried out on two kinds of cell, in order to investigate the influence of the core-hole effects onto the scattering factors: (*i*) the unit cell of pyrite, containing four FeS_2 entities, and (*ii*) a $2 \times 2 \times 2$ where one 1s electron was removed from the electronic configuration of only one of the 32 iron atoms. Since the calculations revealed that the electron-core-hole interaction has negligible effects on the f' and f'' spectra, all the FP calculated spectra described and presented below are the ground state calculations. The charge density was self-consistently calculated within the local density approximation using a 70 Ry cut-off energy for the plane wave expansion. Reciprocal space integrations were performed using $2 \times 2 \times 2$ and $8 \times 8 \times 8$ Monkhorst-Pack $\boldsymbol{k}$-point grids for the charge density and f'', respectively. We consider the (0, 0, 0) iron site as the $\boldsymbol{R}$ absorbing atom site. Thus the $f''_{||}$ and $f''_{\perp}$ components of f'' were obtained with $\hat{\varepsilon} \,||\, [111]$ and $\hat{\varepsilon} \perp [111]$, respectively. The continued fraction (Eq. (1)) was evaluated with $\gamma = 0.01$ Ry. More details about calculations may be found in [31].

5. Results and discussion

The measured values of the ASF anisotropy $f_{||} - f_{\perp}$ is shown in Fig. 1 together with the MT and FP calculated values. One can see that both theories provide rather good description of the experimental data. However the MT theory contains many fitting parameters whereas the unique free parameter of the FP calculations is the energy-dependent width at half maximum $\Gamma(E)$ of the Lorentzian function, that is used to convolute the f' and f'' spectra ($\Gamma(E)$ is the same both for the MT and FP calculations).

Abstract

The resonance spectrum of glide-plane forbidden X-ray diffraction have been measured for different temperatures in hexagonal ZnO near the zinc K-edge. This diffraction appears exclusively owing to anisotropy of the Zn atomic scattering factor induced either by thermal motion or by a temperature-independent dipole-quadrupole amplitude. The results provide the first evidence for a complex line shape in the spectrum of thermal motion induced scattering, and the first observation of a dramatic change in resonance spectrum with temperature.

The measurements are in excellent agreement with a phenomenological model, based on a combination of constant and a temperature-dependent amplitudes. This model has provided a means of extracting amplitude spectra of each component, and their relative phase. We find that the strongest spectral feature of the room-temperature resonance spectrum arises from a sudden phase change between the two resonant processes. These results are of great importance for better understanding of the temperature effect on the excited electronic states in crystals like hybridization of different orbitals, *etc.*

1. Introduction

Resonant X-ray diffraction at positions that are exactly forbidden by glide-plane or screw-axis selection rules have received a great deal of attention in recent years. Since such signals vanish in the case of a spherical (scalar) scattering response, the technique has played a key role in identifying orbital anisotropy in, for example, manganites and other strongly-correlated electron systems [1]. Most of these studies have exploited the coupling of the photon polarization to dipolar anisotropy (described by a second-rank tensor and represented geometrically by an ellipsoid) in order to reduce the symmetry of the scattering system. For many materials, however, the crystal symmetry is such that even dipolar anisotropy cancels in the calculation of structure factors, and the lowest-order residual scattering is described by third- or fourth-rank tensors. These effects have been observe experimentally [2–4], and attributed to (electric) dipole-quadruplole (E1E2) and pure quadrupole (E2E2) resonances, respectively.

Of special significance to this work is the series of studies of germanium [5–9], pioneered by Templeton & Templeton [2], who observed a sharp resonance just above the Ge K-edge, which was found to be consistent with the symmetry properties of a third-rank scattering tensor. Interpretation was given in terms of a mixed dipole-quadrupole resonance [2]. Recently, an alternative mechanism has been proposed [10], and observed in germanium [5, 7], whereby a third-rank scattering tensor arises from small thermal displacements from the nominal sites of high symmetry, coupled to local dipolar anisotropy. While the temperature-dependence of the resonant scattering in germanium does indeed show convincing evidence for two competing processes, i.e. a temperature-independent (TI) part, probably dominated by E1E2 events, and a Thermal Motion Induced (TMI) part, the spectra for each process are surprisingly similar, and there is very little temperature dependence in the spectral lineshape.

Since TMI scattering arises from the relative displacement of adjacent atoms, its strength depends crucially on the thermal population of optical phonon modes. The search for suitable materials in which to study this effect is therefore governed by the requirements for: (1) a suitable space-group, which includes glide-plane and/or screw-axis symmetry, (2) site symmetry such that forbidden reflections give no contribution from dipolar anisotropy, (3) an absorption edge resonance at a wavelength suitable for crystal diffraction, (4) a low-lying optical phonon mode, (5) a high quality single crystal sample. ZnO, which crystallizes with the wurtzite structure (space group $P6_3mc$, No. 186) and has an optical phonon mode of energy 12.4 meV at the Γ-point [11], satisfies the above requirements. Moreover, it is of considerable interest as a material for spintronics, and is commercially available as a substrate crystal.

2. Theoretical

The X-ray diffraction intensity for weak scattering can be written, for a fixed geometry, in terms of the electric field components of the incident ($\hat{\varepsilon}$) and scattered ($\hat{\varepsilon}'$) photon, and a Cartesian scattering matrix:

$$I \propto |\hat{\varepsilon}'^{*} F \hat{\varepsilon}|^2. \tag{1}$$

The matrix for TMI scattering is derived from the third-rank structure factor tensor by projecting onto the scattering vector [10]. For either atom type of the wurtzite structure (site symmetry $3m$), for the hhl (l = odd) glide-plane forbidden reflections, the resulting scattering matrix is of the form:

$$F(hhl) \propto h\langle u^2 \rangle \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \tag{2}$$

where the x, y and z axes are parallel to the crystal mirror-plane, glide-plane and 6-fold axis, respectively. $\langle u^2 \rangle$ is the mean square atomic displacement (we assume, for simplicity, that the only important displacement is of a Zn atom relative to all the neighboring atoms, and that the vibration is approximately isotropic). From Eq. (2) it is clear that the reflections of interest

*steve.collins@diamond.ac.uk

will be of the form *hhl*, with $l =$ odd and $h \neq 0$. One cannot infer that the scattering amplitude will simply scale with h, however, as a number of geometrical factors are introduced when transforming to the laboratory frame of reference. Similarly, the coordinate transformation leads to a complex characteristic dependence of the scattered intensity and polarization on the sample azimuthal angle. A more detailed description of the structure factor tensor and scattering matrix will be given in a subsequent communication, where the polarization and azimuthal intensity dependence will be discussed.

An important aspect of this work is that, for materials that crystallize with non-chiral space groups (which include both Ge and ZnO) the third-rank scattering tensors posses *precisely* the same elements, and are thus experimentally distinguishable only via their dependence on other physical variables, such as temperature.

3. Experimental

The experiments reported in this Letter were carried out on the XMaS UK CRG beamline at the European Synchrotron Radiation Facility. The bending-magnet beamline utilizes a Si 111 monochromator and a toroidal focusing mirror. The sample was a large ($10 \times 10 \times 1$ mm) plate, supplied by MaTecK GmbH, which was attached to a 50–800 K cryofurnace, mounted on the Eulerian cradle of a large multi-axis diffractometer. Photon polarization was perpendicular to the scattering plane. The absorption spectrum was measured from a thin ZnO powder, in order to apply absorption corrections to the diffraction data. Anisotropy in the absorption was assumed to be small.

One of the most severe complications with measurements of weak scattering with integer Miller indices is contamination by multiple scattering. Fortunately, the very high quality of the sample (the 004 rocking-curve width was below 0.02°) meant that the majority of such features were very sharp, and easily avoided by performing a modest azimuthal rotation. The azimuthal angles were kept close to zero (with 001 within the scattering plane) for most of the measurements, as this corresponded to the maximum calculated, and measured, resonant scattering intensity. Azimuthal scans were very limited in range, due to the crystal surface orientation, and will be the subject of a future study.

Resonant diffraction signals were observed at the 113 and 115 glide-plane-forbidden positions, with the 115 studied in some detail. No clear diffraction intensity was observed at the 003 position, which would require a structure-factor tensor of at least fourth rank. In stark contrast to the results from Ge, we find resonance spectra at high and low temperatures that are complex, extend over more than 30 eV in energy, and are completely different in line shape (Fig. 1). Weaker resonance features extend well beyond the absorption edge. The evolution of the resonance spectrum with temperature was determined from measurements at 18 temperatures, ranging from 59 to 800 K. The resulting dependence shows a remarkable array of features: at various photon energies, the intensities, with increasing temperature, are found to fall, to rise, to fall and rise, and to remain almost constant.

In the absence of a theoretical model for the resonant scattering, and in an attempt to separate the TI and TMI components, we have performed a least-squares fit of the measured intensities to a phenomenological two-process model [5], via the expression,

$$I(E) = \left| A(E)\,\mathrm{e}^{\mathrm{i}\phi(E)} + B(E)\coth\left(\frac{\hbar\omega_o}{2kT}\right)\right|^2 \mathrm{e}^{-2M} \qquad (3)$$

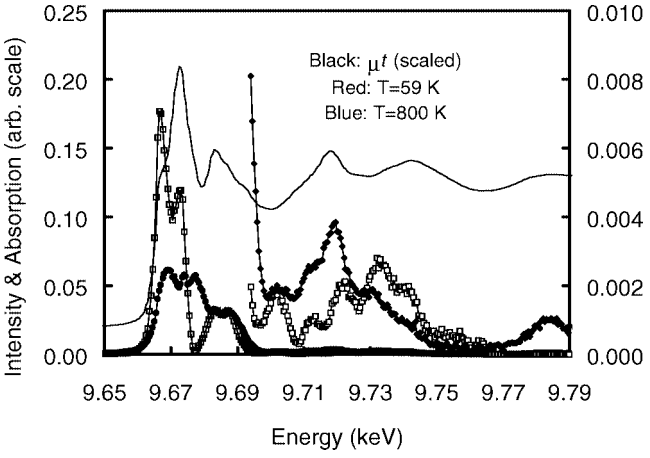

Fig. 1. The ZnO 115 resonance spectrum near the Zn K-edge. Red and blue solid lines correspond to temperatures of 59 and 800 K respectively. Total absorption is shown by the black line. The tails of the curves are shown in larger scale and correspond to the right axis.

where $A(E)$ and $B(E)$ represent energy-dependent (scalar) amplitudes for the TI and TMI scattering components, and $\phi(E)$ is the relative phase angle between the two components, which we assume to be independent of temperature. The factor $\langle u^2 \rangle$ scales with the thermal population of the optical phonon mode $\coth(\hbar\omega_o/2kT)$ if one assumes a simple model in which the phonon energy, $\hbar\omega_o$, is independent of the wavevector. The total scattering intensity is further modified by the Debye-Waller factor e^{-2M}, where M, which is a function of momentum transfer, temperature, atomic mass and characteristic (Debye) temperature, is discussed in detail by James [12]. For the present work, we take the average atomic mass $\overline{m} = 40.7$, and a Debye temperature of 370 K, determined from a crystal structure refinement study [13].

Eq. (3) was found to give a remarkably good fit to the data yielding three separate energy-dependent curves: the TI and TMI amplitudes, $A(E)$ and $B(E)$, and their relative phase, $\phi(E)$. These are shown in Fig. 2, in the form of their contributions to the resonant intensity at low temperature (58 K). The quality of the fit

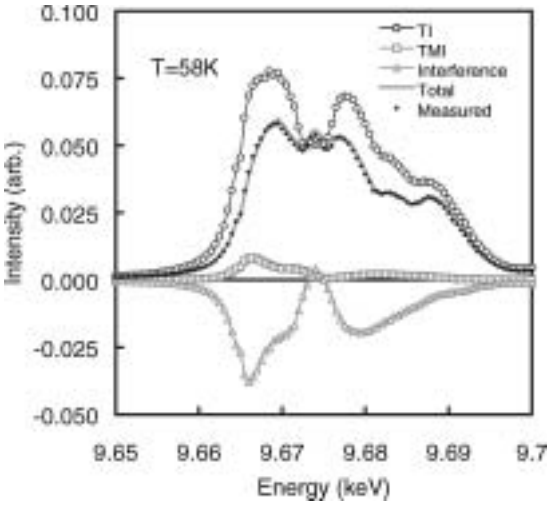

Fig. 2. The results of the least-squares fit to the model outlined in the text (Eq. (3)), shown in the form of intensity contributions (at $T = 58$ K) from thermal-motion-induced scattering (red line), temperature-independent scattering (blue line) and the interference term between these two resonant amplitudes (green line). The total fit is shown by the black line together with experimental points.

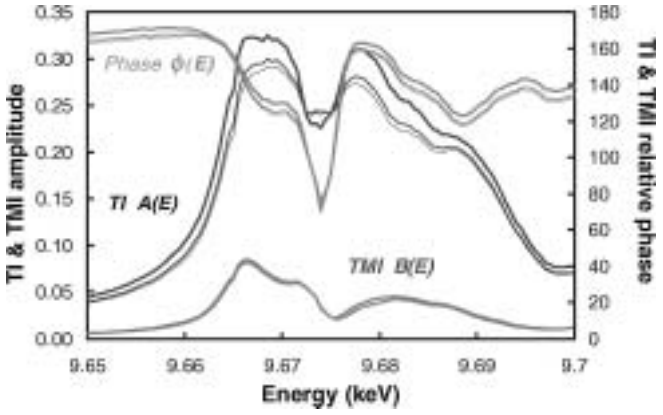

Fig. 3. The results of the least-squares fit to Eq. (3) for the TI and TMI amplitudes, $A(E)$ (blue lines) and $B(E)$ (red lines), and their relative phase, $\phi(E)$ (green lines). Different curves of the same color correspond to different phonon energies $\hbar\omega_o = 6.2$, 12.4, and 24.8 meV.

was found to be relatively insensitive to the value chosen for the optical phonon energy, $\hbar\omega_o$, giving an error interval ranging from 0 to 35 meV (Fig. 3). $A(E)$ and $\phi(E)$ depend very weakly on $\hbar\omega_o$ whereas $B(E)$ simply scales as $1/(\hbar\omega_o)$. While this effectively rules out the possibility of using the TMI scattering technique to extract precise phonon energies, it does, at least, suggest that the known dispersion in the low-lying optical mode [11], and the presence of high energy modes, should have only a modest effect on the above analysis, beyond an overall scaling of $B(E)$. Neglecting the Debye-Waller factor in Eq. (3) led to a significantly worse fit.

4. Results and discussion

The results from ZnO are interesting in several respects. First, they represent convincing evident for TMI scattering in a material other than Ge, suggesting that the phenomenon is more general than may have been inferred from previous work. Secondly, unlike Ge, we observe resonance spectra that are complex and change dramatically with temperature. The phenomenological model has proved extremely useful in establishing that the intensities can be understood very well with the assumptions that two processes are required, one of which has an amplitude that follows closely the population of the low-lying optical phonon mode, and that the phase between the two amplitudes is independent of temperature. Recently, a microscopic theoretical model was suggested for the spectrum and magnitude of TMI scattering [14].

The study of electronic systems in perturbed or excited states is one of the great challenges for the coming decades, towards which thermal-motion-induced scattering can play a small but significant role. The combination of experimental and theoretical studies of forbidden reflections should shed light on a number of important aspects of electronic structure, including hybridization, the evolution of electronic states with nuclear position, and the validity of the Born-Oppenheimer approximation. While recent theoretical work on Ge [9] supports the interpretation of the temperature-independent scattering component as arising from E1E2 processes, one cannot rule out a contribution from pure dipolar scattering, if one takes into account the variation in the scattering tensor with the relative displacement of the scattering centre from the nucleus. It is likely, however, that the limited extent of the 1s core level involved in the resonance will mean that this contribution is weak. Another possible interpretation of the temperature-independent scattering relates to the point-defect-induced anisotropy [15] Finally, it is interesting that the TI and TMI amplitudes for both Ge and ZnO are similar in magnitude, yet the physics of the two processes is very different. This could, of course, simply be coincidental.

Abstract

The Ge(111) surface exhibits a well-known structural transition at high temperature to a metallic phase. The transition is known to occur at about 1040 K and has been interpreted as due to the melting of the first surface layers. We have performed a new experiment with an improved high-temperature set-up which allows us to collect accurate Electron Energy Loss Spectroscopy data near the $M_{2,3}$ excitation edges. A probing depth of about 10 Å on collected EELS spectra was obtained tuning the electron gun at about 500 eV. The metalization of the surface has been clearly detected by the shift of the edge associated with the disappearance of the gap. EELS measurements, performed with a fine temperature step and under thermal equilibrium conditions, allowed us to obtain a new determination of the transition temperature which appears to be located at $T_c = 1010$ K with an accuracy of about 10 K.

1. Introduction

The Ge(111) surface exhibits a well-known structural transition at high temperature to a metallic phase [1–4]. The transition, involving the (1×1) surface reconstruction, is known to occur at about 1040 K, more than 160 K below the bulk melting temperature $T_m \sim 1210$ K [4, 5].

In previous works, different types of spectroscopies detected this transition and the current model for the high temperature phase is an incomplete surface melting involving the first Ge(111) bilayer [6, 7]. Experiments using low-energy electron diffraction (LEED) [1, 2], EELS at the $M_{4,5}$ threshold and near the elastic peak [4, 8], ellipsometry [9], surface X-ray diffraction [10], photoelectron diffraction [3], He atom scattering [11], and photoemission [12, 13] were performed confirming the metallic nature of the new phase occurring in a quite broad range of temperatures 970–1050 K. In spite of these efforts there is still some uncertainty about the temperature of the transition and about the number of layers involved for increasing temperature.

Stimulated by our previous experience in studying the structure of liquid and solid Ge at high temperature [14] by X-ray absorption spectroscopy (XAS) and by the sensitivity of this technique to structural and electronic phase transitions [15], we have performed an $M_{2,3}$-edge electron energy-loss spectroscopy (EELS) experiment aimed to improve our knowledge about the above-mentioned Ge(111) surface phase transition. In fact, the metalization induced by melting of bulk Ge can be easily detected and studied by the change of shape and shift of the edge position in Ge K-edge XAS spectra [14, 15]. These features can be also observed in surface-sensitive XAS-like techniques like EELS using standard laboratory systems. Moreover, a finer temperature step and a more precise calibration and measurement of the sample temperature have been achieved through the development of a new sample heating unit working under high vacuum conditions.

2. Experiment

The experiments were performed in a ultra-high vacuum (UHV) chamber equipped with a LEED system, a coaxial electron gun and cylindrical mirror analyzer (CMA). An ion gun (Ar) has been used for surface cleaning of a Ge(111) sample during proper annealing cycles. The surface was found to be clean according to the usual criteria of Auger electron spectroscopy (AES).

Special care was paid to the temperature control and heating elements. In Fig. 1 we show the design of the high-temperature

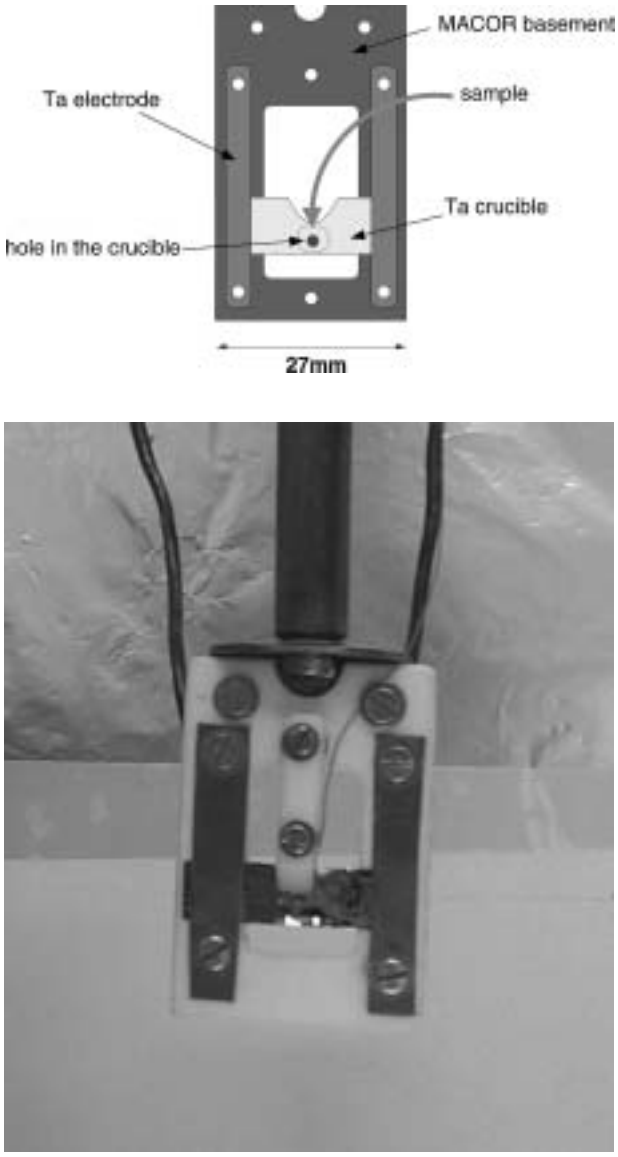

Fig. 1. Design of the high-temperature crucible for EELS measurements (top) and picture of the device (bottom) to be inserted into the ultra high-vacuum chamber.

crucible used for EELS measurements (top) and a picture of the device (bottom) developed for high temperature measurements into the UHV chamber. The heating element of the new device is a 5 μm thin Ta foil which is able to reach very high temperatures using typical currents of a few Amperes with typical voltages of 1–2 Volts. The geometry of the crucible-sample assembly is similar to the one developed for high-temperature XAS studies [16] and guarantees a precise temperature control and an excellent temperature homogeneity. The new device is made with UHV compatible components and allowed us to measure the temperatures with an accuracy better than 5 degrees using a K-type thermocouple placed between the Ta crucible and the sample. Direct contact between the reactive surface of the sample and the Inconel sheath of the thermocouple (Thermocoax, insulated, 0.25 mm diameter) was avoided using a thin boron nitride spacer. A ∼500 μm diameter hole allowed us to collect EELS, AES, and LEED signals from the Ge(111) surface. An important advantage of the present setup is that the presence of the metallic heating device allowed us to collect high-temperature data without using pulsed heating because of the low voltage applied to the crucible and the absence of current flow inside the sample. Clearly this allowed us to collect high-temperature EELS spectra under equilibrium thermal conditions.

The experimental results presented in this work are those related to the high-temperature $M_{2,3}$ EELS data that we collected using a fine temperature spacing near the phase transition temperature. The electron gun was tuned at 500 eV in order to have sufficient statistics, energy resolution and low background from secondary emission at the kinetic energy corresponding to the selected core level (binding energy of the M_3 level is $E_{M_3} \sim$ 120.8 eV). The inelastic mean free path of the electrons in the selected range of kinetic energies ($E_{kin} \sim$ 380 eV) is estimated to be about 10 Å in crystalline Ge (see ref. [17] and ref. therein). Therefore, the measured EELS signal is sensitive to the first 4–5 Ge(111) surface layers.

3. Results and Discussion

In Fig. 2 we report the EELS intensity as a function of temperature in the vicinity of the surface phase transition. EELS spectra have been measured in a range of about 60 eV accumulating 50 scans for each temperature to increase statistics. The intensity of the EELS spectra has been obtained in the usual way, using a polynomial function for the background in the pre-edge region and normalizing the $M_{2,3}$ electron loss above the M_3 and M_2 edges to unity ($E_{loss} \sim$ 150 eV). In this way EELS spectra can be directly compared on the scale of Fig. 2 where changes in the shape and position of the edges can be appreciated.

Looking at Fig. 2, we note that a change of shape and intensity of the EELS spectra occurs at about 1000 K and that a clear shift of the foot of the absorption edge (in the 114–118 eV region) is observed at about 1010 K. The change in the shape and relative intensity of the EELS spectra are also affected by the normalization procedures, that can introduce an uncertainty of the order of 1–2%. Of course, the energy shift near the edge can not influenced by normalization procedures and is a direct manifestation of a drastic change of the empty density of states near the Fermi Energy in the vicinity of the Ge(111) surface. This effect has been already observed in XAS spectra of bulk Ge upon melting [14, 15] and, more recently, in amorphous Ge under pressure [18].

The shift of the edge toward lower excitation energies is associated with the transition from a semiconductor to a metal phase. The energy gap disappears and new states near the Fermi level are available for the excited electrons, resulting in a shift of the order of 1 eV of the absorption and EELS edges. In the inset of Fig. 2 the shift of the EELS edge toward lower excitation energies is clearly visible.

The variation of the EELS intensity (ΔI) at fixed energy is reported in Fig. 3. The energy has been chosen in order to have the maximum contrast between a metallic and a non-metallic phase, i.e. on the rise of the M_3 edge ($E_{\text{loss}} \sim$117.4 eV, see dashed lines in the inset of Fig. 2). The trend reported in Fig. 3 is very clear showing a quite sharp transition occurring between 1010 and 1020 K. The intensity jump exceeds 5% of the total $M_{2,3}$ EELS signal, with a noise level of about 1%. This result shows that the Ge(111) surface undergoes a transition to a metallic phase beginning at about 1010 K. The width of the transition is about 10 K and involves several layers near the surface within the probing depth of the current experiment (about 10 Å). Above 1025 K, the EELS signal at fixed energy changes smoothly with temperature indicating that no further sharp transitions occur in the present temperature range.

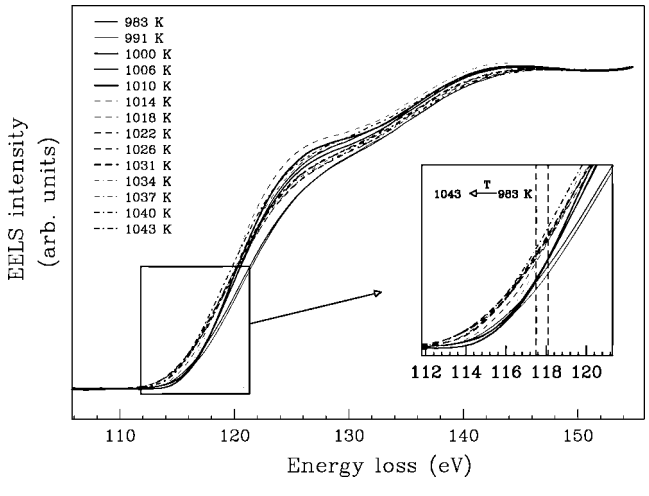

Fig. 2. EELS intensity as a function of temperature in the vicinity of the surface phase transition (983–1043 K, or 710–770 °C). EELS spectra are normalized to the measured intensity above the M_3 and M_2 edges ($E_{loss} \sim$150 eV). In the inset the shift of the EELS edge toward lower excitation energies is clearly visible.

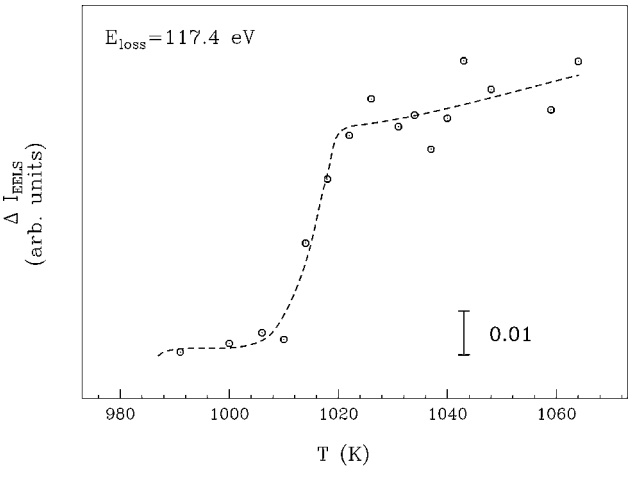

Fig. 3. Variation of the EELS intensity at fixed energy near the M_3 edge (E_{loss}= 117.4 eV). The surface phase transition is observed above 1010 K.

The present determination of the transition temperature is slightly lower than previously indicated (1040–1050 K). It has to be remarked that in previous works, temperature was measured with a pyrometer and sample was heated by direct application of a pulsed current. In these conditions the typical uncertainty for temperature was typically 20 K or worse. In some experiments (see ref. [9]) the transition was found to begin around 980 K. We believe that the present experiment represents probably the most clear observation of the surface phase transition and metalization of the Ge(111) under controlled conditions of temperature, and is likely to be one of the most accurate determinations of the transition temperature.

4. Conclusions

The metalization of the Ge(111) surface at high temperatures has been clearly detected by the shift of the EELS $M_{2,3}$ edges, associated with the disappearance of the gap. We developed a new UHV compatible high-temperature device suitable for EELS measurements with an accuracy of the temperature readout of about 5 K. The transition temperature was found to begin at about 1010 K with a typical width of 10 K. The probing depth of the electrons was about 10 Å.

This experiment shows that accurate EELS data collected using standard equipments can be successfully used to detect and study surface phase transitions. In particular, metalization of the surface can be clearly detected by the shift of the main edge. The accuracy in temperature measurements and fine temperature steps achieved in the present experiment suggest that the present experimental setup can be used for further studies of surface phase transitions. In particular, the energy dependence of the mean free path curve and the tunable energy could be used to study the progressive melting of inner layers.

Abstract

We observe and analyze a considerable enhancement of photoelectron intensity of the valence band features in solid B_2O_3 upon tuning the photon energy across the B $1s \rightarrow \pi^*2p_z$ resonance. This enhancement is an evidence of the strong 2p electron correlations in pre-edge photoionization dynamics in boron oxide. Such strength of the correlation is unusual for a solid, whose valence band is composed of only s and p electrons. We assign these effects to the considerable spatial localization of the highest occupied and lowest unoccupied electronic states of boron oxide on the BO_3^{3-} quasi-molecular anion, as well as to the strong 2p electron coupling between them. Solid state effects in the electronic structure and B $1s \rightarrow \pi^*$ decay dynamics are found to be minor, while molecular effects of the BO_3^{3-} fragment are dominating.

1. Introduction

The vast majority of solid compounds may be naturally considered as being built of chemically stable molecular-like atomic groups, which can be called quasi-molecules. They represent an atom (cation) connected to several more electronegative neighbours by strong covalent bonding. Often these groups have isoelectronic and isostructural counterparts among free molecules. It depends mainly on the strength of chemical bonding between quasi-molecules to what extent the compound "remembers" its molecular origin. Sometimes (for example in III-V binary semiconductors) the interaction between such groups becomes as strong as inside them, the electronic states in the valence and conduction bands become quite delocalized, and a quasi-molecular approach to the description of electronic structure becomes probably meaningless. However for many classes of solid compounds this approach is very instructive and helpful in getting qualitative understanding of their electronic structure. It is also easy-to-use, since it implies comparative analysis of spectra instead of excessive theoretical calculations.

Such quasi-molecular perception of solid compounds may become helpful also in revealing the nature of their core excitations. Recently we reported on the essentially molecular nature of N $1s \rightarrow a_2''(\pi^*2p_z)$ and O $1s \rightarrow a_2''(\pi^*2p_z)$ core excitations in solid $M NO_3$ (M = Li, Na), which are determined mainly by the NO_3^- quasi-molecule [1, 2] (here a_2'' is the lowest unoccupied molecular orbital (MO) of the N π^*2p_z character in the notation of the D_{3h} symmetry group). This is quite understandable, because NO_3^- anions are well separated from each other, and the rather ionic cation-anion bonding is weaker than the covalent bonding inside NO_3^-. Our goal in the present study is to investigate the case of a solid compound with stronger chemical bonding between its quasi-molecules in order to test the prospects of such quasi-molecular approach to the description of electronic structure and core excitations in a more general situation. As a suitable example we consider boron oxide B_2O_3 being particularly interested in its planar BO_3 group. This group (which can be considered as quasi-molecular anion BO_3^{3-}) has almost ideal D_{3h} symmetry, being hence almost isostructural and isoelectronic with NO_3^- in $M NO_3$ and with the gas-phase molecule BF_3. BO_3 is generally accepted as the main building block of both low-pressure forms of B_2O_3: hexagonal crystalline [3] and amorphous (vitreous) [4]. Contrary to quasi-isolated NO_3^- anions in $M NO_3$, BO_3 units in B_2O_3 are linked via their oxygen atoms into chains in both conformations (although the inter-chain linkage in crystalline and vitreous forms is different).

In this paper we apply NEXAFS (near-edge X-ray absorption fine structure) spectroscopy and RAS (resonant Auger spectroscopy) at the B 1s edge in order to demonstrate that the formation and decay of the B $1s^{-1}a_2''(\pi^*2p_z)$ excitation in B_2O_3 has essentially quasi-molecular origin in spite of the partly covalent bonding between BO_3 units. Our data differ in part from the results reported recently by Muramatsu *et al.* [5], possibly because of another sample preparation procedure and/or lower spectral resolution used in Ref. [5]. We discuss our absorption and resonant electron emission spectra in terms of strong 2p-coupling between electrons in the highest occupied and promoted to the lowest unoccupied states of the BO_3 quasi-molecule.

2. Experiment

All spectra were measured at the D1011 beamline at MAX II storage ring in MAX-lab, Lund, Sweden, using a modified SX-700 plane grating monochromator and a high-resolution SES-200 electron energy analyzer. The photon energy resolution was set to 150 meV at the B 1s edge; the kinetic energy resolution was set to 150 meV. The NEXAFS spectra were measured in the total electron yield (TEY) mode with an MCP detector. Thin (20–25 nm) B_2O_3 layers were prepared *in situ* by thermal evaporation of thoroughly dehydrated B_2O_3 powder (Alfa Aesar) from a water-cooled effusion cell onto a polished copper plate pre-cleaned by Ar^+ sputtering. The temperature inside the cell was set to 850 °C in order to ensure reasonable deposition rates of 0.5–0.7 nm/min. The layers produced in this way were found free of contaminations and charging only weakly. All electron spectra presented below are corrected in energy for these charging effects using the position of the B 1s photoline in the second-order light, which were recorded in the same scan as the valence band spectra. We

suppose that the deposited B_2O_3 films were rather amorphous than polycrystalline. Thermal evaporation resulted in a small fraction of decomposed (oxygen-deficient) species. The contribution of the decomposed species into the off-resonance valence band spectra was below 7%, while it was vanishing into the on-resonance spectra. For a comparison and as a check of stoichiometry of the resulting films we measured at the same experimental conditions also the B 1s NEXAFS in ultrapure B_2O_3 and H_3BO_3 powders (Alfa Aesar).

3. Results and discussion

B 1s NEXAFS spectra of B_2O_3 thin film and reference B_2O_3 and H_3BO_3 are shown in Fig. 1. Note that the unusual dip at 195 eV in the spectra of powders is probably due to the sample charging. In accordance with previous studies [6] we assign the strong resonance A at 193.95 eV in the spectrum of B_2O_3 to the transitions of B 1s electrons to the unoccupied π^*2p_z molecular orbital (MO) of the $BO_3{}^{3-}$ anion. The broad feature B at 202.5 eV is caused by electron transitions into $\sigma^*2p_{x,y}$ MOs. The spectra of B_2O_3 and H_3BO_3 powders are practically identical in the energy position, relative intensities and shape of all features. This implies a rather weak influence of the inter-molecular covalent O-O bonding on the formation of both B $1s^{-1}\pi^*$ and $1s^{-1}\sigma^*$ core excitations, because in H_3BO_3 the BO_3 groups are connected via bridging hydrogen atoms [3]. While it is not very surprising in the case of strongly localized pre-edge π^* excitation, it is rather unexpected for the σ^* excitation, providing strong support for a quasi-molecular description of solid B_2O_3.

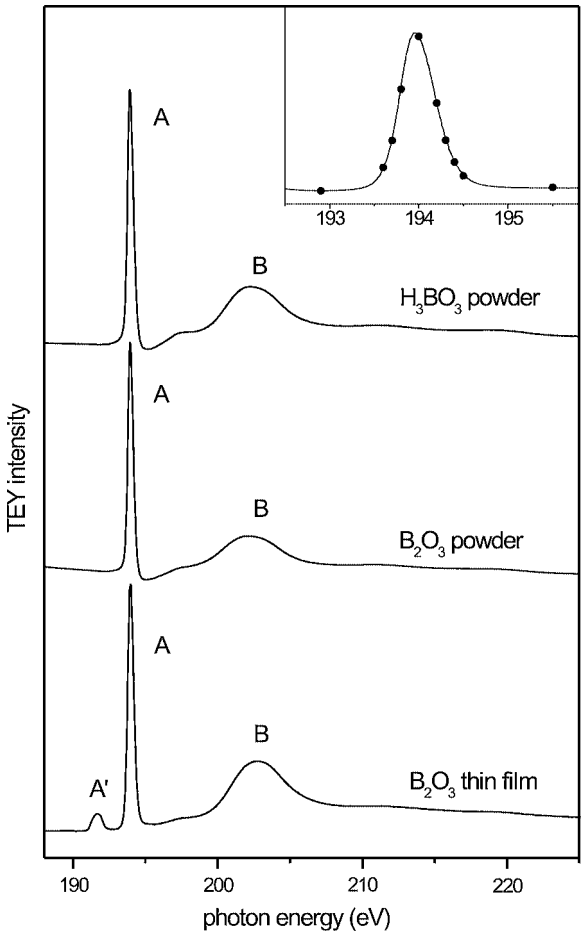

Fig. 1. B 1s NEXAFS spectra of the H_3BO_3 and B_2O_3 powder samples and of the B_2O_3 film prepared by thermal evaporation. Inset: B $1s \rightarrow \pi^*(2p_z)$ resonance measured from the B_2O_3 film; dots denote energies used for resonant excitation (Fig. 3).

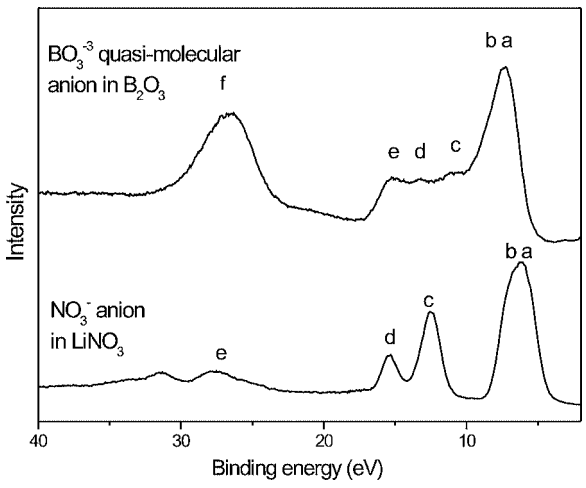

Fig. 2. Non-resonant photoelectron valence band spectra of solid B_2O_3 ($h\nu = 192.9$ eV) and $LiNO_3$ ($h\nu = 150.0$ eV).

In going from the spectra of reference powders to the spectrum of the deposited B_2O_3 film the spectral shape is generally preserved. It experiences only two minor changes: the charging-induced dip at 195 eV disappears and a decomposition-induced peak A′ at 191.7 eV arises. As discussed above, the fraction of decomposed species is small (below 7%) and does not influence further analysis. Close similarity between the overview spectra of the B_2O_3 film and the reference powder (not shown) provides evidence for stoichiometry of the investigated B_2O_3 layers.

Valence band structure of B_2O_3 was studied previously by photoemission and X-ray emission [5, 7, 8]. Fig. 2 shows photoemission valence band spectrum of our B_2O_3 film together with that of a $LiNO_3$ film measured for comparison in the same experimental conditions. In the spectrum of B_2O_3 feature a is commonly assigned to the non-bonding O 2p states, b-e is mainly due to the B 2p states with the contributions of O 2p into b, c and B 2s into e, and f is the O 2s photoline with an admixture of B 2p states. It should be noted that in all previous studies only three distinct features could be revealed in the upper valence band, while we definitely observed four features (a, c, d, e) at different photon energies, probably due to higher resolution and insignificant sample charging. Feature b is not resolved in the non-resonant spectra and can be found only by means of a systematic numerical analysis (not shown here). In Fig. 2 one can see significant similarities in the upper valence band structure of $LiNO_3$ and B_2O_3. The identification of the corresponding structures is also similar. Indeed, in analogy with $NaNO_3$ [1] we assign features a-b in the spectrum of $LiNO_3$ to the non-bonding O 2p states, c – to the mixture of N 2p, O 2p and O 2s states, d – to the mixture of O 2p, O 2s and N 2s states, e – to the mixture of O 2s and N 2p states. All these features have essentially quasi-molecular character and can be correctly described in terms of MOs of the NO_3^- anion [1, 2] Obvious similarities in the valence band structure between B_2O_3 and $LiNO_3$ allow us to assume that the valence band in B_2O_3 is also determined primarily by the electronic structure of the $BO_3{}^{3-}$ quasi-molecule, while the interaction between these units is much less significant. Another argument for the rather molecular character of the occupied electronic states in solid B_2O_3 is the close resemblance of the valence band spectra of B_2O_3

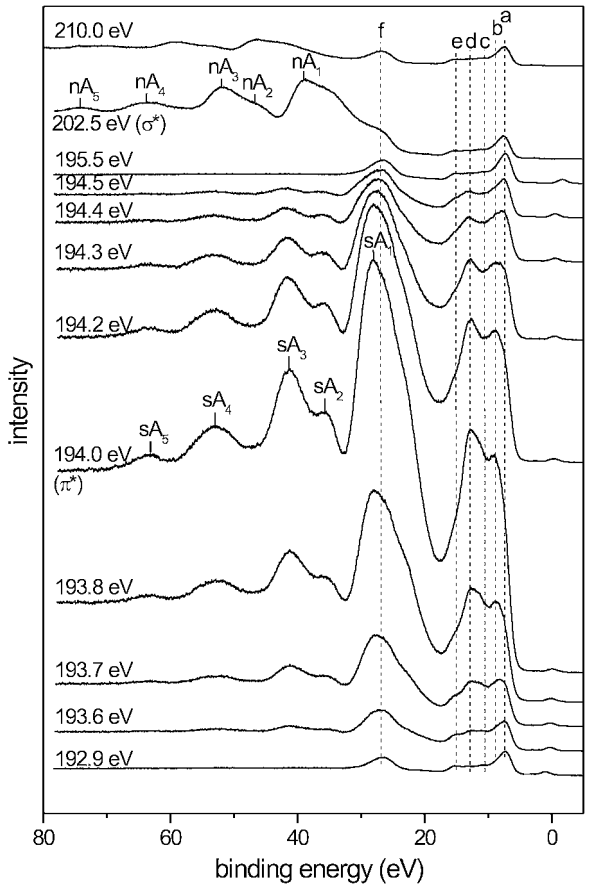

Fig. 3. Resonant Auger spectra of the valence band region of B_2O_3 measured with different photon energies across the B 1s absorption edge. The small peak close to 0 eV is due to the B 1s photoline in the second-order light.

and H_3BO_3 [8] and their B KVV Auger spectra [7] in spite of the essentially different bonding between BO_3 groups in these compounds.

The photon energy dependence of the B_2O_3 valence band spectra across the B 1s absorption edge is shown in Fig. 3. Most energies are chosen on the B $1s \rightarrow \pi^* 2p_z$ shape resonance (denoted by dots in the inset of Fig. 1). The spectra are normalized in intensity to the incident flux and are referred in energy to the Fermi level of the spectrometer. The on-resonance spectrum at 194.0 eV resembles that presented in Ref. [5], whereas off-resonant spectra look differently and resonant enhancement of the upper valence band features is much stronger in our spectra, probably due to considerably better resolution. Note also that the off-resonance spectra before and after the π^* peak (at 192.9 eV and 195.5 eV, respectively) are quite similar both in shape and intensity, which is not the case in Ref. [5].

Two types of spectral features can be clearly identified in the resonant Auger spectrum at 194.0 eV. The first type is due to resonant enhancement of the valence band signals a-f in course of the participator Auger (PA) process, while the second type of features (sA_1-sA_5) results from the spectator Auger (SA) process. In going from π^* to σ^* excitation (at 202.5 eV) PA features disappear completely, while SA features become practically identical with those of the normal Auger (NA) process being denoted nA_1-nA_5 in Fig. 3. All SA signals are shifted by 1.8 eV to higher kinetic energies relative to the corresponding NA ones (so-called spectator shift) due to the screening effect of the spectator electron. Besides that the SA features become narrower and experience changes in their relative intensities. Some additional contribution to the intensity of peak sA_1 may yield the PA enhancement of photoline f, though this effect is probably weak due to rather minor contribution of the B 2p states. The most interesting resonant effect, which can be seen in Fig. 3, is a drastic increase in intensity of the upper valence band signal (binding energy 4–19 eV) upon tuning photon energy across the B $1s \rightarrow \pi^* 2p_z$ resonance. Although a thorough analysis of this effect will be given elsewhere, several notes can be made now. First, the overall PA intensity enhancement in this spectral range (as computed after subtraction of a smooth monotonous background) is as great as by a factor of 27. Second, our numerical analysis (not shown) allows us to suggest that feature a, which is due to the non-bonding O 2p states, is enhanced at resonance just very weakly. Third, the strongest contribution to the overall enhancement gives feature d, which results primarily from the transitions into B 2p states. It should be noted that in ionic-molecular crystals $M NO_3$ (M = Li, Na) the situation with PA decay of the N $1s^{-1}\pi^*$ excitation is very similar [1, 2]. Since in $M NO_3$ it is determined exclusively by the quasi-isolated NO_3^- anion and not by the crystal, the situation should be similar in B_2O_3, where the PA decay of the B $1s^{-1}\pi^*$ excitation has to be determined by the BO_3 group despite the inter-molecular linkage.

The strength of the PA decay of the B $1s^{-1}\pi^*$ excitation observed in B_2O_3 is quite unusual for the solids with valence bands composed of only s and p electrons. Among other prominent examples of that kind one can mention the decay of the B $1s^{-1}\pi^*$ excitation in hexagonal BN [9] and already mentioned PA decay of the N $1s^{-1}\pi^*$ excitation in $M NO_3$ [1, 2]. In all these materials strong 2p electron correlations in pre-edge photoionization dynamics have been documented. These strong correlations result from the fact that the upper occupied and lower unoccupied electronic states in these solids are essentially localized on the corresponding quasi-molecular fragments and strongly coupled to each other. In general, our results for B_2O_3 show that the BO_3^{3-} fragment determines the electronic structure and the nature of formation and decay of the B $1s^{-1}\pi^*$ core excitation almost exclusively, in spite of the partly covalent bonding between BO_3 quasi-molecules.

Abstract

High resolution investigations of polycrystalline FeF_2 and FeF_3 were performed by means of X-ray absorption and resonant X-ray fluorescence spectroscopy. The obtained F Kα fluorescence spectra of ionic FeF_2 and FeF_3 were analysed in comparison with the F Kα spectrum of the covalent anion TiF_6^{2-} in solid K_2TiF_6. The F Kα spectra of compounds under study consist of the main band accompanied by a low-energy shoulder. The latter can be associated with the valence subband of the Fe 3d – F 2p hybridized electron states. Strong high-energy shake-up satellites were observed in the F Kα spectra of these compounds when the excitation energy exceeds the F 1s ionisation threshold (∼690 eV). Information about local partial densities of states for FeF_2 was obtained from a comparative analysis of Fe L and F K X-ray fluorescence and valence-band photoemission spectra.

1. Introduction

Spectroscopic characterization of covalence bonding (hybridization) effects in the electronic structure of 3d transition metal (TM) compounds has a long history, but remains an issue of great fundamental interest. The hybridization between 3d electrons of the TM atom and *n*p electrons of the ligands is known to be responsible for the spatial delocalization of the 3d electron wave function. These effects can be studied by soft X-ray fluorescence (XF) spectroscopy, which is a site and symmetry selective and bulk sensitive tool, commonly used in investigations of electronic structure of matter. In contrast to electron spectroscopies, XF allows to easily probe insulators, since both the exciting and the analyzed particles (photons) are neutral. Nowadays XF becomes more and more popular due to the advent of high-brilliance synchrotron radiation (SR) sources (for review see, e.g., [1]). Tuning excitation energy across a particular absorption threshold may result in changes in XF spectra (resonant XF). In the case of TM compounds these changes provide information on the interplay between intra-atomic Coulomb interaction and interatomic hybridization [1].

The present work is aimed at investigating the hybridization-related features of the valence electron spectra of FeF_2, FeF_3 and K_2TiF_6 by means of resonant soft X-ray fluorescence and X-ray absorption spectroscopy (XAS). The electronic structure of TM fluorides, the most ionic of TM compounds, may provide important reference information for understanding the more complicated electronic structure of covalent TM compounds. We mainly focus on the F Kα and non-resonant Fe Lα fluorescence spectra examining the effect of the TM 3d – F 2p hybridization (resonant Fe $L_{2,3}$ fluorescence spectra will be presented elsewhere). The obtained F Kα spectra of ionic compounds FeF_2 and FeF_3 are analyzed in comparison with the F Kα spectrum of the covalent anion TiF_6^{2-} in solid K_2TiF_6. Furthermore, the F Kα spectra of solid ionic fluorides are particularly suitable for studying the effect of shake-up satellites on the lineshape of the emission spectra as a function of the exciting photon energy [2, 3]. Note that in all compounds under study the TM atom is coordinated in a similar way (octahedrally) to the fluorine atoms.

2. Experiment

The experiments were performed at the "bulk" branch of the undulator beamline I511 at the MAX II storage ring [4]. The powder samples (Alfa Aesar) were fixed on the carbon-tape strips attached to the sample holder. The modified SX 700 monochromator of this beamline was operated with a photon-energy resolution of 0.4 eV at the F K and the Fe $L_{2,3}$ edges. The soft X-ray absorption spectra were measured in the total electron yield mode and normalized to the incident photon flux. The X-ray fluorescence spectra were recorded using a high-resolution grazing-incidence X-ray spectrometer XES 300 with a resolution of 0.9 eV at the F K and the Fe $L_{2,3}$ edges. The optical axis of the X-ray spectrometer was set perpendicular to the beamline axis in the plane of polarization of the incident radiation in order to reduce the intensity of the elastically scattered peak. The angle between the sample normal and the spectrometer axis was 30°. The energy calibration of these spectra was done using the measured positions of the elastically scattered peak and the known position of the Fe Lα band for metallic Fe (705.0 eV [5]).

3. Results and discussion

A comparison between K_2TiF_6 and iron fluorides is quite natural, because the quasi-isolated covalent molecular anion TiF_6^{2-} (the main building block of K_2TiF_6) is almost isostructural with the FeF_6 octahedron. Fig. 1 shows high-resolution F 1s and Fe 2p X-ray absorption spectra of K_2TiF_6, FeF_3 and FeF_2. The F 1s absorption spectra of compounds under study can be divided in two spectral ranges, whose structural features are similar for all spectra. The first range consists of narrow resonance-like peaks a (a′) and b (or/and b′) located below the F 1s ionization threshold (∼690 eV) [6]. The second range is dominated by broader absorption bands c, d and e located slightly above the ionization threshold and significantly overlapping with each other. The crystal structure of all fluorides studied in the present work can be considered as three-dimensional arrays of interlinked (FeF_2 and FeF_3) or quasi-isolated (K_2TiF_6) MF_6 octahedra (M = Ti, Fe), which can be slightly (FeF_3) or strongly (FeF_2) distorted [7]. We suppose that not only in the ionic-molecular K_2TiF_6 crystal, but also in the rather ionic iron fluorides it is the MF_6 octahedra that determine the electronic structure, while the inter-octahedra

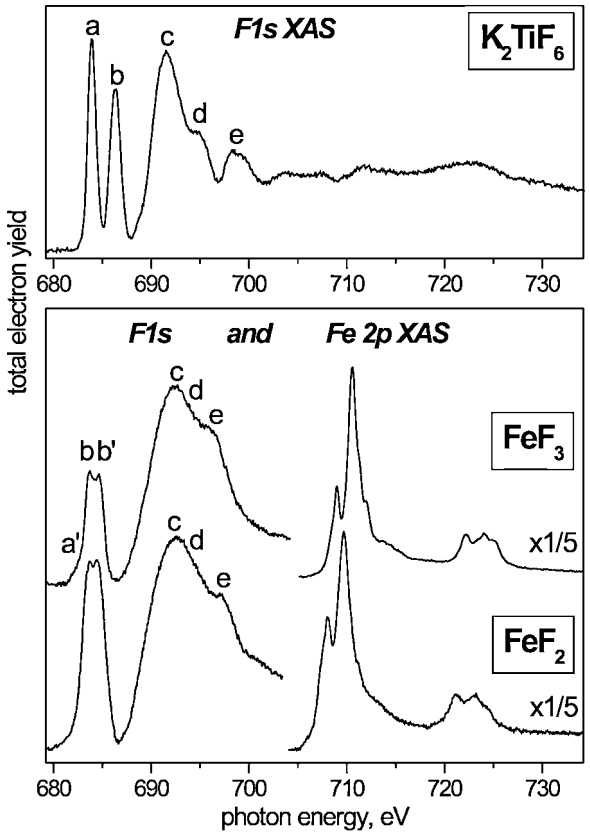

Fig. 1. X-ray absorption spectra of K_2TiF_6, FeF_3 and FeF_2.

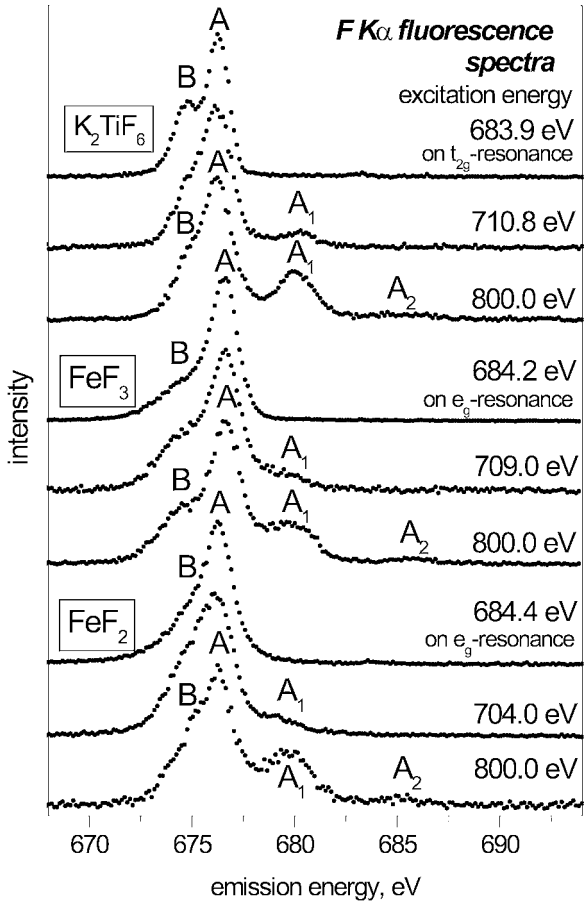

Fig. 2. F Kα X-ray fluorescence spectra of K_2TiF_6, FeF_3 and FeF_2 taken at the resonant and non-resonant excitation energies. The spectra are normalized to the same intensity of band A.

interaction is of less importance [6]. Covalent bonding between the 3d atom and the surrounding fluorine atoms can occur inside the octahedron due to mixing of the metal 3d, 4s,p and the fluorine 2p electron states. Indeed, the narrow resonance-like peaks a (a′) and b (b′) located below the F 1s ionization threshold in K_2TiF_6, FeF_3 and FeF_2 reflect the F 1s electron transitions into the empty t_{2g} and e_g electron states, which have hybridized F 2p – metal $3dt_{2g}$ and metal $3de_g$ origin, respectively [6, 8]. The following broad bands c-e located slightly above the F 1s threshold are caused by electron transitions into the unoccupied F 2p states which are hybridized with the metal 4s,p electron states. The similar shape of the Fe 2p absorption spectra of FeF_2 and FeF_3 results from the similar (octahedral) coordination of the Fe atom in these compounds [6, 8].

The effect of hybridization can also be demonstrated by comparison of the soft X-ray fluorescence spectra of K_2TiF_6, FeF_3 and FeF_2 excited by photons with resonant and non-resonant energies. As seen in Fig. 2 the F Kα spectra of the covalent molecular anion TiF_6^{2-} (in solid K_2TiF_6) and of the ionic compounds FeF_3 and FeF_2 are quite similar to each other revealing the main band A with a low-energy shoulder B. The energy position of A (676.2 eV for K_2TiF_6, 676.3 eV for FeF_2 and 676.6 eV for FeF_3) shows no appreciable change with the photon energy across the F 1s edge. In contrast to these spectra of the 3d TM compounds, the F Kα spectra of more ionic compounds KF and NaF are known to be dominated by only one main band that is located at the energy of band A [3, 9]. Indeed, the valence band of highly ionic fluorine compounds like KF and NaF is mainly of the F 2p character. Therefore, the corresponding fluorescence spectra consist of only one narrow band, which represents the dipole allowed transitions of the valence-band 2p electrons to the 1s core hole of the F^- anion. The energy position of this band reflects the energy separation between 1s and 2p levels of the F^- anion and undergoes no significant changes upon cation substitution. In iron fluorides the valence-band F 2p electron states can be divided into two partly overlapping bands. The energy position of the high-energy band A correlates well with the F Kα energy position in XF spectra of alkali fluorides and can be associated with the transitions from almost purely ionic F 2p states. On the other hand, the F Kα spectrum of the covalent molecular anion TiF_6^{2-} is very similar to that of iron fluorides. Thus, we associate shoulder B in the F Kα spectra of compounds under study with transitions from the valence subband of the metal (Fe, Ti) 3d – F 2p hybridized electron states. A similar hybridization related feature was observed in the O Kα emission spectra of TM oxides [10] and also in the S $L_{2,3}$ spectra of metal sulfides [11].

The XF spectra of K_2TiF_6, FeF_3 and FeF_2 vary differently at the energies of the t_{2g}- and the e_g-absorption resonances. The low-energy shoulder B in the spectrum of the covalent anion TiF_6^{2-} resonates appreciably as compared to the ionic iron fluorides and the energy separation between A and B is larger for K_2TiF_6 and FeF_3 (∼1.6 eV) than for FeF_2 (∼1.3 eV). The difference in the energy separation can originate from the fact that in the case of TiF_6^{2-} and FeF_3 the coordination octahedron is nearly perfect in contrast to the distorted octahedron in FeF_2. The higher intensity of the shoulder B in the resonant XF spectrum of TiF_6^{2-} comparing with that of the iron fluorides results from the stronger metal 3d – F 2p hybridization as well as the higher localization of the electron states in K_2TiF_6 than in FeF_3 and FeF_2.

At excitation energies about 15–20 eV higher than the F 1s ionization threshold high-energy shake-up satellites A_1 and A_2

begin to appear in the F Kα spectra of K_2TiF_6, FeF_3 and FeF_2 (Fig. 2). At energies of incident photons about 800 eV features A_1 and A_2 become quite intense. These shake-up satellites are due to the excitation process (initial-state satellites), since satellites caused by the emission process would have energies lower than the main bands. Shake-up satellites in the low-energy regime (i.e., only a few eV above the threshold) were observed first by Wassdahl *et al*. in resonant $L_{2,3}$ X-ray fluorescence from Cu and Zn metals [12]. Our observation of strong initial-state shake-up satellites in the F Kα spectra of all studied compounds confirms the validity of the sudden approximation for our systems even at low-energy excitations. This result follows the conclusion derived in Ref. [12] for Cu and Zn metals. The intensities of the shake-up satellites are known to rise with increasing excitation energy and to reach their maximum values for X-ray emission induced by high-energy electron or ion impact [9, 13]. To avoid distortion of the spectral shape for valence-band analysis the XF spectra should be excited with photon energies just slightly above the ionization threshold.

In Fig. 3 we compare the F Kα emission bands of FeF_2 and FeF_3 recorded at 684.4 eV (the resonance spectrum has been chosen in the case of FeF_2, because the shake-up satellite A_1 appears already at the excitation energy of 690 eV) and 697.5 eV, respectively, Fe Lα emission bands recorded at the excitation energy of 750.0 eV with the Fe $2p_{3/2}$ and F 1s absorption spectra of iron fluorides. The valence-band X-ray photoemission (XPS) spectrum of FeF_2 single crystal taken from Ref. [14] is shown by the dashed line. The XF and XAS spectra are aligned in the binding-energy scale using XPS binding energies of the core levels measured in the present study: E(Fe $2p_{3/2}$) = 712.1 eV, E(F 1s) = 684.9 eV for FeF_2 and E(Fe $2p_{3/2}$) = 714.5 eV, E(F 1s) = 685.0 eV for FeF_3.

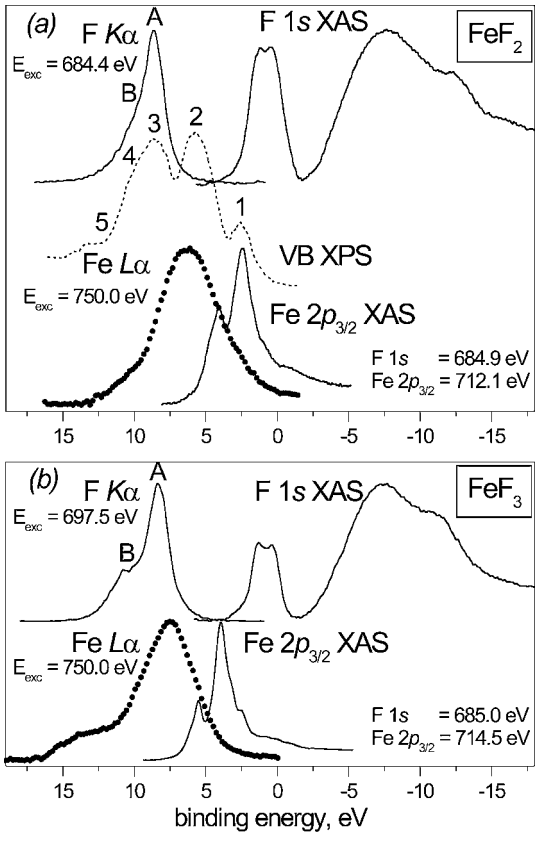

Fig. 3. Comparison of the Fe Lα-, F Kα-fluorescence and Fe $2p_{3/2}$-, F 1s-absorption of FeF_2 (a) and FeF_3 (b). Dashed line shows the valence-band photoemission spectrum of FeF_2 single crystal [14].

As seen in Fig. 3(a) the valence band of FeF_2 consists of three subbands: the upper subband (peak 2) is dominated by the Fe 3d electron states, the middle subband (peak 3) is dominated by the F 2p electron states, while the lower one (shoulder 4 and peak 5) is dominated by the F 2p electron states hybridized with the Fe 3d states (peak 1 is due to final-state multiplets [14]). The same valence-band structure can be derived from comparison of the XF and the XAS spectra for FeF_3 in Fig. 3(b). However, the relative energy positions of the subbands connected with the pure Fe 3d and F 2p electron states and with the hybridized Fe 3d – F 2p electron states differ a little for FeF_3 compared to that for FeF_2. The low-energy shoulder in the Fe Lα XF spectra of iron fluorides is caused also by the Fe 3d – F 2p hybridization.

The overall similarity of the corresponding XF (XAS) spectra of FeF_2 and FeF_3 reflects resembling structure of occupied (unoccupied) electron states for both fluorides. This similarity is surprising in the framework of different ionic-multiplet approaches because of quite different electronic configurations expected for Fe(II) and Fe(III) compounds in the initial, intermediate and final states. However, it can easily be understood within the framework of a quasi-molecular (FeF_6) approach to the electronic structure of FeF_2 and FeF_3. Indeed, if the electronic structure is determined mainly by the FeF_6 octahedra, while the way they are inter-linked is less critical, the spectra should look similar. An important point of this approach is the inclusion of the covalent mixing between the iron and fluorine valence electron states inside the FeF_6 quasi-molecule.

In conclusion, the X-ray fluorescence and the X-ray absorption measurements carried out for the iron fluorides FeF_3 and FeF_2 in comparison with the covalent molecular anion TiF_6^{2-} (in solid K_2TiF_6) demonstrate the significant role of the Fe 3d – F 2p hybridization (covalence bonding) in these ionic compounds. This hybridization effect is responsible for the double-band spectral shape of the F Kα and Fe Lα fluorescence spectra.

Abstract

The sulfur K-edge X-ray absorption near edge spectra (XANES) of the hexakis(dimethyl sulfoxide) solvated trivalent group 13 ions, Al, Ga, In and Tl, in the solid state show larger splitting and different intensity distribution of the main sulfur 1s electronic excitations than for the uncoordinated dimethyl sulfoxide molecule. The transitions have been interpreted by density functional calculations, and the increased splitting is shown to be an effect of metal-oxygen orbital interactions in the bonds to the oxygen coordinated dimethyl sulfoxide ligand.

1. Introduction

The hexakis(dimethyl sulfoxide) solvates of the group 13 metal ions aluminium(III), gallium(III), indium(III) and thallium(III), were previously structurally characterized in the solid state as iodides or perchlorates by crystallography, EXAFS and vibrational spectroscopy (Table I) [1–3]. In the present study, sulfur K-edge XANES spectra are presented for dimethyl sulfoxide, free or as ligand to the group 13 metal ions. Dipole-allowed excitations of the sulfur 1s electron to unoccupied molecular orbitals with some p-character in bound states, dominate the absorption features in the near-edge region, and provide sensitive probes of the bonding because of the relatively narrow line widths and wide energy range. We found significant changes in the sulfur K-edge spectra of dimethyl sulfoxide even for coordination *via* the oxygen atom by the group 13 metal ions (Figure 1).

2. Experimental

Sulfur K-edge XANES spectra were recorded in fluorescence mode on beam line 6-2 of Stanford Synchrotron Radiation Laboratory (SSRL), under dedicated conditions (3 GeV and 75–100 mA). The beam path and sample were kept in helium of atmospheric pressure. A Lytle detector without filter and Soller slit was used for detection of the fluorescence signal from the sample. The X-ray energy was varied using a fully tuned Si(111) double monochromator with the energy scale calibrated by setting the lowest energy peak of sodium thiosulfate ($Na_2S_2O_3 \cdot 5H_2O$) to 2469.2 eV [4]. Higher order harmonics were rejected by means of a nickel-coated mirror. The instrumental broadening of the spectral features is about 0.5 eV. Finely ground metal salts, prepared as described elsewhere [2, 3], were dispersed as a thin layer on a sulfur-free Mylar adhesive tape. A cell with 5 μm sulfur-free polypropylene film windows was used for a 50 mM solution of DMSO in acetonitrile. The data were analyzed using the EXAFSPAK suite of computer programs [5], and normalized intensity spectra are presented in Figure 2.

3. Computational details

Theoretical sulfur K-edge transitions were calculated for dimethyl sulfoxide molecules, free and with different types of simulated coordination (Table II), to assign the transitions observed in the experimental spectra. The computations were performed by means of the deMon StoBe density functional theory (DFT) program, using non-local gradient-corrected functionals throughout [6].

The overall spectrum was first generated by the transition potential DFT method [7], where the potential used to determine the excited states is by exciting half an electron from the 1s orbital. The differential relaxation effects on each excited state were computed separately by Kohn-Sham's excited state (ΔKS) DFT calculation method [8]. The relativistic effect was calculated to shift the ionization potential 7.4 eV for the sulfur K-edge, and was applied as an overall shift of the spectrum. Absolute energies corrected in this way in previous computations show satisfactory agreement with the experimental calibration used (see above) [8].

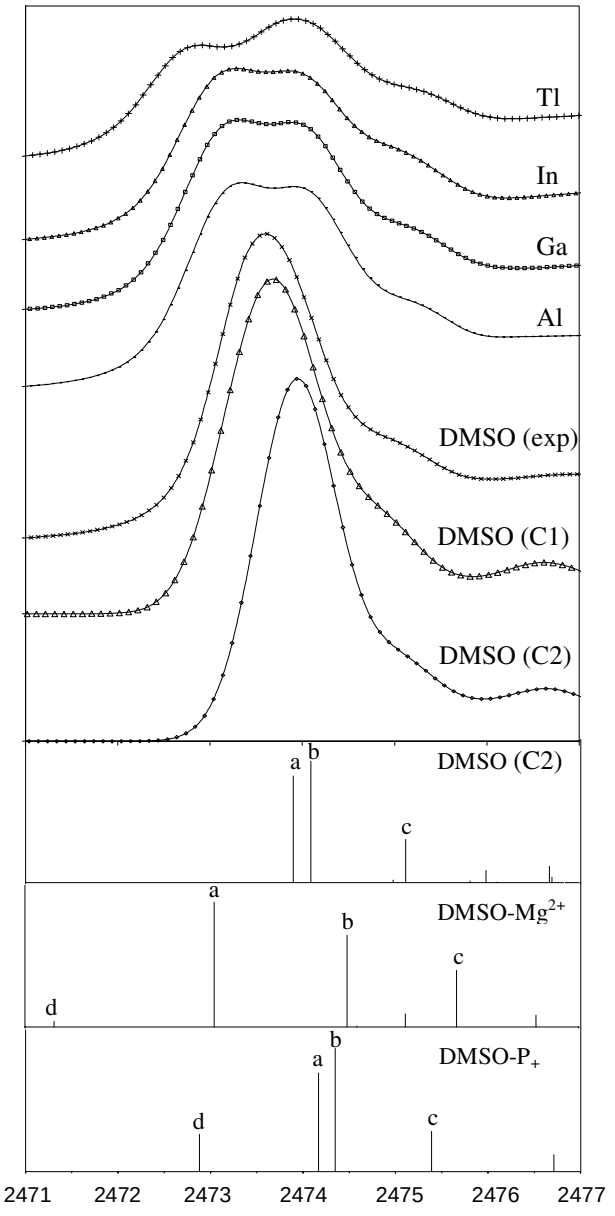

Fig. 2. Experimental sulfur K-edge XANES spectra (normalized intensities) of the hexakis(dimethyl sulfoxide)-M(III) solvates of the group 13 metal ions (from the top M = Tl, In, Ga and Al), and of 50 mM DMSO in acetonitrile. Below calculated spectra for free DMSO, C1 with the S-O distance 1.595 Å, and C2 with 1.495 Å (*cf*. Table II). The rows vertical bars represent the calculated energies and cross-sections for the X-ray induced excitations of the sulfur 1s electron for free DMSO (C2), for DMSO connected to an Mg^{2+} ion, and to a +1 point charge P_+, respectively.

Table II. *Interatomic distances (Å) and angles (°) used in the computation of spectra for free (C1 & C2) and coordinated (M) = Mg^{2+} or P_+) DMSO. P_+ represents a point charge +1.*

	Free	Coordinated
O-S	1.495 & 1.595	1.544
S-C	1.773	1.773
O-S-C	105.7	105.7
M-O	—	2.0
M-O-S	—	125

However, another calibration scheme with the thiosulfate peak set to 2472.02 eV, i.e. +2.8 eV, is also in use [9].

To simulate the interaction between a metal ion and a dimethyl sulfoxide ligand, we have computed the spectra of models with a point charge +1 (P_+) or an Mg^{2+} ion located at a possible coordination site relative to the oxygen atom of the DMSO molecule (Table II). In all calculations, C_s symmetry was assumed. For sulfur the iglo basis of Kutzelnigg was used in order to describe relaxation effects upon core-excitation [10]; this was extended with a very large, diffuse additional basis set for the evaluation of the spectra in a double-basis set approach. The basis sets used were for oxygen and carbon TZVP ((6311/311/1)), for hydrogen (311/1) and for the magnesium ion DZVP (6321/411*/1). The auxiliary bases (5,4;5,4) were introduced for sulfur and magnesium, (5,3;5,3) for oxygen and carbon, and (4,2;4,2) for hydrogen, where the nomenclature ((N_C(s), N_C(spd); N_{XC}(s), N_{XC}(spd)) indicates the number of s and spd-type functions that were used to fit and expand the Coulomb and exchange-correlation potentials, respectively.

4. Results and discussion

The sulfur K-edge XANES spectrum of dimethyl sulfoxide in solution shows an asymmetric peak at about 2473.5 eV with a shoulder at 2475 eV. These features are well explained by the three main calculated transitions (*a*, *b*, *c* in Fig. 2). By applying a Gaussian 1.0 eV broadening of the calculated features up to the computed ionisation potential, followed by a linear increase up to 8 eV over a 10 eV interval from the edge, the calculated curves C1 and C2 result, with a similar shape as the experimental (Figure 2). The calculated (gas phase) spectrum C2 is shifted 0.5 eV relative to the experimental solution spectrum. This shift may be caused by uncertainties in the calculated energy or the experimental calibration [4, 9]. Also, dipole-dipole interactions between the DMSO molecules in the acetonitrile solution may influence the shift, even though a large increase in the S–O bond length (0.1 Å, *cf*. Table II) would be needed to eliminate this shift (C1 in Fig. 2) .

The shapes of the excited state molecular orbitals (MO) show, for the strongest *b* transition (of A″ symmetry species in the C_s point group, *cf*. Fig. 3) excitation of the sulfur 1s electron to an antibonding MO of p character, and for the *a* and *c* transitions (of A′ symmetry) charge transfer from sulfur to the carbon and oxygen atoms.

The site symmetry of the crystalline $[M(dmso)_6]^{3+}$ solvates implies all six oxygen-bonded dimethyl sulfoxide ligands to be equivalent (Fig. 1). The sulfur K-edge XANES spectra for the Al, Ga and In solvates are similar with a slight increase in the splitting between the two main peaks from about 0.7 to 0.8 eV. For the Tl(III) solvate the split increases to 1.5 eV (Fig. 2). To simulate the effect on a coordinated DMSO ligand an Mg^{2+} ion was placed 2.0 Å from the oxygen atom in a similar position as the metal ions in the hexasolvates (Table II). The distance is chosen, based on previous DFT calculations [11], to give a reasonable balance between the electrostatic attraction and the Pauli repulsion effects between the orbitals in the M-O bond.

The Mg^{2+} ion shifts the transition *a* about 1.5 eV to lower energy, and increases its probability to slightly higher than that of *b* (Fig. 2). The orbital character of *a* becomes clearly antibonding with increased charge on the oxygen atom (Fig. 3). The *b* and *c* transitions increase only slightly in energy, and satisfactorily explain the features at 2474 and 2475.3 eV,

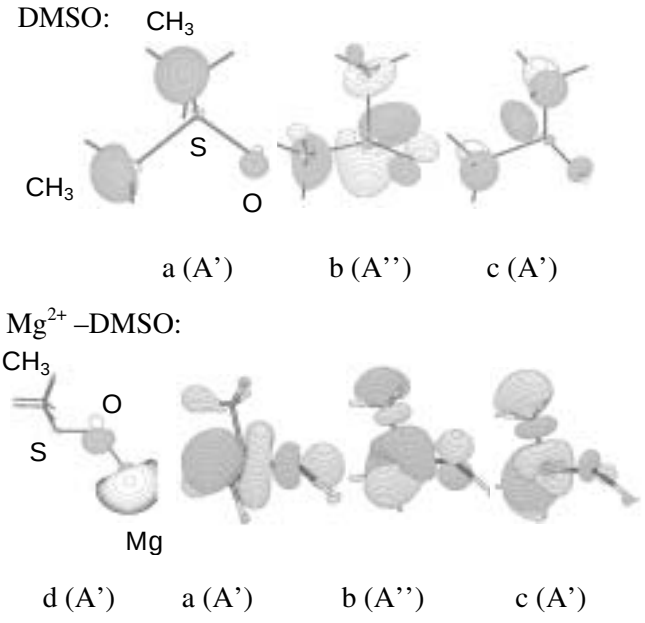

Fig. 3. Electron density contours for MO:s (different gray tones indicate different phase) corresponding to the one-particle excitations in Figure 2 of the sulfur 1s electron in: (top) free DMSO; (bottom) DMSO coordinated to an Mg^{2+} ion at a distance of 2.0 Å (*cf*. Table II).

respectively, which are found throughout the experimental spectra. A new weak transition (*d*) that appears at low energy (2471 eV), corresponds to charge transfer from sulfur to the magnesium ion, as shown by the orbital shapes in Figure 3.

To assess the importance of interatomic orbital interactions versus pure electrostatic effects the Mg^{2+} ion was replaced with a point charge (+1). The main effect is that the charge transfer transition *d* is less shifted but gains intensity, while the transitions *a*, *b* and *c* remain similar in energy and intensity to those in the free DMSO molecule (Figure 2). Thus, the orbital interactions induced by the M-O bond seem to cause the observed splitting in the spectra. The gradual increase in covalency from Al to In is only reflected in a small increase in the split between the main transitions, with the Tl(III) sulfur XANES spectrum clearly deviating from that trend. Thus, the large split in the Tl(III) spectrum indicates a substantial increase in the orbital interaction. Even though the Tl-O bond is the longest of the group 13 M-O bonds, it is the most covalent [3]. This is indicated by e.g. the trends of the vibrational force constants, the M-O-S angles and the S-O bond length (Table I). For the thallium(III) solvate the disorder parameters indicate vibronic mixing in the M-O bonds of the $5d_z^2$ and 6s orbitals, which are close in energy [2]. It seems probable that the isoelectronic hexakis(dimethyl sulfoxide) mercury(II) solvate, which is affected by vibronic mixing (or pseudo Jahn-Teller effect) to a higher extent [2], would show an even larger split in its sulfur spectrum (not studied yet).

5. Conclusions

The orbital interactions in the M-O bonds are the reason for the increase in the splitting observed between the main electronic transitions in the sulfur K-edge spectra of DMSO as oxygen coordinated ligand to a metal ion. The large splitting in the hexakis(dimethyl sulfoxide) thallium(III) solvate is probably connected to the close energy levels causing vibronic mixing between valence shell atomic orbitals in the Tl-O bonds.

Abstract

The Ti Kα″ satellite was investigated using a Johann-type spectrometer at the BL15XU undulator beam line, SPring-8. Ti Kα spectra were measured varying the excitation energy between 4996 eV and 10000 eV. The relative intensity of the Ti Kα″ satellite to that of the $K\alpha_{1,2}$ abruptly increases from 0% to 1.2% within 10 eV around 5010 eV. This indicates that shake-up process is likely to be concerned with creation of a 3p spectator hole which induces the Kα″ satellite. Onset energy of the satellite appearance experimentally determined is 5005 eV, and this value corresponds to the [1s3p] double ionization threshold energy in $Z + 1$ approximation. The experimental results of this work confirm that the origin of the Kα″ satellite is a 3p spectator hole as predicted by Scott theoretically.

1. Introduction

It is well-known that many satellite lines of X-ray emission spectra can be attributed to multi-electron excited states. For example, the $K\alpha_{3,4}$ satellite lines orginate from a $[1s2p] \rightarrow [2p^2]$ transition [2, 4]. Kα″ is the satellite which appears on the high energy side of the $K\alpha_1$ peak in elements having an atomic number of around 20. In 1936 Parratt measured the Kα″ spectra of all the $16 \leq Z \leq 23$ elements except argon changing the tube voltage [1]. He concluded that the origin of the Kα″ satellite was a KM → LM transition. But he did not specify what subshell contributes to the satellite. That may be because the energy distribution of the incident electron beam was widely spread. In 1986, half a century after Parratt's work, Scott theoretically predicted, using non-relativistic single configuration Hartree Fock calculation, that a 3p spectator hole is the origin of the Kα″ satellite [3].

On the other hand, the advent of the third generation synchrotron facilities provides us with intense well-tuned incident X-rays, very useful for investigations on evolutions of satellites associated with multi-electron excited states. Taking advantage of synchrotron radiation, some interesting work on evolution of satellites was made in the last decade. Fritsch *et al*. and Sternemann *et al*. investigated the evolution of the Cu $K\alpha_{3,4}$ satellite lines and that of the Ge Kβ‴ satellite lines respectively [4, 5]. Most recently, the dependence of the Cu $K\alpha_{1,2}$ profile on the excitation energy around 1s ionization threshold was studied by Galambosi *et al*. discussing the contribution of a 3d spectator hole [6]. This work is important not only because it elucidates the origin of the satellites but also because it provides us with information on how the probabilities of the shake processes depend on excitation energy.

Considering the situation described above, it seems significant to make investigations on the evolution of the Kα″ satellite in order to confirm experimentally that its origin is a 3p spectator hole as predicted by Scott. In the present work, the Ti Kα spectra were measured changing excitation energy from onset (a threshold for [1s3p] ionization) in the adiabatic to saturation in the sudden approximation limit. Our results indicate that the orgin of the Kα″ satellite is a [1s3p] double hole state produced by shake processes.

2. Experiment

The measurements were carried out at the BL15XU undulator beam line in SPring-8. To get monochromatic X-rays for excitation, a Si(111) double crystal monochromator with a bandpass of $\delta E/E \sim 10^{-4}$ was used, and the flux obtained was over 10^{12} photons/s. The sample was a pure Ti plate with a thickness of 1 mm.

The spectrometer employed was a Johann-type spectrometer whose Rowland circle radius was 750 mm. The signal was collected using a CCD detector of horizontally 1340 pixels × vertically 400 pixels (Roper Scientific Model LCX-400). A Be window with a thickness of 800 μm was placed in front of the CCD chip to cut visible lights and prevent the CCD chip from contact with air. The surface of the CCD chip tangentially touches the Rowland circle.

Besides measurements of the Ti Kα spectra, dark current was also measured every three hours. The exposure time for one frame was 10 seconds and 100 or 200 frames were acquired at each excitation energy while 100 frames were acquired for dark current. For each spectrum contribution of dark current was subtracted using corresponding dark current data.

A Johann-type spectrometer equipped with a position sensitive detector permits measuring data over the investigated energy range without scanning the 2θ angle formed by sample, analyzing crystal and detector. Si(220) crystal was used to analyze fluorescence X-rays with a detector of 26.8 mm length, which means the effective energy range of the detector is ∼75 eV at $2\theta = 91.42^\circ$ except for an inactive region at both ends of the CCD chip. With this effective energy range of the detector, the Ti $K\alpha_{1,2}$ and Kα″ spectra can be measured with one shot of the CCD at $2\theta = 91.42^\circ$ where the Ti $K\alpha_1$ (4508.4 eV) peak is located at the center of the effective energy range of the detector.

3. Data Analysis

Five Lorentzians were fitted to the measured Ti Kα spectra. Each Lorentzian corresponds to the $K\alpha_1$(diagram line), the $K\alpha_2$(diagram line), the $K\alpha_1$ satellite on the low-energy side of the $K\alpha_1$ peak, the $K\alpha_2$ satellite on the low-energy side of the $K\alpha_2$ peak, and the Kα″ satellite, respectively. Two satellites on the low-energy side of the $K\alpha_{1,2}$ peaks on copper were discussed by Deutsch *et al*. [7], Ito *et al*. [8], and Galambosi *et al*. [6] suggesting that they were the satellites originating from a

*Email address: yosi@elec.kuicr.kyoto-u.ac.jp

[1s3d] → [2p3d] transition. Both the position and the width of each fitting component were fixed and only its intensity scale factor was refined in the fit. Fixed values for Lorentzians except for that of the Kα″ satellite were determined by fitting four Lorentzians to the $K\alpha_{1,2}$ spectrum measured at an excitation energy of 4978 eV which is free from the effect due to the existence of the satellite caused by a [1s3p] double hole state or resonant Raman scattering. Fixed parameters of the satellite component were determined by fitting Lorentzians to the $K\alpha_{1,2}$ spectra at excitation energy of 6000 eV, where the satellite is well matured.

It was theoretically predicted that the Kα″ satellite distributes over not only the high energy side of $K\alpha_1$ but also between $K\alpha_1$ and $K\alpha_2$ [3]. However, it is difficult to fit Lorentzians to the latter component of the Kα″ satellite in the spectra because it is buried in the valley between $K\alpha_1$ and $K\alpha_2$. Full widths at half maximum of the Ti $K\alpha_{1,2}$ peaks in each spectrum were obtained by fitting two asymmetric Lorentzians to each experimental spectrum in order to clarify the contribution of the satellite to the whole $K\alpha_{1,2}$ spectra.

4. Results and Discussion

The results of the fitting done for the Ti $K\alpha_{1,2}$ spectra with excitation energies of 5005 eV, 5011 eV, 5018 eV and 6000 eV are shown in Fig. 1. The Lorentzian corresponding to the Kα″ satellite is drawn with a solid curve in the figure.

The dependence of the intensity of the satellite on the excitation energy obtained by the fitting is shown in Fig. 2. The relative

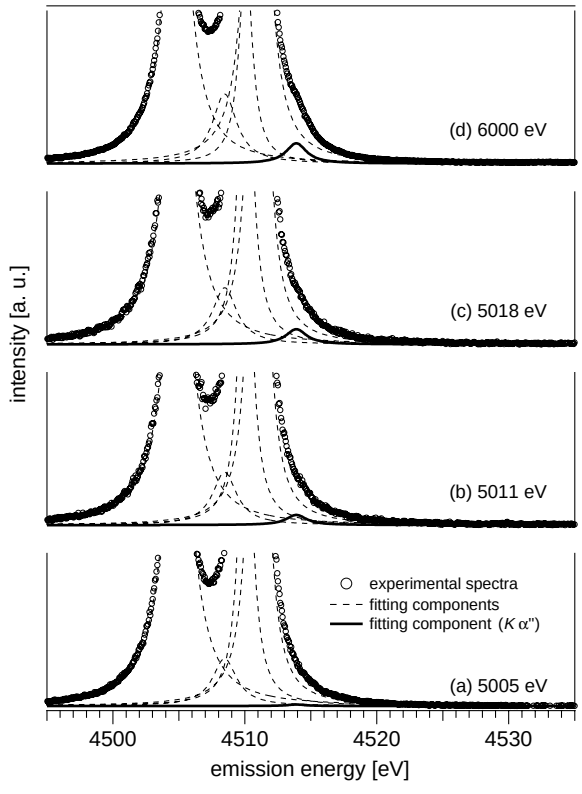

Fig. 1. Evolution of the Kα″ satellite (solid curve) with increasing excitation energy. The Kα″ satellite has no intensity in (a) where the excitation energy (5005 eV) is the threshold energy of the [1s3p] ionization. The intensity increases when excitation energy gets higher than the threshold (b, c). The evolution ceases when the excitation energy reaches around 5500 eV. The satellite in saturation is shown in (d).

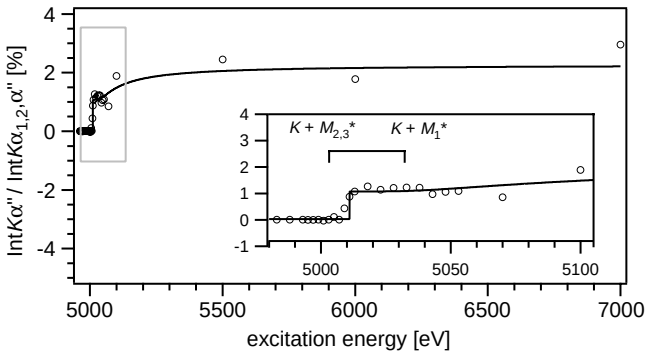

Fig. 2. The data shown as circles are the intensity of the Ti Kα″ satellite relative to that of the Kα lines as a function of excitation energy. The ionization threshold of $K + M_{2,3}^*$ and $K + M_1^*$ shown in the inset are estimated with $Z + 1$ approximation, where M_i^* means the binding energy of the M_i sub-shell of vanadium. The solid curve is the result of the fitting using Thomas model with a step function. Detailed explanations are in the text.

intensity of the Kα″ satellite to the whole $K\alpha_{1,2}$ intensity shows an abrupt jump from 0% to 1% within a range of 10 eV around 5010 eV as seen in Fig. 2. Although it stops increasing once around 5070 eV, it starts to increase again around 5100 eV and continue to increase until it almost saturates around 5500 eV. The relative intensity of the satellite is about 2.5% in saturation.

The solid curve in Fig. 2 is the result of fitting to the experimental data which was performed using the Thomas model [9, 10] with a step function. The Thomas model describes an excitation energy dependence of the shake-off probability and a step function describes that of the shake-up probability. The function fitted is expressed as

$$P(E) = P_{shake\text{-}up}(E) + P_{shake\text{-}off}(E)$$

where E is excitation energy. $P_{shake\text{-}up}$ is a step function defined as

$$P_{shake\text{-}up}(E) = \begin{cases} C & (E > E_{threshold}) \\ 0 & (E < E_{threshold}) \end{cases}$$

where C is a constant and $E_{threshold}$ is the onset energy of the satellite. P_{Thomas} is expressed as

$$P_{Thomas} = P_\infty \exp\left(-\frac{r^2 E_s^2}{15.32(E - E_{threshold})}\right),$$

where P_∞ is the saturated shake-off probability, r is the distance covered by an outgoing electron, E_s is the ionization threshold energy of a shaken electron. In our case the value of E_s was set to be 37.2 eV which corresponds to an ionization threshold energy of an $M_{2,3}$ electron determined by $Z + 1$ approximation. The other parameters were refined by the fitting and the following results were obtained: $C = 1.05 \pm 0.13$, $P_\infty = 1.19 \pm 0.19$, $r = 4.03\,\text{Å} \pm 1.05\,\text{Å}$ and $E_{threshold} = 5011.0\,\text{eV} \pm 0.14\,\text{eV}$.

The fitting result of $E_{threshold}$ shows an agreement with 5003.2 eV which is the [1s3p] ionization threshold energy obtained by $Z + 1$ approximation.

The probabilities of shake-up and shake-off processes by which an electron in the $M_i (i = 1, \ldots, 4)$ subshell is excited and ionized respectively were calculated in a manner described by Mukoyama and Ito [11]. The results are tabulated in Table I showing that the probabilities of $K + M_{2,3}$ double excitation (or ionization) due to the shake-up processes and the whole shake processes are $PM_{2,3(\text{shake-up})} = 2.71 \times 10^{-2}$ and $PM_{2,3(\text{shake})} = 6.55 \times 10^{-2}$, respectively.

Table I. *Probabilities of shake-up processes and shake-off processes involving an electron in M shell accompanying an ionization of an electron in K shell in Ti obtained by Dirac-Fock-Slater calculations. n stands for the principal quantum number of the orbital which a shaken M electron jumps into.*

	Initial shells			
Destinations	M_1	M_2	M_3	M_4
$n = 4$		6.508×10^{-3}	1.280×10^{-2}	3.085×10^{-2}
$n = 5$	7.032×10^{-4}	1.423×10^{-3}	2.811×10^{-3}	7.085×10^{-3}
$n = 6$	2.576×10^{-4}	5.628×10^{-4}	1.113×10^{-3}	2.934×10^{-3}
$n = 7$	1.243×10^{-4}	2.834×10^{-4}	5.608×10^{-4}	1.532×10^{-3}
$n = 8$	6.979×10^{-5}	1.636×10^{-4}	3.239×10^{-4}	9.103×10^{-4}
$n = 9$	4.317×10^{-5}	1.033×10^{-4}	2.045×10^{-4}	5.883×10^{-4}
$n = 10$	2.859×10^{-5}	6.946×10^{-5}	1.375×10^{-4}	4.035×10^{-4}
Total shake-up	1.227×10^{-3}	9.114×10^{-3}	1.795×10^{-2}	4.430×10^{-2}
Shake-off	6.662×10^{-3}	1.287×10^{-2}	2.551×10^{-2}	2.963×10^{-2}
Total	7.889×10^{-3}	2.198×10^{-2}	4.346×10^{-2}	7.393×10^{-2}

The ratio of the probability of the shake-up processes to that of the whole shake processes in the $K + M_{2,3}$ double excitation (or ionization) is

$$PM_{2,3(\text{shake-up})} : PM_{2,3(\text{shake})} \simeq 0.42 : 1$$

where $PM_{2,3(\text{shake-up})}$ means the sum of the probabilities of M_2 and M_3 shake-up processes accompanying a K shell ionization and $PM_{2,3(\text{shake})}$ is that of the whole shake processes. According to the results of the fitting in this work, the ratio of the contribution from the shake-up processes and that of the whole shake processes is approximately $1.05/(1.05 + 1.19) \simeq 0.47$. This indicates that the contribution of shake-up processes to the $K\alpha''$ satellite is much higher than that to the $K\alpha_{3,4}$ satellite which is less than one tenth of the shake-off processes.

The intensity distribution profiles of the $1s \rightarrow 2p$ diagram lines ($K\alpha_{1,2}$) and the $[1s3p] \rightarrow [2p3p]$ satellite emission were calculated using the code of GRASP [12] shown in Fig. 3. The $[1s3p] \rightarrow [2p3p]$ satellite spectra distributes over the high energy side of $K\alpha_1$ and between $K\alpha_1$ and $K\alpha_2$ similar to that in [3].

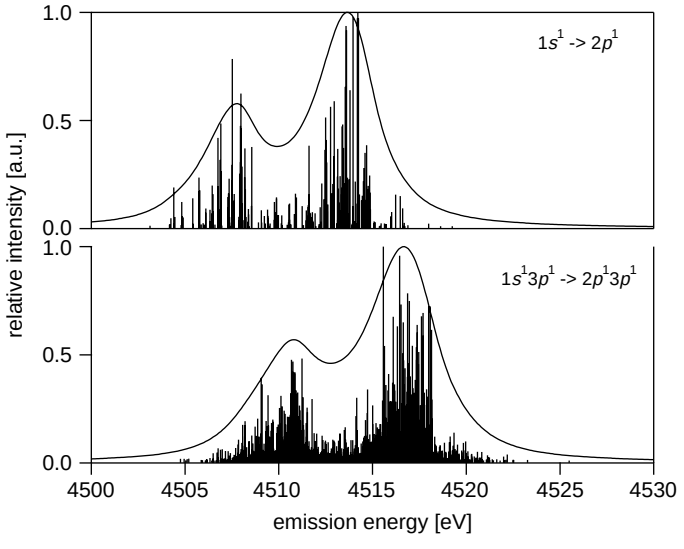

Fig. 3. Intensity distribution of $1s \rightarrow 2s$ transitions and $1s3p \rightarrow 2s3p$ transitions calculated using the code of GRASP. The results are shown as stick diagrams and as spectra obtained by a convolution with Lorentzians of 1.2 eV width. The intensity of each line is shown relative to the strongest one.

Table II. *Experimental and calculated values of the emission energies of the diagram lines and the satellite. Separation is the energy position of the emission line relative to that of $K\alpha_1$ line in both cases.*

Emission line	Energy (eV)	Separation (eV)
Experiment		
$K\alpha_1$	4510.8	
$K\alpha_2$	4505.0	−5.8
$K\alpha''$	4513.9	3.1
Calculation		
$K\alpha_1$	4513.7	
$K\alpha_2$	4507.8	−5.9
$K\alpha''$	4516.7	3.0

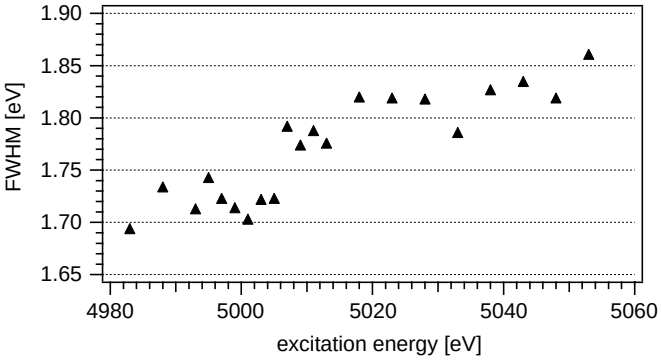

Fig. 4. Full width at half maximum of the Ti $K\alpha_1$ peak obtained by fitting an asymmetric Lorentzian to each peak in experimental data, respectively. Each data is shown as a function of excitation energy.

The peak positions of the diagram lines and satellite in the experimental and calculated spectra are compared with each other in Table II.

Full widths at half maximum of the $K\alpha_1$ peak obtained by fitting two asymmetric Lorentzians to each measured spectrum are shown in Fig. 4. As can be seen from the figure the width of the $K\alpha_1$ peak increases from ∼1.7 to ∼1.8 around an excitation energy of 5007 eV. It is obvious that the increase of the FWHM of the $K\alpha_1$ peak is ascribed to the appearance of the $K\alpha''$ satellite.

5. Conclusion

We investigated here the dependence of the intensity in the Ti $K\alpha''$ satellite on the excitation energy. The relative intensity of the satellite to the whole $K\alpha$ emission lines as a function of excitation energy jumps from 0% to 1.2% around 5005 eV, corresponding to the [1s3p] ionization threshold energy in $Z + 1$ approximation. It almost saturates around 5500 eV where its intensity is ∼2.5%.

Our results show that the origin of the $K\alpha''$ satellite is a 3p spectator hole as predicted by Scott. Judging from how the intensity of $K\alpha''$ increases, what creates a 3p spectator hole is considered to be shake-processes. Although the probability of the shake processes experimentally obtained (2.5%) is less than half of the theoretically calculated value (6.5%), this discrepancy may be lessened when we take it into consideration that one third of the satellite intensity is probably hidden between $K\alpha_1$ and $K\alpha_2$ in the measured spectra.

The dependence of the satellite intensity on the excitation energy was interpreted by combining Thomas model (for shake-off) with a step function (for shake-up). The results show that 47% of the Kα″ satellite is caused by shake-up processes. We also calculated the ratio of the probability of the [1s3p] shake-up processes to that of the whole shake processes in the sudden approximation and the result (42%) is close to the experimentally determined one (47%). The agreement between these values indicates that, for 3d transition elements, shake-up processes are more important in creating a 3p spectator hole accompanying an ionization of a 1s electron than in creating a 2p spectator hole accompanying an ionization of a 1s electron.

Abstract

Fe $K\alpha_{3,4}$ satellite spectra are investigated using a Johann-type spectrometer at the BL15XU undulator beam line, SPring-8. Intensity of the $K\alpha_{3,4}$ satellite relative to the $K\alpha_1$ emission line is found to increase asymptotically with excitation energy up to 9000 eV, and almost saturates at around 9500 eV. Satellite threshold energy is found to be 7882 eV ± 14 eV. This corresponds to the ionization energy of Fe $1s + 2p^*$, where * indicates that the value is from the $Z + 1$ approximation. The growth of satellite intensity with the excitation energy suggests that the 2p spectator holes are mainly created by shake-off in Fe, as suggested by Fritsch *et al.* [Phys. Rev. A **57**, 1686 (1998)] in a previous work on copper.

1. Introduction

Most studies into the contributions of shake processes in solids, vapors, etc. on X-ray absorption for elucidating electron correlations in atoms have been carried out by an Italian group, a Slovenian group, and a Japanese group *etc.* [1–10]. Extended shake-off saturation profiles are of special interest in X-ray absorption spectroscopy, as well as sharp multielectron photoexcitation features caused by resonance and shake-up [4, 5, 7, 10].

X-ray absorption of 3d transition metals has been examined in the K + L double photoabsorption energy region. However, no significant features attributable to multiple photoexcitation have been found in the spectra, and thus K + L edges in 3d elements have not been confirmed [3, 11]. This result could be explained by theoretical predictions of lower shake-up probabilities for K + L transitions [11], which predict that the transition edges observed in X-ray absorption spectra are due entirely to the shake-up process. That is, resonance and shake-up probabilities in the K + L transition of 3d elements are typically lower than detection accuracy so that pure long-range shake-off profiles in XAFS oscillations are difficult to obtain.

With the advent of third generation synchrotron radiation, experiments can be conducted on the threshold behavior of satellites, including the excitation dynamics of atoms. In particular, X-ray emission spectroscopy is suitable for studying satellites for electron correlation. The first detailed photoexcitation measurements were performed by Deslattes *et al.* [12], who examined multielectron vacancies in atomic argon using a combination of both emission and absorption spectroscopy. Deutsch and co-workers [13, 14] found pure shake-off behavior in the copper Kα X-ray satellite complex, and Sternemann *et al.* [15] measured the valence fluorescence satellite KM-$N_{2,3}$M transition of a solid germanium target. More recently Raboud *et al.* [16] measured the KL X-ray emission of argon induced by impact with monoenergetic photons to investigate the K + L double excitation from threshold to saturation.

The contributions of the 2s and 2p spectator transitions in 3d transition metals have only been investigated in copper. As investigation of lower Z 3d metals is needed to further understand multielectron excitation processes, spectator transitions in iron are investigated and presented.

2. Experiment

Measurements were carried out at the BL15XU undulator beam line, SPring-8, using a Johann-type spectrometer. A Si(111) double-crystal monochromator was used to generate a tuned X-ray excitation source, which has a bandpass of $\delta E/E \sim 10^{-4}$ and flux of over 10^{12}. A Johann geometry fluorescence spectrometer consisting of a 1.5-m-diameter Rowland circle on a horizontal plane and a curved Si(400) crystal was used to resolve fluorescence spectra. The spectrometer had a scanning range of 67° to 95°, and was evacuated to $\sim 10^{-3}$ torr using a scroll pump. A 20-μm-thick pure Fe foil was used as the sample. A NaI(Tl) scintillation counter was used to correct the signal and a N_2-gas-filled ionization chamber was used to monitor incident X-ray intensity in front of the target.

Two types of scan were used to investigate the excitation energy dependence of Fe $K\alpha_{3,4}$ spectra. First, the spectrometer was fixed in the Fe $K\alpha_{3,4}$ position ($2\theta \sim 91°$) and incident X-ray energy was scanned. X-rays were incident on the target at 75° to minimize the influence of fluctuations in incident beam spot position during the energy scan. From the first scan, a rough estimate of the $K\alpha_{3,4}$ satellite energy threshold was obtained, and energy values for the angle scan were determined. Several spectrometer angle scans were then conducted around $2\theta \sim 91°$, with excitation energy varied from 7850 eV to 10000 eV to trace variations in satellite spectra with excitation energy. During the angle scan, the incident angle of X-rays on the target was set to 45° to maximize fluorescence intensity at the detector.

3. Results and discussion

Results of the first scan around the threshold energy are shown in Figs. 1 and 2. The intensity of emissions at the Fe $K\alpha_{3,4}$ satellite complex energy can be seen to gradually increase as the excitation energy increases from around 8000 eV, and almost saturates at around 9500 eV, as shown in Fig. 1. Two lines are drawn in Fig. 2 to highlight the threshold of the satellites. Threshold values obtained from the $Z + 1$ approximation are shown in the inset [17]. Values of [1s2p] ionization threshold energy are in agreement with the experimental results. Calculations of shake-up and shake-off probabilities in K + L double electron transitions were performed in a manner similar to Mukoyama and Ito [18] using the Dirac-Fock-Slater method [19], with results listed in Table I.

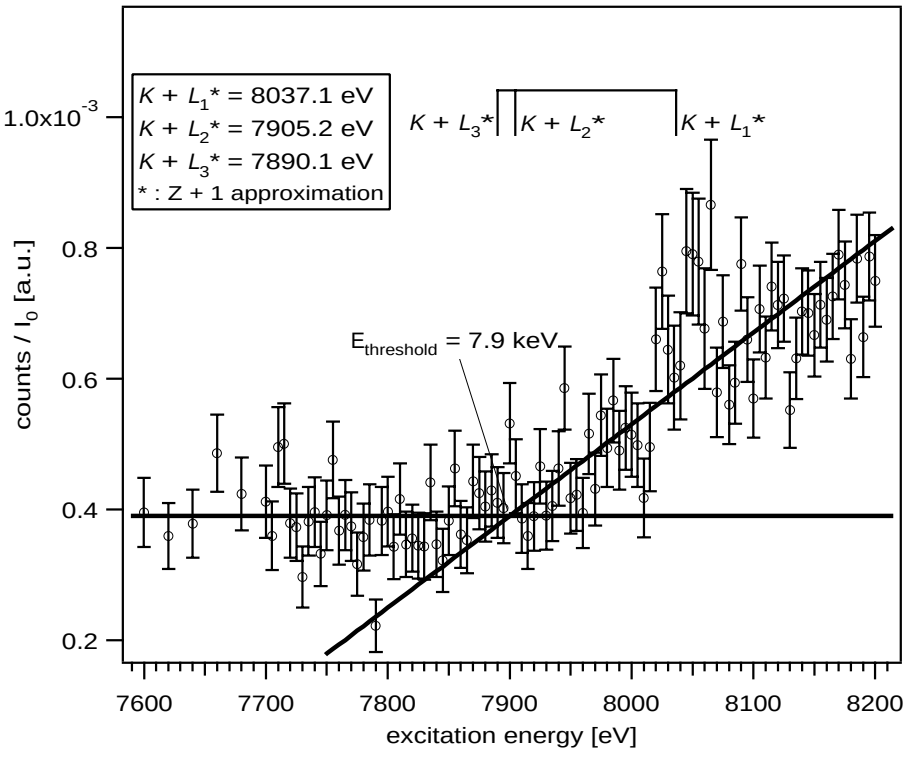

Fig. 2. Detailed plot of the data shown in Fig. 1 at around 7900 eV. Two lines have been drawn to highlight the threshold energy of satellite emissions. Values in the inset show the double hole creation threshold energies obtained by $Z + 1$ approximation. * indicate L sub-shell ionization energies in cobalt.

Moreover, a small intensity peak was clearly observed around the [1s2s] ionization threshold energy, possibly due to the appearance of a 2s hole. It is plausible that this peak is attributed to a resonance.

The observation of emissions influenced by 2s spectator holes is difficult compared to 2p holes because 2s spectator holes disappear faster than 2p holes through strong 2s2p Coster-Kronig transitions. Therefore contributions from [1s2s] shake processes may be observed as a part of satellite emissions with 2p spectator holes. If a 2s spectator hole is created and left around the small intensity peak in Fig. 2, the shape of the satellite complex may change due to the spectator hole itself. However, no clear evidence

Table I. *Probabilities of shake-up and shake-off involving L shells accompanied by K shell ionization in Fe using Dirac-Fock-Slater calculations. The $n = l$ column ($4 \leq l \leq 10$) shows the probability of shake-up to each $n = l$ shell.*

	Initial shells		
Destinations	L_1	L_2	L_3
$n = 4$		6.720×10^{-5}	1.323×10^{-4}
$n = 5$	1.300×10^{-5}	1.829×10^{-5}	3.645×10^{-5}
$n = 6$	4.990×10^{-6}	7.745×10^{-6}	1.549×10^{-5}
$n = 7$	2.448×10^{-6}	4.014×10^{-6}	8.040×10^{-6}
$n = 8$	1.382×10^{-6}	2.350×10^{-6}	4.711×10^{-6}
$n = 9$	8.567×10^{-7}	1.494×10^{-6}	2.998×10^{-6}
$n = 10$	5.675×10^{-7}	1.009×10^{-6}	2.025×10^{-6}
total shake-up	2.324×10^{-5}	1.021×10^{-4}	2.020×10^{-4}
shake-off	1.225×10^{-3}	1.975×10^{-3}	3.909×10^{-3}
total	1.248×10^{-3}	2.077×10^{-3}	4.111×10^{-3}

of contributions from 2s spectator holes could be confirmed within the accuracy of our experimental data.

Integrated intensity of the $K\alpha_{3,4}$ satellite complex is shown in Fig. 3 relative to the total $K\alpha_{1,2,3,4}$ emissions. Four reference data are also shown for comparison. The relative intensity of satellite complex can be seen to increase from 7900 eV and almost saturate at around 9500 eV. The data indicated by diamonds are experimental results from a conventional Fe X-ray tube measured using the same spectrometer as in the present work and an X-ray tube excitation voltage of 30 kV. The data indicated by triangles were measured using a double-crystal spectrometer. The target was pure Fe metal and a Rh X-ray tube with an excitation voltage of 40 kV was used. These values are in good agreement with the present 10000 eV experimental results, in which the satellites are almost fully developed. Data indicated by circles are calculated values of [1s2p] shake-off probability during K-shell ionization using the sudden approximation [20], and the circle with cross indicates the sum of calculated probabilities of [1s2s] and [1s2p] shake-off. The theoretical values, especially the latter, are in good agreement with the experimental results at an excitation energy of 10000 eV.

A small intensity peak is observed at an excitation energy of 8040 eV in Fig. 3 as well as in Fig. 2. This may be due to [1s2s] double electron excitation.

The solid line is the result of fitting the Thomas model [21] to the experimental data. In this model, the probability of creating a spectator hole via shake-off two-step-one (knockout of a second electron by the departing photoelectron) process is given by

$$P_{Thomas}(E_{ex}) = P_\infty \exp\left(\frac{-mr^2E_s^2}{2\hbar^2E_{ex}}\right),$$

where P_∞ is the probability at saturation, m is the mass of an electron, r is the distance covered by the photoelectron during the excitation process, and E_{ex} is the energy which is needed to excite a second electron. Replacing m and $\hbar$ with numerical values gives

$$P_{Thomas}(E) = P_\infty \exp\left(-\frac{r^2E_s^2}{15.32(E - E_{threshold})}\right).$$

During the fitting, E_s was fixed at 783.1 eV, P_∞ was fixed at 0.738% and other parameters were left free. The fixed E_s value was calculated from the weighted average of $L_{2,3}$ sub-shell binding energies of cobalt, obtained from the $Z + 1$ approximation. P_∞ was taken from the experimental value of the Fe X-ray tube (diamond in Fig. 3) that was measured using the same spectrometer as that in this work, but with an

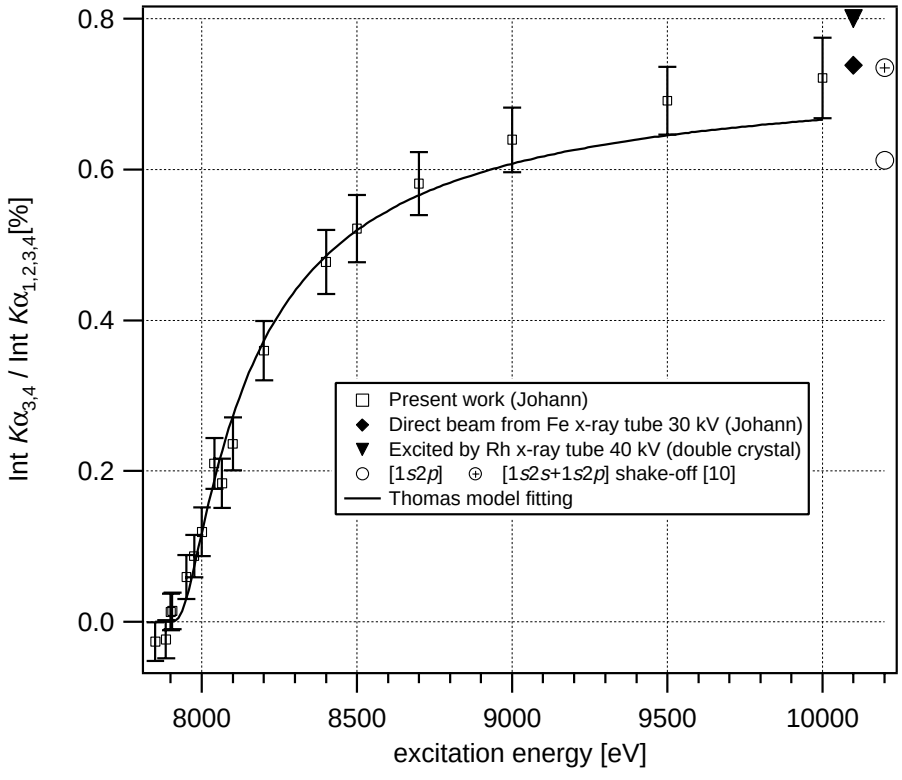

Fig. 3. Integrated intensity of $K\alpha_{3,4}$ satellite complex relative to total $K\alpha_{1,2,3,4}$ emissions. Squares with error bars show experimental data from the present work. Triangle, diamond, circle and circle with cross indicate experimental and theoretical reference values, as given by the legend. The solid line shows the results fitting to the Thomas model.

excitation voltage of 30 kV at which the satellite is expected to be saturated. Results of the fitting were: $r = 0.074\,\text{Å} \pm 0.003\,\text{Å}$ and $E_{threshold} = 7881.6\,\text{eV} \pm 14.2\,\text{eV}$. The threshold energy of these fitting results is in good agreement with the [1s2p] excitation threshold energy from the $Z + 1$ approximation. The origin of the Fe $K\alpha_{3,4}$ satellites may be 2p spectator holes created by [1s2p] shake-off.

Less agreement between the fitting results and experimental values of excitation probability occurs for $E > 9000\,\text{eV}$, with the fitting function dropping below the experimental values. This may suggest that contribution of 2p spectator holes created by combination of matured [1s2s] shake-off and 2s2p Coster-Kronig transitions.

A shake-off process seems to dominate 2p spectator hole creation processes because the integrated intensity of satellite complex exhibits monotonic increase. The theoretical values listed in Table I also suggest that 2p vacancies in L shells are mainly created by the shake-off process.

4. Conclusion

The experimental evolution of Fe $K\alpha_{3,4}$ satellite complex from threshold to saturation was presented. The threshold energy of satellite complex was found to be around 7890 eV, matching the [1s2p] ionization threshold energy given by the $Z + 1$ approximation. The origin of Fe $K\alpha_{3,4}$ satellites seems to be spectator holes in the 2p levels (L_2 or L_3 shell).

The integrated intensity of Fe $K\alpha_{3,4}$ satellite complex exhibited a simple increase from threshold, indicating that a shake-off process is the origin of 2p spectator holes.

A small intensity peak was observed at around 8040 eV, corresponding to $K + L_1$ ionization threshold energy. The shape of this peak did not match shake-off or shake-up, but appeared to be a sharp resonance. The 2s hole also seems to appear around the same energy, but no clear change in the satellite was observed within the measurement accuracy. Strong 2s2p Coster-Kronig transitions may fill 2s holes quickly, with contributions from [1s2s] shake-off observed as satellite emissions with 2p spectator holes.

The conclusion is supported by the good agreement between the relative intensities at an excitation energy of 10000 eV and theoretical [1s2s + 1s2p] shake-off probabilities.

The experimental data in the saturated region agree well with theoretical values from the sudden approximation [20], but there are few models that can reproduce the evolution of this kind of shake-off satellite. The Thomas model of shake-off probabilities [21] agrees to some extent with our experimental data, and also with copper [13, 14] and argon [16] data, but the model still has room for improvement [14]. Therefore, a new model that describes the evolution of shake-off probability on a solid theoretical grounding is required in this field of investigation.

Further experimental work is also needed to push theoretical developments. Copper, argon and iron have now been measured, with further experiments on other 3d transition elements, rare gases and higher-Z elements needed to allow more detailed discussion in this field.

Abstract

X-ray absorption fine structure (XAFS) spectra of Ge-K edge of liquid GeO_2 polymorphs (quartz-type and rutile-type GeO_2) at temperature 1126 °C were collected at Beijing Synchrotron Radiation Facility (BSRF) and Spring-8. Reversed Monte Carlo (RMC) method was used to simulate the XAFS spectra with k^2-weight. More than 200 independent configurations were used to do statistic analysis. There are 3.7 oxygen atoms surrounding Ge with Ge-O bond length of 1.74 Å for rutile-type GeO_2 melt, and 3.6 oxygen atoms surrounding Ge with Ge-O bond length of 1.75 Å for quartz-type GeO_2 melt. The long-range order was completely destroyed and partial short-range and intermediate-range order were kept in the two kinds of liquid GeO_2 (at 1126 °C). Because partial Ge-O bonds were broken, the local atomic structures of liquid GeO_2 were reconstructed. Besides the four-folded Ge-O coordination, three-folded and five-folded coordinations were also found. The liquid structures of the two GeO_2 polymorphs are similar but not the same. The averaged Ge-O-Ge and O-Ge-O coordination triangles are larger in $QGeO_2$ melt than in $RGeO_2$ melt.

1. Introduction

GeO_2, as an analog of SiO_2, was widely used to study the structures and properties of glasses, liquid and minerals. Crystal structure, density and modulus, thermal expansivity, volume-temperature relationship, pressure-induced phase-transform, heat capacity, multielectron excitation, as well as amorphization were respectively, reported [1–7]. Many theoretical calculations including molecular dynamics simulation [8, 9] were also performed. Whereas a reverse Monte Carlo simulation for the liquid structures of GeO_2 polymorphs has never been found.

Germanium dioxide has two types of stable structure, one is the α-quartz-type GeO_2 with four oxygen atoms surrounding the germanium atom in $P3_221$ ($z = 3$) space group [10], another is the rutile-type GeO_2 with six oxygen atoms surrounding the germanium atom in $P4_2/mnm$ space group [11]. In this paper, (α-quartz-type GeO_2 and rutile-type GeO_2 are, respectively, abbreviated to $QGeO_2$ and $RGeO_2$. $RGeO_2$ was reported to have a melting point at 1086 °C, while $QGeO_2$ was reported to have a melting point at 1115 °C. We are interested in whether the melts structure is correlative with the crystalline structure of the counterpart or not. As the two GeO_2 crystalline phases ($QGeO_2$ and $RGeO_2$) are heated to same temperature above their melting points, are there the same structures of the melts?

High-temperature extended X-ray-absorption fine-structure [12] (EXAFS) technique and Reverse Monte Carlo [13] (RMC) simulation were used to get the structural information of the melts. We believe that this study could offer new opportunities for both fundamental research and technological applications.

2. Experimental

In order to avoid the impurities in samples, $QGeO_2$ single crystal was chosen as the starting material. By grinding the single crystal, $QGeO_2$ powder was obtained fined than 400 mesh (about 10 μm). Partial $QGeO_2$ powder was mixed with 0.5% of Li_2CO_3. The mixture was compressed into a tablet of ϕ10 and heated at 950 °C for 20 hours. Repeatedly the procedure until the mixture has been completely transformed into $RGeO_2$ as confirmed by X-ray diffraction, then $RGeO_2$ powder was obtained by grinding the mixture fined than 400 mesh. A rhodium foil with rough surface was used as the sample holder. $QGeO_2$ and $RGeO_2$ powders were, respectively, directly smeared on the rhodium foil and put into a high-temperature furnace used for EXAFS measurement. EXAFS spectra were collected with fluorescence mode at Beijing Synchrotron Radiation Facility (BSRF) in China and Spring 8 Facility in Japan. The samples were positioned in 45 degree corresponding to the X-ray beam and the entrance of the Lytle fluorescence detector. A Gallium foil was used as the filter to decrease the unnecessary background. An aluminium foil with thickness of 10 μm was positioned between the furnace and the filter to prevent the detector from thermal radiation. More than three independent EXAFS scans of Ge-K absorption were carried out. A Si(311) monochromator was used to monochromize the incident X-ray at Spring 8 and the storage ring was run at 8 GeV with 300 mA current. A Si(111) monochromator was used at BSRF with storage ring running at 2.2 GeV and 100 mA. An ion chamber installed in front of the sample was optimum filled the mixture of Ar and N_2 gases to record the incident X-ray intensity. The energy resolution ($\Delta E/E$) is about 2×10^{-4}.

3. Data analysis

EXAFS spectra of Ge K-absorption were, respectively, recorded at 1126 °C for $QGeO_2$ and $RGeO_2$. Figure 1 shows the X-ray-absorption near-edge structure (XANES) spectra of $RGeO_2$ and $QGeO_2$. The EXAFS signals were extracted by a careful background removal using the derivate method [14]. The measured EXAFS signal is the sum of contributions from all atomic pairs α-β, where α is the central atom and β is the backscattering atom. If we define the partial radial distribution function as:

$$g_{\alpha\beta}(r) = \frac{n_\beta(r)}{4\pi r^2 \Delta r \rho_\beta}. \quad (1)$$

Here, $n_\beta(r)$ is the number of atom β at a distance between r and $r + \Delta r$ from a central atom α. ρ_β is the average number-density of atom β in the studied sample. Then, the EXAFS formula at atom

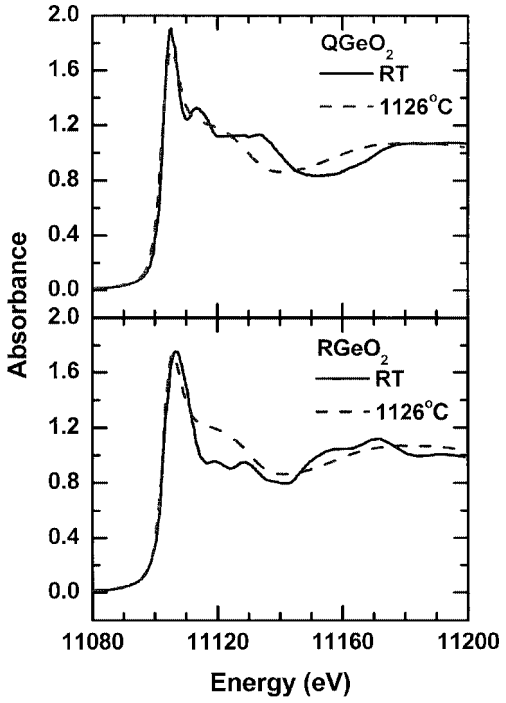

Fig. 1. X-ray-absorption near-edge spectra of Ge in $QGeO_2$ and $RGeO_2$.

α absorption-edge can be written as [13]:

$$\chi_\alpha(k) = \sum_\beta 4\pi\rho_\beta \int_0^\infty r^2(g_{\alpha\beta}(r) - 1)\chi_{\alpha\beta}(k, r)\,\mathrm{d}r. \quad (2)$$

Here, $\chi_{\alpha\beta}(k, r)$ is the EXAFS contribution of the single atomic pair (α, β) at distance r. The single atom-pair EXAFS function $\chi_{\alpha\beta}(k, r)$ was calculated with the FEFF program [15], its amplitude and phase shift were revised by using the experimental ones extracted from the bulk GeO_2 at room temperature. The systemic error of experiment in the measured EXAFS functions was largely compensated. Model-independent RMC method was used to simulate the experimental XAFS function $\chi_\alpha(k)$.

In RMC simulation, the crystal structures with 1944 atoms of room temperature GeO_2 was chosen as the initial configurations. The only constraint condition is the total number density ρ, which was fixed at 0.06056 $Å^{-3}$ for $RGeO_2$ and $QGeO_2$ melts according to the previous report [1, 2].

The k-region was chosen from 3.0 to 12.0 $Å^{-1}$ with spacing of 0.1 $Å^{-1}$. The r-region was chosen below 7.0 Å with spacing of 0.1 Å. Different step sizes were tested in the simulation, a best one of 0.2 Å was used to get the best simulation and avoid the local minimum. Figure 2 shows the experimental EXAFS curves and the RMC simulation ones for $RGeO_2$ (lower) and $QGeO_2$ (upper).

After the system reach the equilibrium, more than 200 independent configurations were randomly taken out. Average structural information can be counted from these configurations. There are about 3.7 oxygen atoms surrounding the central Ge atoms with Ge-O bond length of 1.74 Å in $RGeO_2$ melt, and 3.6 oxygen atoms at 1.75 Å in $QGeO_2$ melt. Ge-O pair distribution functions were obtained from these configurations as shown in Fig. 3.

4. Discussion

The XANES spectra of solids and melts are compared in Fig. 1. They are obviously different between solids and melts. The spectral characteristics of melts are closer to crystalline $QGeO_2$

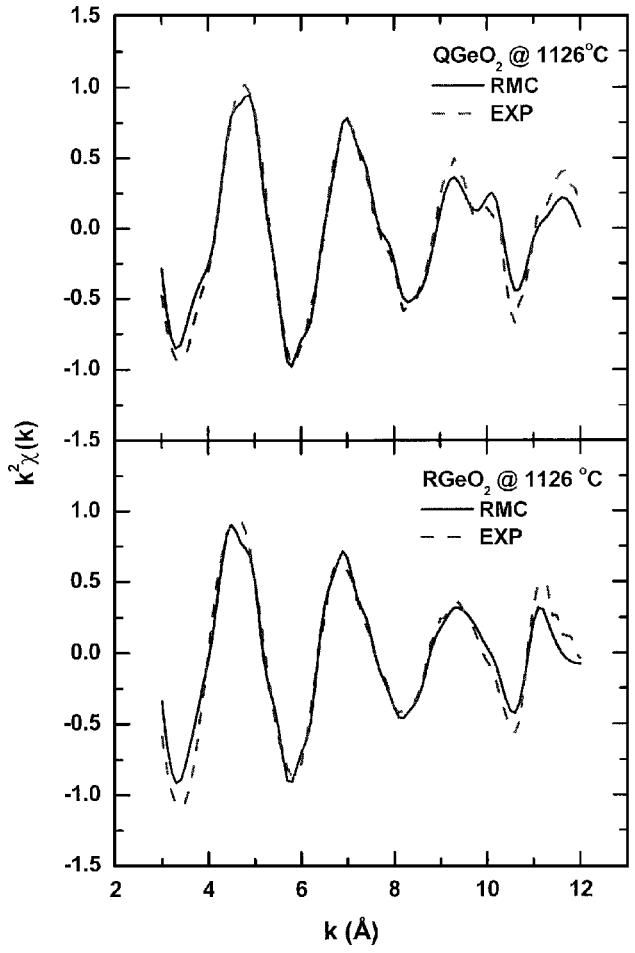

Fig. 2. Ge K-absorption XAFS spectra of $QGeO_2$ and $RGeO_2$ at 1126 °C. Solid lines are the RMC simulation curves. Dot lines are the XAFS experimental curves.

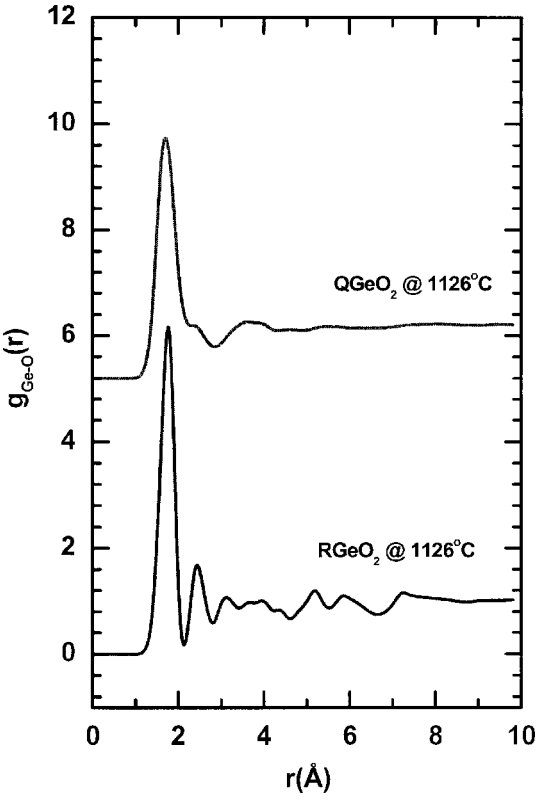

Fig. 3. Ge-O pair distribution functions in $QGeO_2$ and $RGeO_2$ melts at 1126 °C.

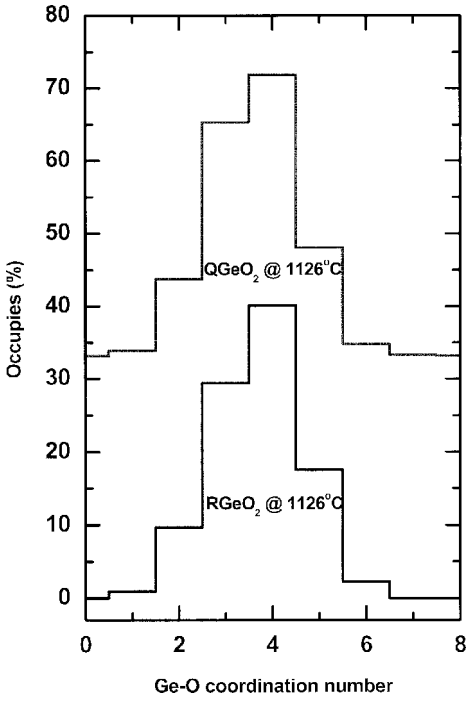

Fig. 4. Ge-O coordination number distribution in $QGeO_2$ and $RGeO_2$ melts at 1126 °C.

than $RGeO_2$ in local atomic structure. There is no change in the absorption jump that demonstrates that the samples keep the uniform thickness as they were heated from room temperature to high temperature (1126 °C).

Excellent RMC simulations to the experimental XAFS spectra are shown in Fig. 2. Figure 3 compares the Ge-O pair distribution functions $g_{\text{Ge-O}}(r)$ for $QGeO_2$ (upper) and $RGeO_2$ (lower). The room-temperature samples have an obvious long-range order distribution. The first peak of $g_{\text{Ge-O}}(r)$ defines the local atomic contributions. The near-neighbor bond length and coordination number can be obtained by directly counting the 200 independent atomic configurations with a maximum atom-pair distance restricted to 2.1 Å.

It can be seen that the two melts have similar structural parameters. Roughly, their structures are more similar to $QGeO_2$ instead of $RGeO_2$. In the RMC simulation, the atom number density is lower in melts than solids and the ratio of Ge and O atom numbers was kept at 1 : 2. Although the local structures are of shrinkage, the averaged volumes of melts are still larger than the corresponding solids.

The possibilities of coordination number for Ge-O bonds are shown in Fig. 4. The coordination number distribution is wider in melts than solids. The most probable coordination number is close to the averaged coordination number. For crystalline $QGeO_2$ and the two melts, the most probable Ge-O coordination number is 4. For solid $RGeO_2$, the most probable Ge-O coordination numbers is 6. The coordination distributions of the two melts are quite similar.

Other atom-pairs information can also be counted from these independent configurations. Generally speaking, they have similar coordination numbers and bond lengths. Two kinds of coordination triangle can be found from the two melts. One is the Ge-O-Ge triangle. Another is the O-Ge-O triangle. The average Ge-O-Ge and O-Ge-O angles are bigger in $QGeO_2$ melt than $RGeO_2$ melt. This is the statistic difference between the two GeO_2 melts.

5. Conclusion

The local atomic structures of the two GeO_2 melts at 1126 °C are similar to that of the crystalline $QGeO_2$, the most probable atomic configuration around Ge is Ge-O tetrahedron with Ge-O bond lengths of 1.74 Å. The long-range orders in melts were completely destroyed. There are two kinds of coordination triangles existing in these samples. Statistically, the Ge-O-Ge and O-Ge-O and O-Ge-O coordination triangles are bigger in $QGeO_2$ melt than $RGeO_2$ melt.

Keldysh's Green Function Approach to the Radiation Field Screening in MARPE and XAFS

Hiroko Arai* and Takashi Fujikawa

Graduate School for Science, Chiba University, Yayoi-cho 1-33, Inage, Chiba 263-8522, Japan

Received June 26, 2003; accepted October 16, 2003

Abstract

We study the radiation field screening in MARPE and XAFS in the non-relativistic Keldysh Green's function theory. So far these terms have rarely been investigated, however they are crucial to analyse resonant effects in XPS and XAFS. In this work we demonstrate the importance of the dynamical screening to discuss these resonant effects. We find that the resonant term in XAFS is written in terms of X-ray absorption factor $f(\omega)$ and related factor $\tilde{f}(\omega)$.

1. Introduction

EXAFS analyses of the backscattering amplitude identify the backscattering atomic species. It is, however, quite difficult to distinguish Mn from Fe or Co from the EXAFS analyses, because their backscattering amplitudes $f(\pi)$'s are quite similar.

Recent experimental developments of multi-atom resonant photoemission (MARPE) permit direct determination of near-neighbour atomic identities [1, 2]. So far much efforts has been paid to observe MARPE: Some have failed to observe them [3]. Theoretical approach based on scattering theory has been proposed by Garcia de Abajo *et al*. [4]. The present authors have used an alternative more sophisticated approach based on Keldysh Green's function theory [5]. Further refinement to include radiation field screening is also proposed [6]. These works have explicitly shown the structure factor of MARPE transition operator, which reflects the local symmetry around an X-ray absorbing atom. Despite these successful results, the MARPE intensities are too small compared with the experimental ones, since the dynamical screening has been neglected.

In this work we point out the importance of the polarization part W_p (dynamical screening part) of the screened Coulomb interaction to analyse MARPE by using skeleton expansion of Keldysh Green's function. This term also plays an important role in other resonant phenomena such as intra-atomic resonant photoemission spectra and in the discussion of the white line intensity in XAFS spectra.

2. MARPE

XPS intensity measuring photoelectrons with momentum $\boldsymbol{p}$ excited by photon energy ω near resonance is given by use of the skeleton expansion of Keldysh Green's function theory [5, 6]

$$I(\boldsymbol{p},\omega) \propto \sum_n |\langle f_{\boldsymbol{p}}^- |\Delta| g_n\rangle + \mathrm{i}\langle f_{\boldsymbol{p}}^- |X(\omega)| g_n\rangle + \mathrm{i}\langle f_{\boldsymbol{p}}^- |Z(\omega)| g_n\rangle|^2 \delta[\varepsilon_p + E_n(N-1) - \omega - E_0(N)] \quad (1)$$

where the particle Dyson orbital f_p and the hole Dyson orbital g_n are define by ($x = (\boldsymbol{r}, \sigma)$)

$$f_p(x) = \langle 0, N|\psi(x)|p, N+1\rangle,$$
$$g_n(x) = \langle n, N-1|\psi(x)|0, N\rangle. \quad (2)$$

The function $f_{\boldsymbol{p}}^-$ is a damping photoelectron wave under the influence of the optical potential. The first term of eq. (1) describes the normal photoemission processes. The second and the third terms describe the resonant processes. The latter includes contribution from the radiation field screening. Operators $X(\omega)$ and $Z(\omega)$ defined in ref. [5, 6] is written in terms of screened Coulomb interaction $W(\omega)$, $W(\omega) = v + v\pi(\omega)v$. We study the effect of the polarization part $W_p = v\pi v$ in detail. We notice that the reducible polarization propagator π is related to the irreducible polarization P, $\pi = P + PWP$. In this work we use an approximation $\pi \sim P_0$, where P_0 is the lowest order skeleton expansion of P

$$P_0(x, x'; \omega) = \sum_{mq} \left(\frac{f_q(x) f_q^*(x') g_m(x') g_m^*(x)}{\omega + \varepsilon_m - \varepsilon_q + \mathrm{i}\eta} - \frac{f_q(x') f_q^*(x) g_m(x) g_m^*(x')}{\omega - \varepsilon_m + \varepsilon_q - \mathrm{i}\eta} \right), \quad (3)$$

where $\varepsilon_m = E_0(N) - E_m(N-1)$, $\varepsilon_q = E_q(N+1) - E_0(N)$. In the analyses of MARPE the second term in eq. (1) can be neglected as discussed in ref. [6]. The polarization part in the element $\mathrm{i}\langle f_{\boldsymbol{p}}^- |Z(\omega)| g_n\rangle$ is given by neglecting the terms with large energy denominator

$$\langle f_{\boldsymbol{p}}^- g_j |W_p(\omega)| g_n f_s\rangle \sim \langle f_{\boldsymbol{p}}^- g_j |v P_0 v| g_n f_s\rangle \sim \sum_{mq} \frac{\langle f_{\boldsymbol{p}}^- g_m |g_n f_q\rangle \langle g_j f_q |f_s g_m\rangle}{\omega + \varepsilon_m - \varepsilon_q + \mathrm{i}\eta}. \quad (4)$$

To specify the problem, let us consider O1s MARPE in MnO, where ω is close to Mn 2p threshold. In this case g_m and g_j are approximated by Mn 2p core functions multiplied by intrinsic amplitudes, and g_n O 1s, f_s and f_q Mn 3d, and ε_m corresponds to the threshold of Mn 2p core excitation $\varepsilon_m \sim -I_d$. We stress the importance of the skeleton expansion; in the denominator we have exact ionization energy $-\varepsilon_m$ instead of orbital energy in the Hartree-Fock approximation. Since the incident X-ray energy ω is close to the Mn 2p threshold ($\omega \sim -\varepsilon_m$), eq. (4) has a large contribution near the core excitation energy. So far the influence of W_p has been neglected. However, this plays an important role in particular near the resonant energy.

*Electronic address: hiroko@graduate.chiba-u.jp

By using the procedure discussed in the next section, we can rewrite the inter-atomic resonant photoemission intensity

$$I(\boldsymbol{p},\omega) \propto \sum_n \left| \langle f_p^- |\Delta| g_n\rangle + \sum_{sj} \frac{\langle f_p^- g_j | g_n f_s\rangle \langle f_s|\Delta|g_j\rangle}{\omega+\varepsilon_j-\varepsilon_s+\mathrm{i}\Gamma} \times \left(1+\frac{\gamma}{\omega+\varepsilon_j+\mathrm{i}\Gamma}\right)\right|^2 \times \delta[\varepsilon_p + E_n(N-1) - \omega - E_0(N)] \tag{5}$$

where γ can be related to the deep core X-ray absorption factor f_d defined by eq. (16).

To study the influence of W_p on MARPE intensity, we calculate O1s MARPE for some MnO model clusters. Since the MARPE amplitude is proportional to r^{-3} (r is Mn-O distance), it is sufficient to consider only the nearest-neighbour Mn atoms. We should also note that O1s MARPE of this system is sensitive to the surface, because the O 1s photoelectron kinetic energy is ∼100 eV so that the photoelectron mean free path is quite small. Figure 1 shows the calculated MARPE for "MnO(001) surface model", where Mn atom along the $+z$ direction is lost and is in lower than octahedral symmetry keeping the Mn-O distance at 2.23 Å. Photoelectrons are detected along the surface normal. The MARPE without W_p is compared with that including W_p; the former gives weak MARPE whose relative intensity to the main photoemission band is about 1%. In contrast to this result the latter including the dynamical polarization gives a prominent peak comparable with the experimental one (∼12%), and still shows Fano like asymmetric shape. In this case we have used the parameter $\gamma = -1$ eV.

A different model studied here is a "distortion model" where two Mn atoms along the z axis have longer distance (+5%) than four Mn atoms in the xy plane. This model also gives rise to MARPE, however, it is much weaker (∼2%) than the "surface model". We again find an important contribution of the polarization part W_p to the MARPE intensity.

3. Resonant effect in XAFS

We have obtained the X-ray absorption intensity of photon energy ω by taking the radiation field screening into account [6]

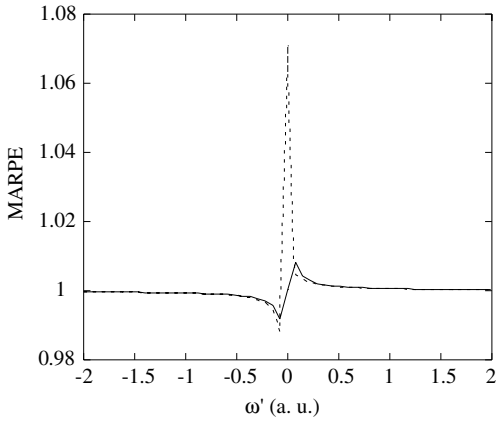

Fig. 1. Calculated O1s MARPE function of MnO (001) surface. We set the energy 0 at the resonant energy (Mn 2p threshold). Solid line shows the result without W_p and the dashed line with W_p.

$$I(\omega) \sim 2\pi \times \sum_{np}\left|\langle f_p|\Delta|g_n\rangle + \sum_{mq}\frac{\langle f_p g_m|W(\omega)|g_n f_q\rangle\langle f_q|\Delta|g_m\rangle}{\omega+\varepsilon_m-\varepsilon_q+\mathrm{i}\eta}\right|^2 \times\delta(\omega+\varepsilon_n-\varepsilon_p). \tag{6}$$

The second term can describe the resonant effect and is rewritten below. In the approximation $W \sim v$, we have

$$\sum_{mq}\frac{\langle f_p g_m|g_n f_q\rangle\langle f_q|\Delta|g_m\rangle}{\omega+\varepsilon_m-\varepsilon_q+\mathrm{i}\eta} \sim \sum_{\mathrm{d}q}\int \mathrm{d}x_1\,\mathrm{d}x_2\,\mathrm{d}x_3\; f_p^*(x_1)\phi_d^*(x_2)v(\boldsymbol{r}_1-\boldsymbol{r}_2)\phi_c(x_1) \times\Delta(x_3)\phi_d(x_3)g_{sc}(\boldsymbol{r}_2,\boldsymbol{r}_3;\omega+\varepsilon_d), \tag{7}$$

where the hole Dyson orbital $g_n(x)$ is approximated by $S_n^c\phi_c(x)$, whereas $g_n(x)$ is approximated by $S_m^d\phi_d(x)$: We only use one channel $S_n^c \sim \delta_{n0}, S_m^d \sim \delta_{m0}$ for simplicity, and g_{sc} is defined

$$g_{sc}(\boldsymbol{r}_2,\boldsymbol{r}_3;\omega+\varepsilon_d) \equiv \sum_q \frac{f_q(x_2)f_q^*(x_3)}{\omega+\varepsilon_d-\varepsilon_q+\mathrm{i}\eta}. \tag{8}$$

We thus reduce the problem to the calculation of the Green's function g_{sc}. In the lowest approximation we only consider the contribution from the X-ray absorber A, and neglect scattering terms, which yields

$$g_{sc}(\boldsymbol{r}_2,\boldsymbol{r}_3;\omega+\varepsilon_d) = \sum_L g_l(r_2,r_3;\omega+\varepsilon_d)Y_L^*(\hat{\boldsymbol{r}}_2)Y_L(\hat{\boldsymbol{r}}_3). \tag{9}$$

Substituting eq. (9) into eq. (7) we obtain

$$\text{eq. (7)} = \langle f_p|\lambda(\omega+\varepsilon_d)Y_{10}|\phi_c\rangle, \tag{10}$$

$$\lambda(\omega+\varepsilon_d;r_1) \equiv \sum_l \int \mathrm{d}r_2\,\mathrm{d}r_3\, r_2^2 r_3^3 R_{l_d}(r_2)R_{l_d}(r_3)\frac{r_<}{r_>^2} \times\frac{(2l_d+1)(2l+1)}{9}\langle l_d 0\, l0|1\rangle^2 g_l(r_2,r_3;\omega+\varepsilon_d), \tag{11}$$

where $r_< = \min(r_1,r_2)$, $r_> = \max(r_1,r_2)$, and R_{l_d} is the radial part of ϕ_d.

Next we consider the effects from W_p. By using the same approximation used above, we have

$$\sum_{mq}\frac{\langle f_p g_m|W_p(\omega)|g_n f_q\rangle\langle f_q|\Delta|g_m\rangle}{\omega+\varepsilon_m-\varepsilon_q+\mathrm{i}\eta} = \langle f_p|\lambda'(\omega+\varepsilon_d)Y_{10}|\phi_c\rangle \tag{12}$$

where λ' is the radial integral including λ, g_l and R_{l_d}. Finally we have the resonant X-ray absorption intensity summing up all terms considered above

$$I(\omega) = 2\pi\sum_{pc}|\langle f_p|\{r+\lambda(\omega+\varepsilon_d;r) + \lambda'(\omega+\varepsilon_d;r)\}Y_{10}(\hat{\boldsymbol{r}})|\phi_c\rangle|^2\delta(\omega+\varepsilon_n-\varepsilon_p). \tag{13}$$

The X-ray absorption factor f_d at the deep core ϕ_d is now defined by

$$\sum_{m_d}\langle\phi_d|\Delta^\dagger g_{sc}(\omega+\varepsilon_d)\Delta|\phi_d\rangle = -\tfrac{1}{2}f_d(\omega). \tag{14}$$

The resonant excitation operator λ is closely related to the deep core (ϕ_d) X-ray absorption factor f_d

$$\lambda(\omega+\varepsilon_d;r) = -\frac{2\pi}{3}\frac{1}{r^2}f_d(\omega). \tag{15}$$

In a similar way let us define $\tilde{f}_d$ by use of $\tilde{\Delta} = Y_{10}(\hat{\boldsymbol{r}})/r^2$

$$-\tfrac{1}{2}\tilde{f}_d(\omega) = \sum_{m_d}\langle\phi_d|\Delta^\dagger g_{sc}(\omega+\varepsilon_d)\tilde{\Delta}|\phi_d\rangle. \tag{16}$$

We thus obtain an interesting relation between $\lambda'(\omega+\varepsilon_d;r)$ and f_d and $\tilde{f}_d$,

$$\lambda'(\omega+\varepsilon_d;r) = \left(\frac{2\pi}{3}\right)^2 \frac{1}{r^2} f_d(\omega)\tilde{f}_d(\omega). \tag{17}$$

We thus have the X-ray absorption intensity near the resonant threshold in terms of Green's function g_{sc}

$$I(\omega) \sim -2\mathrm{Im}\sum_c \langle\phi_c|\Delta'(\omega+\varepsilon_d)^\dagger g_{sc}(\omega+\varepsilon_d)\Delta'(\omega+\varepsilon_d)|\phi_c\rangle,$$

$$\Delta'(\omega+\varepsilon_d) = \{r+\lambda(\omega+\varepsilon_d;r)+\lambda'(\omega+\varepsilon_d;r)\}Y_{10}(\hat{\boldsymbol{r}}), \tag{18}$$

where the sum over c means the sum over m_c. The resonant contribution from shallow core X-ray absorption near deep core threshold was first discussed in ref. [7]. We frequently use the $L_{2\,3}$ white line intensity to discuss the 3d hole population. From the above discussion 3d X-ray absorption intensity shows additional resonant behaviour near the 2p threshold, which makes the white-line analyses difficult and complicated.

4. Conclusion

We study the influence of the polarization part W_p of the screened Coulomb interaction $W(\omega)$ on MARPE and XAFS. We successfully relate the resonant term to the X-ray absorption factor f_d from the deep core ϕ_d, which has been used in the analyses of the resonant X-ray scattering. We should note that W_p also plays an important role in the other resonant phenomena accompanied by core excitations.

Abstract

Resonant inelastic X-ray scattering (RIXS) is uniquely related to X-ray absorption oscillator strength distribution by Kramers-Heisenberg equation via lifetime widths of the states involved. By using RIXS spectra of CuO it is shown that XANES, where the lifetime broadening (LB) of the 1s core-hole is removed and that of the 2p hole determines the resolution, can be analytically deduced from RIXS profiles. Furthermore, it is demonstrated that numerical procedures can eliminate also the remaining 2p broadening, providing LB-free XANES.

1. Introduction

X-ray absorption near edge structure (XANES) provides one of the most useful tools for studying the density of the electronic states around selected atomic species. XANES features are, however, often smeared out because of the natural lifetime width of the core holes. In order to overcome this fundamental limitation, high-resolution fluorescence excitation (HRFE) spectroscopy has been proposed to obtain lifetime-broadening-removed (LBR) XANES spectra [1], where highly monochromatic incident X-ray energy is scanned across an absorption edge while monitoring the characteristic fluorescent X-rays with better resolution than the lifetime width. However, later it was suggested that, rigorously speaking, HRFE spectra can not be viewed as genuine LBR-XANES [2–4]. In addition, this technique is limited to atomic species where suitable high-resolution crystal analyzers are available for the characteristic lines [1, 3].

An alternative method of obtaining LBR-XANES by the use of resonant inelastic X-ray scattering (RIXS) has been theoretically suggested by Tulkki and Åberg [5] even before the proposition of the HRFE spectroscopy. Intense monochromatic X-rays recently available at third generation of synchrotron radiation facilities have made it possible to experimentally substantiate the observation of LBR-XANES from RIXS spectra [6]. In this work using CuO data it is demonstrated that 1s lifetime-broadening-removed (LBR) and 1s as well as 2p lifetime-broadening-removed or lifetime-broadening-free (LBF) XANES can be deduced from experimental RIXS spectra.

2. Experimental

The experiments were carried out at the BL47XU beamline at SPring-8. The experimental details were described elsewhere [6]. In short, incident X-rays (flux= $\sim 10^{14}$ photons/s; spectral width = 0.9 eV at 8 keV) were horizontally focused by a cylindrically-bent mirror and irradiated onto the sample, with an ion chamber monitoring the beam intensity. The scattered radiation was analyzed with a spherically-bent ϕ 75 mm Si(444) crystal having an 820 mm radius of curvature, and detected by a scintillation counter. To acquire 1s2p RIXS spectra, the incident energy remained fixed and the scattered photon energy was analyzed by moving the analyzer and the detector synchronously. In these measurements, the active area of the analyzer was limited to 40 mm in diameter, which resulted in the overall energy resolution (ΔE_{exp}) of 1.1 eV as determined by the FWHM of the elastic line. All data were taken on powder CuO at room temperature at a constant scattering angle of 80°.

For comparison, HRFE spectrum was derived from the intensity at Cu $K\alpha_1$ energy, 8047.8 eV, of each RIXS spectrum. Conventional XANES spectrum was obtained by monitoring the intensity of total fluorescence by a pin-photo diode while excitation energy is scanned.

3. Results and Discussion

3.1. *RIXS spectra of CuO*

Figure 1 shows excitation energy dependence of RIXS spectra of CuO. Spectral shape and intensity change with excitation energy significantly. Excitation with X-ray energies well above

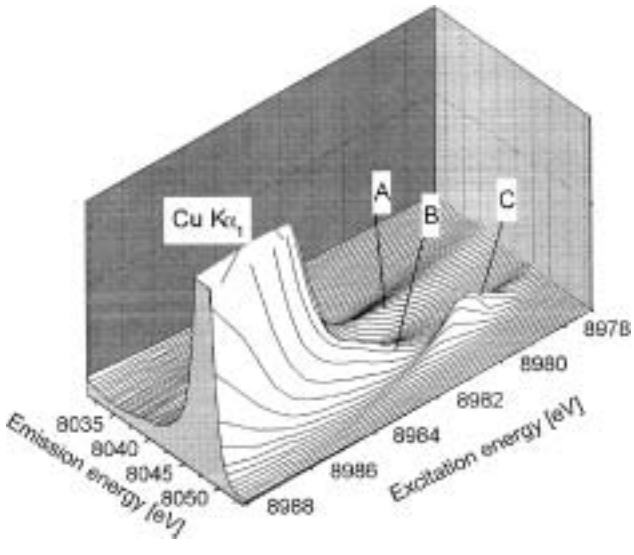

Fig. 1. Excitation energy dependence of resonant inelastic X-ray scattering (RIXS) spectra of CuO as a function of excitation energy and emission energy.

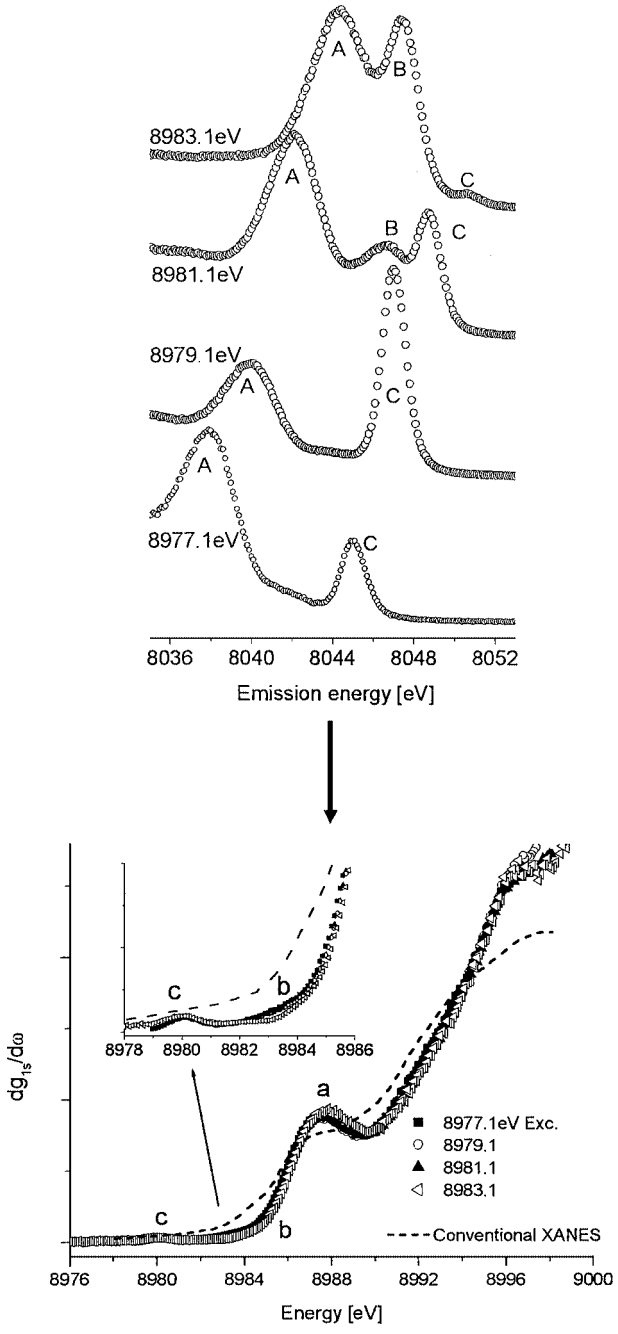

Fig. 2. Selected RIXS spectra of CuO (upper panel) and LBR-XANES profiles analytically calculated from them (lower panel). Conventional XANES is also shown in the lower panel for comparison.

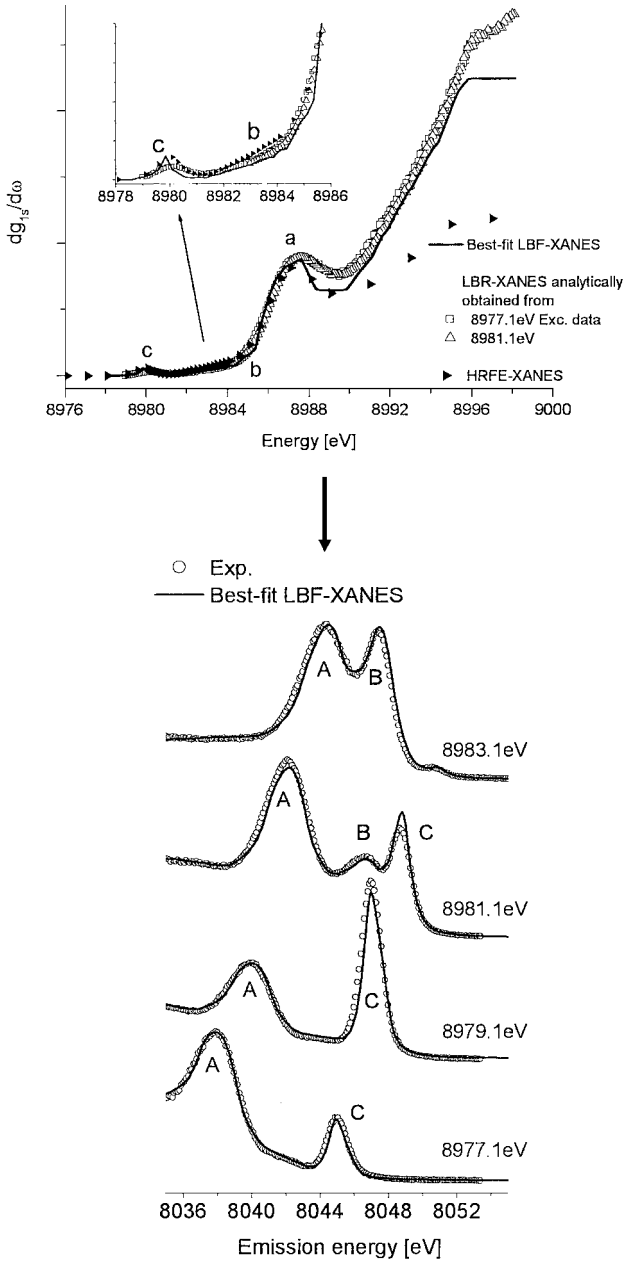

Fig. 3. Upper panel: the best-fit LBF-XANES ($dg_{1s}/d\omega$) as well as LBR-XANES spectra analytically obtained from RIXS by 8977.1 eV and 8981.1 eV excitation. Also shown is the HRFE spectrum. Lower panel: comparisons of the observed RIXS spectra and calculated ones by the use of best-fit ($dg_{1s}/d\omega$) model.

the K-absorption edge energy (∼8986 eV) yields a single band at 8047.8 eV, which is the well-known Cu Kα_1 fluorescence line (In Fig. 1 the Kα_1 peak is out of the scale). As the excitation energy lowered below the K-edge, the main feature corresponding to the Kα_1 (denoted A) is shifted down with its width broadened. By lowering the excitation energy to ∼8983 eV, a new branch, labeled B, appears, which can be seen as a distinct peak in Figs. 2 and 3. Another feature labeled C is prominent at the excitation energy below 8983 eV. As the excitation energy further lowered, the peak energy of A continues to shift to lower energy, preserving the energy loss (E_{loss}) of 939 eV. At the same time, the scattering intensities decrease monotonously. In contrast to the consecutive changes with excitation energy observed for A, the branch B is only observable within a small range of excitation energy, from ∼8981 to ∼8984 eV. Furthermore, the E_{loss} of the branch B varies with the excitation energy. On the other hand, E_{loss} for C remains constant (932 eV) and is independent of the excitation energy, as is the branch A. As the excitation energy is tuned to ∼8980 eV, which is the transition energy from 1s to the vacant 3d [7], the band C is the strongest with the band width much narrower than the normal Kα_1 fluorescence. These excitation energy dependencies of RIXS spectral features have been already reported [6, 8].

3.2. *Analytical deduction of LBR-XANES*

The differential cross section of 1s2p RIXS process can be deduced from the well-known Kramers-Heisenberg equation as follows [5]:

$$\frac{d\sigma(\omega_1)}{d\omega_2} \propto \int \frac{(\omega_2/\omega_1)(\Omega_{1s}+\omega)(dg_{1s}/d\omega)}{((\Omega_{1s}+\omega-\omega_1)^2+\Gamma_{1s}^2/4\hbar^2)((\omega_{2p}+\omega_2+\omega-\omega_1)^2+\Gamma_{2p}^2/4\hbar^2)}\,d\omega. \quad (1)$$

Here $\hbar\omega_1$ and $\hbar\omega_2$ are incident and scattered photon energies, $\hbar\omega$ refers to the kinetic energies of the excited electron or binding energy of the bound electron in the intermediate state, and Γ_{1s} and Γ_{2p} are the widths of the 1s and 2p levels, the energies of which are represented by $\hbar\Omega_{1s}$ and $\hbar\Omega_{2p}$. The $\mathrm{d}g_{1s}/\mathrm{d}\omega$ is the oscillator strength distribution for K-absorption, which is in general a superposition of discrete and continuous features.

Under the approximation that $\Gamma_{2p}/2\hbar \ll 1$, Eq. (1) can be transformed to a more transparent form [6] by using the Kα-emission condition $\hbar\omega_{K\alpha} = \hbar(\Omega_{1s} - \Omega_{2p}) = 8047.8\,\mathrm{eV}$ and employing the absorption energy $\omega_{abs} = \Omega_{1s} + \omega = \omega_{K\alpha} + \omega_1 - \omega_2$.

$$\frac{\mathrm{d}\sigma(\omega_1)}{\mathrm{d}\omega_2} \propto \frac{(\omega_2/\omega_1)\omega_{abs}(\mathrm{d}g_{1s}/\mathrm{d}\omega_{abs})}{(\omega_{K\alpha} - \omega_2)^2 + \Gamma_{1s}^2/4\hbar^2}. \tag{2}$$

This equation means that the cross section of 1s2p RIXS is, apart from the factor $(\omega_2/\omega_1) \times \omega_{abs}$, proportional to $\mathrm{d}g_{1s}/\mathrm{d}\omega_{abs}$ multiplied by a Lorentzian centered at $\omega_{K\alpha}$. Hence it is possible to calculate $\mathrm{d}g_{1s}/\mathrm{d}\omega$ analytically from the experimental RIXS spectra directly, or vice versa. Under the approximation employed here, $\mathrm{d}g_{1s}/\mathrm{d}\omega$ derived from RIXS by Eq. (2) is free from lifetime-broadening by Γ_{1s} and the width is determined only by ΔE_{exp} and Γ_{2p}.

In the upper panel of Fig. 2 the RIXS spectra of CuO excited at several excitation energies are shown. In the lower panel shown are LBR-XANES profiles of CuO analytically derived from the RIXS spectra by the use of Eq. (2). The inset shows 1s→3d transition region below the absorption edge in an expanded scale. It is rather striking that, in spite of significant differences in RIXS spectra employed, LBR-XANES derived by Eq. (2) almost overlaps with each other. Although not shown for clarity of the figure, a use of RIXS spectra at other excitation energies produces almost the same results as long as the excitation energy is below about 8984 eV.

In the lower panel of Fig. 2 conventional XANES is also shown. It is clear from the comparison that features in LBR-XANES are much more distinct than those in conventional XANES. This endorses that line-broadening by Γ_{1s}, which often hampers detailed analysis of conventional XANES, is removed in LBR-XANES derived from RIXS.

3.3. *Lifetime-broadening-free XANES by simulation*

In the derivation of Eq. (2) it has been assumed that Γ_{2p} is zero. Since the quality of the present RIXS data allows us to examine the profiles in detail numerically, attempted next is to derive $\mathrm{d}g_{1s}/\mathrm{d}\omega$ by numerical simulation based on Eq. (1) without such an assumption. The $\mathrm{d}g_{1s}/\mathrm{d}\omega$ profiles obtained from this procedure correspond to lifetime-broadening-*free* (LBF) XANES. Detailed procedures are described elsewhere [6].

In the upper panel of Fig. 3 a $\mathrm{d}g_{1s}/\mathrm{d}\omega$ model that reproduces observed RIXS spectra best is shown. Also shown are LBR-XANES profiles obtained in the previous section together with the HRFE spectra. It is evident that $\mathrm{d}g_{1s}/\mathrm{d}\omega$ obtained here shows much more distinct features than those obtained in the previous section and the HRFE spectra, demonstrating that the core-hole lifetimes of 2p as well as 1s are removed. Well above the absorption edge the HRFE spectra show significant deviation from LBR-XANES, the reason of which we believe is in the re-absorption effects. In the present method, since both the incident energy and the scattering energy are below the absorption edge, absorption is relatively weak and changes only slightly with excitation energy.

In the lower panel of Fig. 3 calculated RIXS profiles from the best-fit $\mathrm{d}g_{1s}/\mathrm{d}\omega$ model are compared with some of the experimental RIXS spectra. It is evident that the observed RIXS spectra, which vary enormously with excitation energy, almost exactly coincide with the corresponding ones generated by the *single* $\mathrm{d}g_{1s}/\mathrm{d}\omega$ model.

Roughly speaking, there are the following relations between $\mathrm{d}g_{1s}/\mathrm{d}\omega$ features and RIXS peaks. First, the main RIXS feature, which is indicated by A in Figs. 1–3, is essentially determined by the profile of the prominent features in XANES indicated by a in Figs. 2 and 3. The shape of the low-energy tail of the features a, indicated by b, determines the RIXS feature B. The discrete 1s→3d band c at 8980 eV is responsible to the prominent feature C in the RIXS spectra. From these observations it is confirmed that complicated behavior of the RIXS spectra, found in Figs. 1–3, can be explained qualitatively as the reflection of the LBF-XANES profile.

Many exciting applications of the present LBR-or LBF-XANES spectroscopy, e.g., the in-situ determination of the catalysts or batteries during reactions, could be envisaged.

Abstract

A newly designed multi-crystal X-ray spectrometer equipped with a two dimensional position sensitive proportional counter is described. The spectrometer employs five cylindrically bent rectangular Ge(4 4 0) crystals with $35 \times 100\,\mathrm{mm}^2$ in size, whose radius of curvature is 550 mm. Diffracted X-rays from each crystal are horizontally dispersed and vertically focused onto different portions of the detector, and spectra are constructed by adding data from five crystals. Resonant Kβ emission spectra of Mn compounds obtained with this spectrometer are presented.

1. Introduction

Resonant and near resonant X-ray fluorescence spectra, obtained by exciting around the absorption edge, varies significantly with excitation energy and contain invaluable information about the electronically excited states. What is essential to the resonant X-ray fluorescence experiments is a high-resolution spectrometer to analyze emitted radiation together with highly monochromatized intense exciting X-rays. Because the emission intensity sharply decreases with decrease in excitation energy from the absorption edge, the analyzer has to be also highly efficient. To achieve this goal, several attempts have been made so far. For example, Bergman *et al.* [1] have developed a *focusing-type* spectrometer having 8 spherically bent crystals. In this work, a *dispersive-type* spectrometer with 5 cylindrically bent crystals combined with a position sensitive detector, which has evolved from our previous design [2], is described. A large acceptance angle, high experimental resolution, and wide energy range make this spectrometer particularly suited for studies of resonant fluorescence spectroscopy.

2. A multi-crystal spectrometer with a two-dimensional position-sensitive detector

Fig. 1 shows the principle of a spectrometer employing a cylindrically bent crystal. The diffraction plane is illustrated as a hatched area. The X-rays from the sample point are horizontally dispersed according to their energies. On the other hand, vertically dispersed components are focused on a point along the central axis of the cylinder shown in Fig. 1. The distance from the diffracted point can be expressed as $f = R/\sin\theta_B$, where the θ_B and R are the Bragg angle and the radius of curvature of the crystal, respectively. Thus by placing a position-sensitive detector at the focus area, a wide spectrum can be obtained simultaneously.

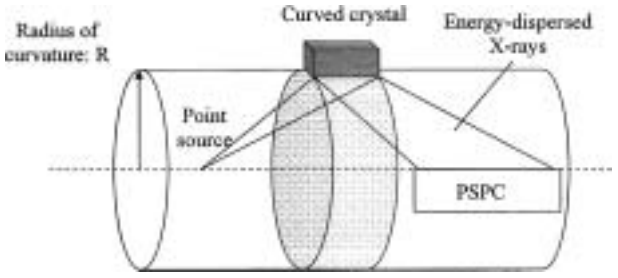

Fig. 1. The principle of a spectrometer employing a cylindrically bent crystal.

In this dispersive-type setting the energy resolution of the spectrometer ($\Delta E/E$) can be described by the following equation,

$$\Delta E/E = \cot\theta_B\,\Delta\theta, \tag{1}$$

where $\Delta\theta$ is the angular divergence, and is estimated from

$$\Delta\theta \simeq (d+s)/f. \tag{2}$$

Here d and s mean the horizontal beam size on the sample and the spatial resolution of the detector [3]. It should be noted that, unlike for the focusing modes [4], $\Delta\theta$ in the dispersive optics is independent of $\cot\theta_B$. Hence the dispersive-type optics can cover a wider energy range by one kind of crystal plane than the focusing-type optics, without severely deteriorating the resolution. This makes it possible to extend the atomic species to be investigated.

Fig. 2 illustrates a schematic geometry of the present spectrometer. Scattered radiation from the sample was analyzed with five cylindrically bent rectangular Ge(440) crystals with $35 \times 100\,\mathrm{mm}^2$ in size whose radius of curvature (R) is 550 mm. They are aligned with different tilt angles to focus images on different places of the detector. The crystals were held on a plate, which can be moved in horizontal direction to change the Bragg angles (θ_B). Analyzed X-rays are detected with a 2-dimensional position sensitive proportional counter (Hi-STAR, Bruker AXS) which is filled with Xe gas and equipped with 2D multiwire grid for readout.

Resultant 2D images, five horizontally-dispersed patterns, are converted to 1D spectrum by adding them after energy calibration.

3. Resonant Kβ emission measurements of MnO

To demonstrate the performance of the spectrometer, Kβ emission spectra of several Mn compounds were measured at various excitation energies across the Mn K-edge. In these experiments the overall energy resolution, estimated from FWHM of elastic lines, was about 1.4 eV. Owing to largely increased detection solid angle, the required data acquisition period is from only a few

*e-mail: udagawa@tagen.tohoku.ac.jp

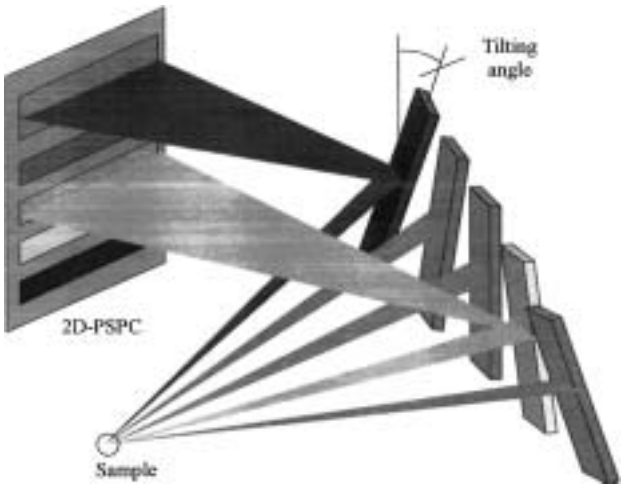

Fig. 2. A Schmatic diagram of dispersive-type 5-crystal spectrometer with a 2-dimensional position-sensitive detector.

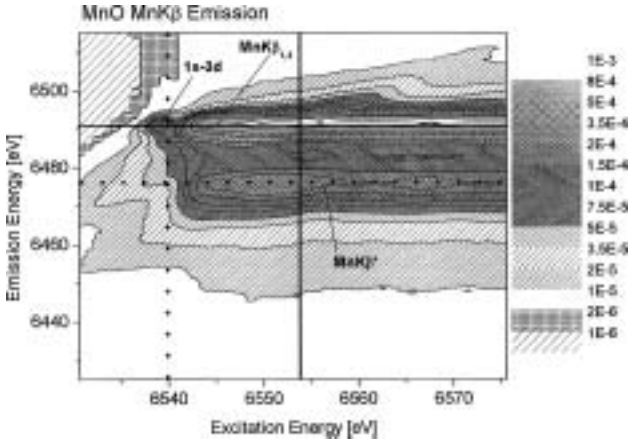

Fig. 3. A contour map of KB emission intensities of MnO as a function of both the excitation and emission energies.

minutes (resonant) to an hour (non-resonant) for each emission spectrum. Such short data acquisition period opens up a new possibility of X-ray emission spectroscopy; instead of a series of one-dimensional spectra, two-dimensional mapping is now possible. The results on MnO are shown in Fig. 3 as a contour plot, where the abscissa and the ordinate are excitation and emission energies; 46 spectra taken at different excitation energies are complied to make this map.

Traversing the contour plot parallel to the ordinate yields a usual emission spectrum obtained by exciting the X-ray energy as indicated at the abscissa. For example, by 6554 eV excitation, which is indicated by a vertical solid line, an emission spectrum with two prominent peaks corresponding to $K\beta_{1,3}$ and $K\beta'$ at 6491 and 6476 eV is obtained. Similarly, excitation at 6540 eV, indicated by a vertical dot, yields an asymmetric peak at 6491 eV. On the other hand, by traversing the contour plot along a horizontal line, one obtains excitation spectra for constant final state energy. The spectrum along the horizontal solid line in the figure will show strong 3d resonance, while another one along the horizontal dot will not exhibit 3d resonance.

Spin – dependent X-ray absorption of Mn compounds has been studied by Hämäläinen *et al.* [5]. They observed that XANES obtained by monitoring the $K\beta_{1,3}$ band is different from the one by $K\beta'$; in particular 3d resonance is observed only in the former. The observation is exactly what is obtained along the two horizontal lines in Fig. 3.

Of particular importance is the existence of structures that stretch diagonally in the plot. These correspond to resonant inelastic (Raman) scattering spectra, and from the analysis of these structures it is possible to deduce lifetime-broadening-removed or lifetime-broadening-free XANES spectra [6].

In summary, by a spectrometer combining 5 cylindrically bent dispersing crystals with position sensitive proportional counter, it is possible to obtain high-resolution emission spectra within a reasonable period of time. It opens up a new possibility of resonant X-ray emission spectroscopy.

Abstract

We have measured and analyzed Si L_{23}-edge electron energy loss near edge structure (ELNES) spectra for silicon, silicon oxide and their interface. ELNES spectra have been recorded by a combination of high resolution electron energy loss spectroscopy and an installed slit built in a 300 keV transmission electron microscope. The projected slit allows us to have signals about each 0.7 nm width area of the specimen. These spectra change site by site from Si to SiO_2. With the aid of multiple scattering calculations, we have discussed the local structure near the interface.

1. Introduction

Si and SiO_2 are among the most important materials and are widely studied becasue of their fundamental and industrial importance. To obtain local structural and electric information, Si L_{23}-edge ELNES spectra have been measured by several authors [1, 2]. In particular much effort has been paid to study Si-SiO_2 interface structures. Si 2p core level angle-resolved photoemission was studied with some simple models based on the statistical cross-linking between Si and SiO_2 [3]. Si-SiO_2 bonds length in the interface region are estimated by an analysis for O K-edge EXELFS [4], and it was concluded that the interface bond length is slightly larger than that of SiO_2.

ELNES and XANES are commonly used to investigate short range structures and electronic states. Both of them mainly originate from the electric dipole transition from a selected core orbital to unoccupied states [5, 6]. The structures of ionization edges reflect the density of states with some excitonic contribution from the core hole that is created in this inelastic scattering process. In low energy ionization edge regions such as Si L_{23}, EELS is suited for investigating at high energy resolution.

Si L_{23}-edge EELS spectra for Si wafer covered with SiO_2 are successfully measured in a narrow domain with a width of each 0.7 nm on the sample. These spectra change site by site from Si to SiO_2.

In this study, we report full multiple calculations of Si L_{23}-edge ELNES for Si, SiO_2 Si-SiO_2 and their interfaces. We also discuss the theoretical results for Si and SiO_2 near the interface.

2. Experiment

(100)-oriented silicon wafer covered with thermally grown silicon oxide and SiN_x are studied in this work. A sample was prepared by a sliced specimen, 60 nm thick. EELS measurements were carried out by using high resolution electron energy loss spectroscopy built in a 300 keV TEM. In the TEM is installed a slit which allows having a signal on a region 0.7 nm times 27 nm at the position of the sample. This system has been developed as a useful tool to study a narrow region so we can distinct Si, SiO_2 and their interface spectra.

3. Theory

In the ELNES region, scattering from surrounding atoms are strong enough that the multiple scattering renormalization is crucial. The full multiple scattering ELNES formula used in this article is developed by one of the authors [5, 6] and obtained in the closed form as a typical XANES formula.

$$I(\boldsymbol{p}', \boldsymbol{p}) = -4\pi \mathrm{Im}[i^{\ell_1-\ell} t^A_{\ell_1} \mathrm{e}^{\mathrm{i}(\delta^A_{\ell_1}+\delta^A_{\ell})} \times \langle c|u^{\dagger}|L_1\rangle [(1-X)^{-1}]^{AA}_{L_1,L} \langle L|u|c\rangle] \quad (1)$$

where $u = u(\boldsymbol{p}', \boldsymbol{p})$ is one electron inelastic amplitude from $\boldsymbol{p}$ to $\boldsymbol{p}'$ and one electron state $|L\rangle = |R_{\ell}(r)Y_L(\hat{\boldsymbol{r}})\rangle$ is a partial wave of an EXAFS electron with angular momentum $L = (\ell, m)$. $(1-X)^{-1}$ represents a renormalized infinite order multiple scattering term, where the matrix $X^{\alpha\beta}$ can be written as

$$X^{\alpha\beta}_{L_1,L_2} = t^{\alpha}_{\ell_1}(k) G_{L_1,L_2}(kR_{\alpha} - kR_{\beta})(1-\delta_{\alpha\beta}) \quad (2)$$

where t^{α} and $G_{LL'}$ represent the T-matrix at site α and the Green function in an angular momentum representation. This matrix element describes a physical process where a photoelectron wave propagates from site β with angular momentum $L_2 = (\ell_2, m_2)$ to site α and is scattered off with angular momentum $L_1 = (\ell_1, m_1)$. The t-matrix reflects the electronic structure whereas G reflects the geometric structure. Thus ELNES spectra can give us useful information on electronic and geometric structures around the excited atom.

4. Results and Discussion

4.1. *Si and SiO₂*

We first consider the Si L_{23}-edge ELNES for Si and SiO_2. Figures 1(a) and 1(e) show a comparison between the experimental and theoretical Si L_{23}-edge ELNES spectra for SiO_2 and Si. To calculate these spectra, we use clusters with diamond structure for Si and crystalline quartz structure for SiO_2. These clusters have atoms up to 8 Å around an excited Si atom. To calculate the phase shift for SiO_2, electronic structures of Si and O atoms were referred to the density functional results [7].

The structure of theoretical ELNES spectra for Si is in good agreement with the experimental data in both the shape and the loss intensity.

In the case of Si L_{23}-edge ELNES for SiO_2, the agreement between the experimental and the theoretical spectra is good for

*Electronic address: matumoto@graduate.chiba-u.jp

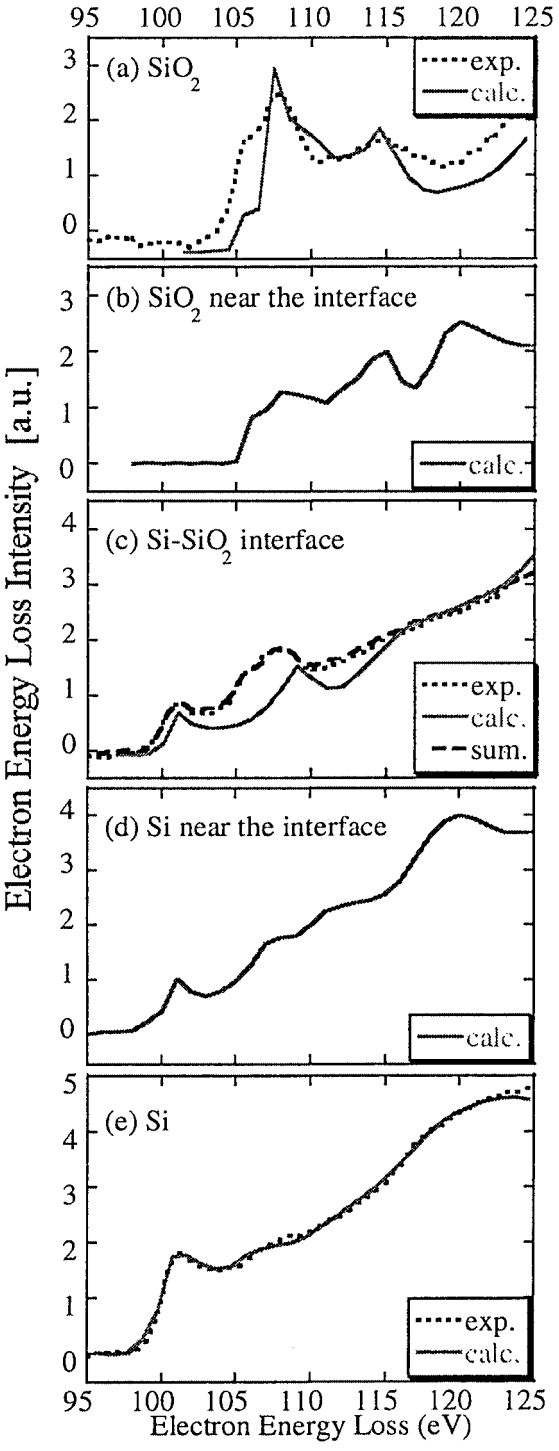

Fig. 1. Observed Si L_{23}-ELNES spectra (dotted lines) for SiO_2 (a) and Si (e) compared with the calculated ones (solid lines). The observed ELNES for the Si-SiO_2 interface is shown in (c), where we also show the weighted sum of observed spectrum (dashed line) for Si and SiO_2, compared with the calculated result at the interface. The ELNES spectra (b) show the calculated one for SiO_2 and (d) is for Si near the interface. The interface model is shown in Fig. 2.

the peak positions, however little worse in loss intensity. We have sharp peaks in the calculated results at 108 eV and 114 eV.

4.2. *Si-SiO_2 interface*

In this paper, we consider a abrupt interface model to calculate ELNES spectra for interface Si atoms. The interface geometry used in this model is shown in Fig. 2 where the interface Si atom is labeled (c). This model is obtained by joining a bulk truncated Si(111) lattice to pure SiO_2, with all the dangling bonds from

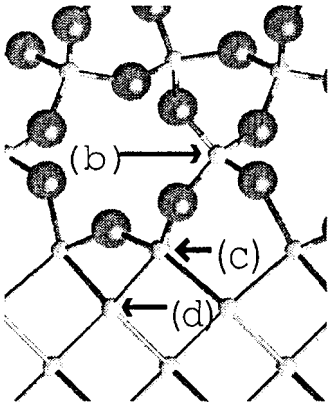

Fig. 2. A model of a Si-SiO_2 interface viewed from the side. Results of calculations for Si atom labeled (b), (c) and (d) correspond to the spectra in Figs. 1(b), 1(c) and 1(d) respectively. This model is obtained by joining a Si lattice, terminated by Si atoms with two back bonds each and two dangling bonds, to a pure SiO_2 lattice. Here each interface Si atom is with suboxide bonds.

both sides stitched together [3]. Below the terminating Si lattice, we assume each interface Si atom has two back bonds and two dangling bonds protruding to the other side of the interface. Then we join these protruded dangling bonds to O of SiO_2.

In Fig. 1(c), the observed ELNES for Si atoms in the interface region is compared with the weighted sum spectrum of these for Si and SiO_2 (*sum*-spectrum) and also with the calculated one for the interface. The observed interface spectrum reflects EELS passing through the window of the 0.7 nm width slit near the interface. We can see that the observed interface spectrum and the *sum*-spectrum show same structure. Hence we can conclude that the interface ELNES has information about the interface region and consists of linear combination spectra of Si and SiO_2.

The calculated Si L_{23}-edge ELNES for site (c) has two peaks. We found that one peak at 101 eV also observed in Si, as shown in Fig. 1(e), and an other at 108 eV.

4.3. *Near the interface*

Figures 1(b) and 1(d) show theoretical Si L_{23}-edge ELNES spectra for SiO_2 (*near*-SiO_2) and Si (*near*-Si) near the interface respectively. The corresponding excited Si atoms for *near*-Si and *near*-SiO_2 are represented in fig. 2, labeled (b) and (d) respectively.

The result for *near*-SiO_2 has similar structure as that of bulk spectra for SiO_2 and has small and broader peak at 108 eV and exhibits a additional peak at 115 eV.

The calculated result for *near*-Si has similar structure as that of bulk spectra for Si. The *near*-Si spectrum exhibits a smaller peak at 101 eV, compared with the observed Si spectrum in Fig. 1(e).

5. Concluding Remarks

Si L_{23}-edge ELNES spectra for Si, SiO_2 and their interface were measured by high resolution EELS spectroscopy. In order to investigate their detailed features, we have used full multiple scattering theory of ELNES for Si, SiO_2 and their abrupt interface. We assumed that their structures were diamond-Si, α-quartz and their abrupt interface model respectively. The calculated Si spectrum is good agreement with the experimental one. The calculation result for SiO_2 agrees for the peak positions. The observed interface ELNES spectrum has the structures of both the observed Si and SiO_2. Therefore, the interface region

spectrum consists of a linear combination of Si and SiO_2 spectra. In fact, the *sum* spectra agree with experimental interface ELNES.

We also calculated Si L_{23}-edge ELNES for the Si-SiO_2 interface and the neighbors in an abrupt interface model. The essence of this model is an abrupt transition from Si to SiO_2, with the dangling bonds from the two sides of the interface plane stitched together. The calculated spectrum for Si-SiO_2 interface has two peaks in the ELNES region, one is at 101 eV and the other is at 108 eV, and the feature of both observed Si and SiO_2 spectra as the observed interface region spectrum has the character of both Si and SiO_2. The calculated results for *near*-Si and *near*-SiO_2 spectra show similar structures to observed Si and SiO_2 ones respectively.

Acknowledgments

We would like to thank Yoshifumi Ogawa for supplying the experimental data.
