Subscriptions
The Royal Swedish Academy of Sciences
PO Box 168, Didcot D.O., Oxford, OX11 7WD, United Kingdom

Subscription enquiries
May be made to the above address or by email to subscriptions@physica.org

Subscription Rates
Subscription to Physica Scripta for 2005 (includes Topical Issues) at **Sterling Pounds 995** for EEC countries: Austria, Belgium, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Italy, Ireland, Latvia, Lithuania, Luxembourg, Malta, Netherlands, Poland, Portugal, Slovakia, Slovenia, Spain, Sweden, United Kingdom along with Iceland and Norway. Payment for all other countries can only be accepted at **US$1638**. Payment by credit card will be converted at the prevailing rate for Sterling pounds. Further details are available from **subscriptions@physica.org**. Topical Issues are supplied in CD format. Printed versions of Topical Issues are available at an additional charge.

Back numbers and single issues
Can be ordered separately. Price information on request to the above address or by email to subscriptions@physica.org

Manuscripts
Shall be submitted electronically to submissions@physica.org
Please see Instructions to Authors or consult http://www.physica.org. Enquiries as to the status of submitted manuscripts should be made to physica@kva.se

Offprints
The corresponding author will receive a .pdf file upon completion of publication

Typeset by J. W. Arrowsmith Ltd and Printed in Great Britain by Marston Book Services Ltd, Didcot, Oxon.

Contents

Committees 16

Foreword 17

Lars Hedin and the Quest for a Theory of Excited States. *J. J. Rehr* 19

Invited and plenary

Nonspherical Potential, Vibronic and Local Field Effects in X-Ray Absorption. *A. L. Ankudinov and J. J. Rehr* 24

Advances in the Theoretical Analysis of the XANES (X-ray Absorption Near Edge Structure) Energy Region for Quantitative Structural Use. *M. Benfatto, S. Della Longa and P. D'Angelo* 28

Modeling Core-Hole Screening in Core-Excitation Spectroscopies. *E. L. Shirley, J. A. Soininen and J. J. Rehr* 31

Relativistic Keldysh Green's Function Approach to XAFS Theory. *T. Fujikawa* 35

New Insights for Materials Science Characterisation Using Different Complementary Techniques Combined with X-ray Absorption Spectroscopy. *V. Briois, S. Belin, F. Villain, F. Bouamrane, H. Lucas, R. Lescouëzec, M. Julve, M. Verdaguer, M. S. Tokumoto, C. V. Santilli, S. H. Pulcinelli, X. Carrier, J. M. Krafft, C. Jubin and M. Che* 38

Lattice Dynamics Information Obtained from EXAFS Measurements on Ta. *H. H. Rossner, E. Holub-Krappe, M. Fieber-Erdmann and H. J. Krappe* 45

X-ray Magnetic Dichroism: The Technique of Choice to Study Magnetism Element Specifically. *K. Baberschke* 49

Magneto-Electric Interactions Probed by X-ray Optical Activity. *J. Goulon, A. Rogalev, F. Wilhelm, N. Jaouen, C. Goulon-Ginet, P. Carra, I. Marri and Ch. Brouder* 54

Time-Resolved Energy-Dispersive XAFS for *In-situ* Characterization of Nano-Structures and Catalysts. *Y. Iwasawa, A. Suzuki and M. Nomura* 59

Evolution of Catalyst Structure under Reaction Conditions from Time-resolved *in situ* XAS Investigations. *T. Ressler, J. Wienold and O. Timpe* 66

In Situ Monitoring of Oxide-Supported Platinum-Group Metal Catalysts by Energy Dispersive EXAFS. *A. J. Dent, S. Diaz-Moreno, J. Evans, S. G. Fiddy, B. Jyoti and M. A. Newton* 72

In-situ Al K-edge Spectroscopy on Zeolites: Instrumentation, Data-interpretation and Catalytic Consequences. *J. A. van Bokhoven* 76

Environmental Interfaces, Heavy Metals, Microbes, and Plants: Applications of XAFS Spectroscopy and Related Synchrotron Radiation Methods to Environmental Science. *G. E. Brown, Jr., J. G. Catalano, A. S. Templeton, T. P. Trainor, F. Farges, B. C. Bostick, T. Kendelewicz, C. S. Doyle, A. M. Spormann, K. Revill, G. Morin, F. Juillot and G. Calas* 80

Energy-Dispersed Near-Edge X-Ray Absorption Fine Structure: a New Technique to Study Dynamic Surface Processes. *H. Kondoh, K. Amemiya, I. Nakai, M. Nagasaka, A. Nambu, T. Shimada, T. Yokoyama and T. Ohta* 88

Capturing Excited State Molecular Structures in Disordered Media with 100 ps Time Resolution by Laser Pump X-ray Probe XAFS. *L. X. Chen, G. B. Shaw, T. Liu, G. Jennings and K. Attenkofer* 93

Capacitance XAFS Method: A New Site-Selective and Microscopic X-Ray Absorption Spectroscopy. *M. Ishii, A. Nakao and T. Uchihashi* 97

Picosecond Time-Resolved X-Ray Absorption Spectroscopy of Solvated Organometallic Complexes. *W. Gawelda, C. Bressler, M. Saes, M. Kaiser, A. N. Tarnovsky, D. Grolimund, S. L. Johnson, R. Abela and M. Chergui* 102

Sub-Nanosecond Time Resolved XAFS of Laser Excited Thin Ge Films. *E. A. Stern, D. L. Brewe, K. M. Beck, S. M. Heald and Y. Feng* 1044

This page contains the contents of this issue. Full contents are contained on the CD and in the online version at www.physica.org. The following pages contain these additional contents.

Theory and fundamental aspects

Local Structure of Spin-Crossover Complex Studied by X-Ray Absorption Spectroscopy: Nature of Photo-Induced Phase. *H. Oyanagi, T. Tayagaki and K. Tanaka* 107

Size- and Site-Dependence of XMCD Spectra of Iron Clusters from *ab-initio* Calculations. *O. Šipr and H. Ebert* 110

XMCD Study on Electronic and Magnetic States of Rare-Earth 5d Electrons in Laves Compounds, RFe$_2$ (R = Rare-Earth). *A. Fujiwara, K. Asakura, I. Harada, H. Ogasawara and A. Kotani* 113

Structure of New Heterometallic Complexes in Hexane on Modelling the Recovery of Ruthenium From Radioactive Solutions. *S. B. Erenburg, N. V. Bausk, L. N. Mazalov, R. S. Shulman, T. V. Us and V. G. Torgov* 115

Strong Electron Correlation in Ca 2p, Sr 3d and Ba 4d Core Hole States Investigated by Means of Photoelectron Spectroscopy and MCDF Calculations. *J. Nikkinen, H. Aksela, S. Heinäsmäki, E. Kukk, N. Berrah and S. Aksela* 119

Theoretical Study of X-ray Photoemission, X-ray Absorption and Resonant X-ray Emission Spectroscopy of Mn Films on Ag. *M. Taguchi, P. Küger, J. C. Parlebas and A. Kotani* 122

Conjugate Shake Processes upon 2p-Photoabsorption of Atomic Sulphur. *A. G. Kochur and D. Petrini*. . . 125

Oxygen 1s NEXAFS Spectra of theV_2O_5(010) Surface: Theoretical Studies Using *ab initio* DFT Cluster Models. *C. Kolczewski and K. Hermann*. 128

XANES Calculation with an Efficient ''Non Muffin-Tin'' Method: Application to the Angular Dependence of the Al K-Edge in Corundum. *D. Cabaret, E. Gaudry, M. Taillefumier, P. Sainctavit and F. Mauri* 131

Self-Consistent Non-Local Optical Potential for XANES. *K. Hatada, M. Benfatto and C. R. Natoli* 134

Ab Initio R-Matrix/MQDT Method for Near-Edge X-ray Absorption Fine Structure. *M. Hiyama and N. Kosugi* 136

Temperature Dependence of Local Structure of Ge Impurity in Si (001)Thin Film Probed by Multiple-Scattering XAFS. *S. Wei, Z. Sun, H. Oyanagi, W. Zhong and D. Chen* 140

EXAFS and Local Thermal Expansion. *P. Fornasini, S. a Beccara, G. Dalba, R. Grisenti, J. Purans, A. Sanson, F. Rocca and D. Diop* 143

Multi-Channel Multiple Scattering Theory for XAFS. Application to $L_{2,3}$ Edges of Ca. *P. Krüger and C. R. Natoli*. 146

XANES and EXAFS Modelling of Configurational Disorder in Silver Borate Glasses. *G. Dalba, P. Fornasini, A. Kuzmin, F. Monti, A. Sanson, O. Sipr and F. Rocca* 149

A Quantitative Structural Investigation of the XANES Spectra of Potassium Ferrocyanide (III) at the Iron K-Edge. *K. Hayakawa, K. Hatada, C. R. Natoli, P. D'Angelo, S. D. Longa and M. Benfatto* 152

The Mean Square Variation of Multiple Scattering Path Length by Molecular Dynamics Simulation. *N. Binsted, A. B. Edwards, J. Evans and M. T. Weller* 155

Using Bond Valence Sums as Restraints in XAFS Analysis. *M. Newville* 159

X-ray Spectra and Electron Densities of States of the Complicated Semiconductors $TlAsS_2$, Tl_3AsS_3, Tl_3AsS_4 and Tl_3PS_4. *A. A. Lavrentyev, B. V. Gabrelian, I. Ya. Nikiforov, J. J. Rehr and A. L. Ankudinov* 162

Sodium K Edge XANES Calculation in 'NaCl' Type Structures. *R. J. Prado and A. M. Flank* 165

The Fourier-Transform Analysis of Ti K-XANES in Metamicts and Glasses. *L. Bugaev, F. Farges, E. Rusakova, A. Sokolenko,Ya. Latokha and L. Avakyan* 168

Aluminium K-edge XANES Study of Mica Preiswerkite. *Z. Wu, A. Marcelli, G. Cibin, A. Mottana and G. D. Ventura* 172

Initial Results of the One-Dimensional XAFS Debye-Waller Models for Active Sites of Cu Histidine and Cystein Metalloproteins. *N. Dimakis and G. Bunker* 175

Similarities and Differences Between XANES Spectra at Analogous Edges of Ternary Semiconductors $CuGaSe_2$, $ZnGeAs_2$ and $CuFeS_2$. *O. Šipr, J. Drahokoupil, P. Machek and A. Šimůnek* 179

Localized Nature of Valence-Hole States in $Ca_{2+x}Y_{2-x}Cu_5O_{10}$ Shown by O 1s XAS. *K. Okada* 182

Real Space Approach to Thermal Factor in EXAFS for Asymmetric Double-Well Potential. *K. Nitta, T. Miyanaga and T. Fujikawa*. 185

Selective Detection of Deep Level Centers by X-ray Absorption Fine Structure Questioned. *J. Bollmann, S. Knack, J. Weber, V. Koteski, H.-E. Mahnke and E. Welter* 188

Ab Initio Calculation of the Cr K Edge in α-Al_2O_3:Cr^{3+}. *E. Gaudry, D. Cabaret, Ph. Sainctavit, Ch. Brouder, F. Mauri, A. Rogalev and J. Goulon* 191

Overlapping XAFS L Spectra of 3d Metals: A New Application of the Regularization Method. *Yu. Babanov, S. Kiryanov, A. Sidorenko, L. Romashev, D. Vyalikh, S. Molodtsov, G. Guentherodt, U. Ruediger, Yu. Dedkov, M. Fonine, K. Baberschke, H. Wende and Y. U. Idzerda* 194

Thickness Inhomogeneity Effect in EXAFS Spectroscopy. *A. V. Ryazhkin, Yu. A. Babanov, T. Miyanaga, E. D. Crozier, R. A. Gordon, T. Reich and H. Funke* 197

Improvement of Double-Shell *R*-Space Resolution by the EXAFS Regularization Method. *D.-S. Yang and J. M. Lee* 200

Improved Self-Absorption Correction for Fluorescence Measurements of Extended X-Ray Absorption Fine-Structure. *C. H. Booth and F. Bridges* 202

REX2000: Yet Another XAFS Analysis Package. *T. Taguchi, T. Ozawa and H. Yashiro* 205

Final-State Rule vs the Bethe-Salpeter Equation for Deep-Core X-ray Absorption Spectra. *J. J. Rehr, J. A. Soininen and E. L. Shirley* 207

Nonlinear Energy Dependence of the Forbidden Energy Band in the Solid Solutions $Cu_xAg_{1-x}B^{III}C_2^{VI}$. *A. A. Lavrentyev, B. V. Gabrelian, I. Ya. Nikiforov, J. J. Rehr and A. L. Ankudinov* 212

Fe Coordination Environment in Fe(II)- and Fe(III)-Silicate Glasses via the Fourier-Transform Analysis of Fe K-XANES. *L. Bugaev, F. Farges, E. Rusakova, A. Sokolenko, Ya. Latokha and L. Avakyan* 215

Atomic Absorption Background in EXAFS of Rb in Inter-Alkaline Alloys. *A. Kodre, I. Arčon, J. P. Gomilšek and A. Mihelič* 218

Continuous Cauchy Wavelet Transform of XAFS Spectra. *M. Muñoz, F. Farges and P. Argoul* 221

A Study of the Pre-Edge X-Ray Absorption Fine Structures in Ni Monoxide. *S. J. Li, Z. Y. Wu, T. D. Hu, Y. N. Xie, J. Zhang, T. Liu, C. R. Natoli, E. Paris and A. Marcelli* 223

3D Molecular Graphical user Interface Add-On for Analysis Program for EXAFS: A New Prospect. *N. Dimakis and G. Bunker* 226

Lifetime dependency of the VUV-excited resonant photoemission spectra of ionic molecules. *M. Huttula, E. Kukk, H. Aksela, R. Sankari and S. Aksela* 229

Wavelet Analysis of Extended X-Ray Absorption Fine Structure Data. *H. Funke, M. Chukalina and A. Rossberg* 232

Cs L-Edge EXAFS Atomic Absorption Background. *I. Arčon, A. Kodre, J. P. Gomilšek, M. Hribar and A. Mihelič* 235

Efficient Determination of Optimal Regularization Parameter for Inverse Problem in EXAFS Spectroscopy. *M. Kunicke, I. Yu. Kamensky, Yu. A. Babanov and H. Funke* 237

Simultaneous Fitting with Constraints for EXAFS Study of Anharmonic Vibrational System. *D.-S. Yang, H.-M. Park and I. Nakai* 240

Multi-pole Representation of the Dielectric Matrix. *J. A. Soininen, J. J. Rehr and E. L. Shirley* 243

Calculation of Grazing Incidence EXAFS: Fresnel Theory Versus DWBA. *P. Keil, D. Lützenkirchen-Hecht and R. Frahm* 246

Local Structures of GaAs Semiconductor in High Shells Studied by Multiple-Scattering Extended X-ray Absorption Fine Structure. *Z. Sun and S. Wei* 249

Thermal-Motion-Induced Resonant Reflections at the Ge K-edge: Calculation of the Intensity Dependence on Atomic Displacements. *E. N. Ovchinnikova, A. P. Oreshko, Y. Joly, A. Kirfel, B. P. Tolochko and V. E. Dmitrienko* 252

Materials

DAFS and XAFS Investigation of Structural Short-Range Order of Decagonal Al-Co-Ni. *A. Kupsch, D. C. Meyer, P. Gille and P. Paufler* 255

Near-edge Absorption Spectroscopy of Interplanetary Dust Particles. *S. Brennan, K. Luening, P. Pianetta, J. Bradley, G. Graham, A. Westphal, C. Snead and G. Dominguez* 261

Correlations in the Vibrations of Atoms in Complex Unit Cells. *F. Bridges and D. Cao* 264

Thermal Vibration of the Rutile-Type Difluorides of First-Row Transition Metals. *K.-i. Murai, A. Yoshiasa, T. Yamanaka and I. Nakabayashi* 267

EXAFS and XRD Study of Local Dynamics in Cu_2O and Ag_2O. *A. Sanson, G. Dalba, P. Fornasini, R. Grisenti, F. Rocca, G. Artioli, M. Dapiaggi and W. Tiano* 271

XAFS Analysis of Layered $Li_xNi_{0.5}Mn_{0.5}O_2$ ($0 < x \leq 2$) Electrodes for Lithium Batteries. *A. J. Kropf, C. S. Johnson, J. T. Vaughey and M. M. Thackeray* 274

X-Ray Studies of Pd/Ag Membranes for Hydrogen Separation. *L. C. Witjens, J. H. Bitter, A. J. van Dillen, F. M. F. de Groot, D. C. Koningsberger and K. P. de Jong* 278

Combined XAFS/Powder Diffraction Analysis of Randomly Substituted Cation Sites in Crystalline Oxides. *N. Binsted, M. Stange, H. Fjellvåg and M. T. Weller* 281

Local Structure Analyses of Contamination Metals on the Silicon Wafer After LSI Processes Using XAFS Technique. *H. Hashimoto, J. Tsuji, H. Yokoi, S. Murakami and Y. Hanada* 285

Evidence by XAS of Tin Oxide Coating Layered Double Hydroxides. *M. Intissar, V. Briois, J.-P. Besse and F. Leroux* 288

Densification of Mn-Doped Tin Oxide Films by Conventional Heating and Microwave Heating Treatment. *A. P. Rizzato, C. V. Santilli, S. H. Pulcinelli, D. Stuerga, D. Chaumont and V. Briois* 291

Short Range Structure of Lanthanum Chloride/Oxychloride Determined by EXAFS. *H. Matsuura, S. Watanabe, T. Kanuma, H. Akatsuka, T. Honma, N. Umesaki, A. Kajinami, A. K. Adya and R. Fujita* 294

Short Range Structure of Lead-Lithium Fluoride Obtained by XAFS Analysis. *S. Watanabe, R. Toyoyoshi, T. Sakamoto, Y. Okamoto, Y. Iwadate, H. Akatsuka and H. Matsuura* 297

XAFS and Spectroscopic Characterization for the Structure and Electronic Structure of Ce-DMDPhPDA Complexes in Methanol. *T. Yaita, H. Shiwaku, S. Suzuki, Y. Okamoto, A. Shimada, Z. Assefa and R. G. Haire* 302

Structural Analysis of Co-Extracted Heptavalent, Technetium and Rhenium Complexes by EXAFS. *S. Suzuki, T. Yaita, Y. Okamoto, H. Shiwaku and H. Motohashi* 306

C K-Edge NEXAFS of 6H-SiC and 3C-SiC Systems. *M. Pedio, A. Giglia, N. Mahne, S. Nannarone, S. Giovannini, C. Cepek, F. Boscherini, R. Carboni, M. Benfatto and S. D. Longa* 308

Zinc Oxynitride Powders Examined by X-ray Absorption Near Edge Spectroscopy. *T. Moriga, T. Sakamoto, R. Saki, K.-i. Murai, I. Nakabayashi and J. B. Metson* 312

Local Structure of Six-Coordinated Silicon in Li_2O-SiO_2-P_2O_5 Glasses by Transmission XAFS Experiments. *K. Handa , J. Ide, K. Yamamoto, N. Kurosawa, K. Ozutsumi, T. Harami, K. Kojima and N. Umesaki* 314

A XANES Study at the Na and Al K-edge of Soda-Lime Aluminosilicate Glasses and Crystals. *D. R. Neuville, L. Cormier, A.-M. Flank and P. Lagarde* 316

XAFS Study of BI*ME*VOX Ionic Conductors for *ME* = Mg, Si, Zr, Zn. *A. Twaróg, R. Bacewicz, A. Kozanecka, W. Wróbel, F. Krok and I. Abrahams* 318

Behavior of Sodium Deposited on SiO_2 at High Coverages. *R. J. Prado, P. Lagarde, A.-M. Flank and J. Jupille* 320

Unoccupied Electronic States of MgS, CaS, FeS: X-Ray Absorption Fine Structure Theoretical Analysis. *A. V. Soldatov, A. N. Kravtsova, M. E. Fleet and X. Liu* 323

Characterization by XAS of NiO Thin Films Prepared by Pulsed LASER Deposition. *J. Moscovici, I. Bouessay, A. Rougier and A. Michalowicz* 326

EXAFS Study of SnO_2 Xerogel Doped with Sb and PTCDA. *J. P. Gomilšek, U. L. Štangar, A. Š. Vuk, G. Bratina, I. Arčon and A. Kodre* 329

XANES Study of Tribofilms Generated from Belt-Drive Continuously Variable Transmission Fluids. *Y. Iwanami, H. Wada and M. Nomura* 332

Near Edge X-Ray Absorption Spectroscopy: a Novel Approach for Determining Conduction Band Edge States in Transition Metal Oxide Gate Dielectrics. *G. Lucovsky, Y. Zhang, J. L. Whitten, D. G. Schlom and J. L. Freeouf* 335

Determination of the Short-Range Structure of $ZnCl_2$ in its Liquid, Vitreous and Crystalline Phases by XAS, at High Pressure and High Temperature. *C. Fillaux, B. Couzinet, C. Dreyfus, J. P. Itié and A. Polian* 339

X-ray Absorption Studies of Borosilicate Glasses Containing Dissolved Actinides or Surrogates. *C. Lopez, X. Deschanels, C. D. Auwer, J.-N. Cachia, S. Peuget and J.-M. Bart* 342

Characterization of Lithium Battery Materials During their Functioning in Using Dispersive XAS. *G. Ouvrard, N. Bourgeon, D. Guyomard, F. Baudelet and S. Belin* 346

EXAFS Study on Disorder in Microstructure of Amorphous Mesoporous Titania with Large Surface Areas. *H. Yoshitake, T. Sugihara and T. Tatsumi* 349

Combining EXAFS and X-Ray Powder Diffraction to Solve Structures Containing Heavy Atoms. *C. Hennig, T. Reich, W. Kraus, G. Reck, F. Prokert and N. Schell* 352

Lattice Location of N in $In_xGa_{1-x}As_{1-y}N_y$ Dilute Nitrogen Alloys. *G. Ciatto, F. Boscherini, F. D'Acapito, D. De Salvador, D. Batchelor, R. Carboni, L. Grenouillet, H. Mariette and S. Mobilio* 356

XAFS Study of Local Structure Change in Perovskite Titanates. *K. Sato, T. Miyanaga, S. Ikeda and D. Diop* 359

XAFS Study of Cu(II), Ni(II) and Co(II) β-Aminovinylketone Complexes. *V. G. Vlasenko, A. I. Uraev and A. D. Garnovskii* 362

Determination of Tm Charge State in PbTe(Tm) by XANES Method. *A. I. Lebedev, I. A. Sluchinskaya, S. G. Nikitenko and S. G. Dorofeev* 365

Lattice Relaxation around Arsenic and Selenium in CdTe. *V. Koteski, H. Haas, E. H.-Krappe, N. Ivanovic and H.-E. Mahnke* 369

XAFS Study of A-site-Deficient $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ Perovskite. *A. Yoshiasa, M. Okube, H. Okudera, A. Nakatsuka, M. Yashima, A. Sakai, M. Mori and R. Ali* 372

XAFS Study of the Perovskite-Type Proton Conductor $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$. *M. Okube, A. Yoshiasa, M. Yashima, K. Ohuchi, T. Ishimura, C. Numako and K. Koto* 375

XANES Study of Lanthanum-Doped Lead Titanate Ceramics. *P. P. Neves, V. R. Mastelaro, A. Michalowicz, J. A. Eiras, L. P. Lopes, A. C. Doriguetto and Y. P. Mascarenhas* 378

Pressure Induced Phase Transitions in Amorphous Ge. *E. Principi, F. Decremps, A. Di Cicco, F. Datchi, S. De Panfilis, A. Filipponi and A. Polian* 381

Local Order Around Er^{3+} Ions in thin Silicon Oxide Layers Grown in Si by MBE. *F. d'Acapito, S. Mobilio, A. Terrasi, S. Scalese, G. Franzó and F. Priolo* 384

The Structural Role of Ag in Galena (PbS). A XANES Study. *G. Giuli, E. Paris, Z. Wu, S. De Panfilis, G. Pratesi and C. Cipriani* 387

Reflection mode XAFS at the Ti K-edge of Lithium Intercalated TiO_2 Electrodes. *D. Lützenkirchen-Hecht, M. Wagemaker, A. A. van Well and R. Frahm* 390

Linearly Polarized Carbon K-edge X-ray Absorption Spectroscopic Study of Heavily *p*-Doped Polyacetylene Film with Preferred Orientation. *M. G. Kim, H. J. Lee, B. H. Kim, J. S. Kim and Y. W. Park* 393

Cs 3d Absorption and Resonant Photoemission Study of Caesium Halogenides. *R. Ruus, K. Kooser, E. Nõmmiste, A. Saar, I. Martinson and A. Kikas* 396

In-situ XAFS Studies on Local Structures of Molten InSb Compounds. *S. Wei, K. Lu, C. Li, W. Zhong, W. Yan, T. Uruga, W. Chen, X. Niu, Z. Wu, D. Chen and Z. Sun* 399

XAFS Study on Cathode Materials for Li-ion Batteries using X-ray Microbeam. *T. Nonaka, C. Okuda, H. Nakano, Y. Ukyo and Y. Seno* 402

Tin and Niobium in Dry and Fluid-Rich (H_2O, F) Silicate Glasses. *P. C. Piilonen, F. Farges, R. L. Linnen and G. E. Brown Jr.* 405

XANES Study on Solid Electrolyte Interface of Li Ion Battery. *T. Akai, H. Ota, H. Namita, S. Yamaguchi and M. Nomura* 408

Comparison of Photo-Degradation of Polyimide Film by UV Irradiation in Air and in Vacuum . *T. Tanaka, K. K. Bando, N. Matsubayashi, M. Imamura and H. Shimada* 412

Structure Determination by EXAFS of Nb-Peroxo-Citrato Complexes in Aqueous Solution-Gel Systems. *M. K. Van Bael, I. Arčon, K. Van Werde, D. Nelis, J. Mullens and L. C. Van Poucke* 415

Debye-Waller Factor Study of Co, Cu and CoCu Granular Alloy. *J. C. Cezar, N. P. Abreu and H. C. N. Tolentino* 418

Microstructures of Mechanically Alloyed $Fe_{60}Ni_{40}$ Studied by XAFS and XRD. *S. Yin, Z. Xie, J. Zhang, Q. Bian, W. Yan, Z. Jiang and S. Wei* 421

Multiple Scattering Analysis of O K-Edge NEXAFS in Iron Oxides. *S. Giovannini, F. Boscherini, R. Carboni, L. Signorini, L. Pasquini, N. Mahne, A. Giglia, M. Pedio, S. Nannarone, M. Benfatto and S. Della Longa* 424

Local Structure in $LaMnO_3$ Across the Jahn-Teller Transition. *Raquel. A. Souza, Aline Y. Ramos, Helio C. N. Tolentino and E. Granado* 428

Fluorescence EXAFS Analysis of Nanoscale Zinc-Blende MnAs Dots Grown on GaAs(001) by Molecular Beam Epitaxy. *H. Ofuchi, J. Okabayashi, M. Mizuguchi, M. Yamada, K. Ono, Y. Takeda, M. Oshima and H. Akinaga* 431

Soft X-ray XAFS Experiments of SiO_2-P_2O_5 Sol-Gel Film. *J. Ide, K. Handa, H. Takakura, K. Ozutsumi and N. Umesaki* 433

XAFS Study on Silica Glasses Irradiated by High-Energy Particles. *T. Yoshida, T. Tanabe and H. Yoshida* 435

Quantum Dots Microstructure and Energy Spectrum Peculiarities. *S. B. Erenburg, N. V. Bausk, L. N. Mazalov, A. I. Nikiforov and A. I. Yakimov* 439

Orbital Ordering in $Pr_{0.5}Sr_{0.5}MnO_3$: Pr K-Edge XAFS Study. *K. R. Priolkar, V. D. Kulkarni, P. R. Sarode, R. Kumashiro and S. Emura* 442

An Investigation of Valence State and Structural Geometry of Polyvalent Fe and Ti Ions in Sodium Borosilicate Glasses by X-Ray Absorption Spectroscopy. *X. C. Yang, M. Dubiel, D. Ehrt and A. Schütz* 445

Zr K-Edge EXAFS Study of PZT Thin Film Formation From Sols. *I. Arčon, B. Malič, M. Kosec and A. Kodre* . 448

EXAFS and XRD Characterization of Iron Thin Films Prepared by Sputtering at Very Low Temperatures. *F. Jiménez-Villacorta, A. Muñoz-Martín, M. Vila, C. Prieto and A. Traverse* 450

EXAFS Characterization of Nickel Clusters in Ni/Si_3N_4 Sputtered Thin Films. *M. Vila, F. Jiménez-Villacorta, C. Prieto and A. Traverse* 454

Local Structure of $Sr_2FeMo_xW_{1-x}O_6$ Double Perovskites Studied by EXAFS. *F. Bardelli, C. Meneghini, S. Mobilio, S. Ray and D. D. Sarma* 457

Local Structure of Ag Nano-Clusters Deposited on Silicon Wafer by Total Conversion Electron Yield XAFS. *Y. Suzuki, T. Miyanaga, K. Kita, T. Uruga and I. Watanabe* 459

EXAFS Study of $PbPb_{1/3}Ta_{2/3}O_3$ Perovskite. *V. G. Vlasenko, I. V. Pirog, I. P. Raevskii, O. N. Razumovskaya, S. I. Raevskaya and L. A. Shilkina* 462

Changes in the Local Structure of Nanocrystalline Electrochromic Films of Hydrated Nickel Vanadium Oxide upon Ozone-Induced Coloration. *E. Avendaño, A. Kuzmin, J. Purans, A. Azens, G. A. Niklasson and C. G. Granqvist* 464

Application of a Metal Ion-Implantation for the Preparation of Visible-Light Sensitive Zeolite Photocatalyst: V Ion-Implanted Ti-Containing HMS Mesoporous Molecular Sieves. *H. Yamashita, Y. Kanazawa, K. Kida and M. Anpo* 467

XAS Study of A_2FeMoO_6 Double Perovskite. *J. Herrero-Martín, J. García, G. Subías, J. Blasco and M. C. Sánchez* 471

Confined Lead Nano-Granules Investigated with X-ray Absorption Spectroscopy. *A. Witkowska, J. Rybicki, A. Trapananti, E. Principi and A. Di Cicco* 474

Structural Analysis of Manganese Borate Glasses by XAFS Measurement. *A. Kajinami, S. Deki and K. Handa* 477

Chemical State Analysis of 0.2 mass% Mo in Steel by XAFS. *M. Nagoshi, T. Kawano, K. Sato, M. Funakawa, T. Shiozaki and K. Kobayashi* 480

Ce 2p3d Resonant Inelastic X-ray Scattering in Ce–Ni Intermetallic Compounds. *J.-M. Mariot, L. Journel, R. Delaunay, J.-P. Rueff, G. Schmerber, J.-P. Kappler, N. Jaouen, F. Wilhelm, A. Rogalev, C. F. Hague and G. Krill* 483

XANES Study of Titanium Environment in $BaO\text{-}B_2O_3\text{-}TiO_2$ System. *V. R. Mastelaro, C. A. C. Feitosa, L. J. Q. Maia, A. C. Hernandes, A. Ibanez and A. Michalowicz* 486

Mineralogy of Greigite Fe_3S_4. *I. Letard, Ph. Sainctavit, N. Menguy, J.-P. Valet, A. Isambert, M. Dekkers and A. Gloter* 489

Evolution of an Iron Film on GaAs(001)-4 $\times$ 6. *R. A. Gordon, P. S. Budnik, D. T. Jiang and E. D. Crozier* . . 492

Structure of the Magnetic Trilayer System Fe/Pd/Fe Epitaxially Grown on GaAs(001)-4 $\times$ 6. *P. S. Budnik, R. A. Gordon and E. D. Crozier* 495

Valence State of Ru at the Mn sites in $Pr_{0.5}Sr_{0.5}MnO_3$. *J. S. Kim, B. H. Kim, D. C. Kim, M. G. Kim, A. Maignan, B. Raveau and Y. W. Park* 498

Soft X-ray Absorption Spectra of Amorphous Carbon. *Y. Muramatsu, E. M. Gullikson and R. C. C. Perera* . 501

Glancing Angle Fluorescence XAFS Study on Metal Oxide Thin Films Obtained by Oxygen Gas Cluster Ion Beam Assisted Deposition Techniques. *H. Kageyama, T. Asanuma, T. Takeuchi, K. Kadono, J. Matsuo, T. Seki, T. Kitagawa, N. Toyoda, Y. Shimizugawa and T. Uruga* 504

Pseudo Jahn-Teller Effect Observed in $Eu@C_{60}$. *S. Emura, K. Shirai and Y. Kubozono* 507

The Hybridized M3d-F2p Character of Low-Energy Unoccupied Electron States in 3d Metal Fluorides Observed by F 1s Absorption. *A. S. Vinogradov, S. I. Fedoseenko, S. A. Krasnikov, A. B. Preobrajenski, V. N. Sivkov, D. V. Vyalikh, S. L. Molodtsov, V. K. Adamchuk, C. Laubschat and G. Kaindl* 510

Investigation of Structural and Electronic Properties in Ru Perovskite Oxides by XAFS Measurements. *M. Mizumaki, K. Yoshii, Y. Hinatsu, Y. Doi and T. Uruga* 513

Correlation Between Local Structure and Ionic Conductivity of Potassium-Doped Siloxane Poly(propyleneoxyde) Ormolytes. *J. Chaker, K. Dahmouche, V. Briois, C. V. Santilli, S. H. Pulcinelli and P. Judeinstein* 516

Solvation Structure of Bromobenzene Molecule Doped in Supercritical Xenon Studied with Fluorescent XAFS Measurement. *Z. Jin, K. Nakagawa, M. Tanaka, I. Shimoyama, F. Kaneko and T. Murata* 520

XAFS Observations of Initial Growth of (0001) ZnO on {1120} Sapphire Substrates. *P. Fons, K. Nakahara, A. Yamada, K. Matsubara, K. Iwata, H. Takasu and S. Niki* 523

Ge Coordination States in SiO_2-GeO_2 Glasses at High Pressure, Inferred from *in situ* XAFS at the Ge K-Edge. *O. Majérus, L. Cormier, J.-P. Itié and G. Calas* 525

Measurement of Luminescence from Silica Glasses: an Optical X-Ray Absorption Fine Structures Study at Si K-Edge. *T. Yoshida, T. Tanabe, S. Takahara and H. Yoshida* 528

Sodium Adsorption on the TiO_2(110) Surface: an XAFS Structural Study. *R. J. Prado, P. Lagarde, A.-M. Flank, J. Jupille and S. Bourgeois* 531

XANES Studies of Thallium Compounds and Valence States and Local Environment of Thallium in Some of its Superconducting Cuprates. *A. Agarwal and A. N. Vishnoi* 534

High-Pressure EXAFS and XRD Investigation of Unit Cell Parameters of SnO. *H. Giefers, F. Porsch and G. Wortmann* 538

Mn on the Surface of ZnO(0001) – a Resonant Photoemisson Study. *E. Guziewicz, K. Kopalko, J. Sadowski, M. Guziewicz, Z. Golacki, J. Kanski and L. Ilver* 541

X-ray Excited Optical Luminescence Studies of PPh_3AuCl: Site-Specificity at the C and P K-Edges and the Au $M_{5,4}$-Edges. *P.-S. G. Kim, Y. F. Hu, R. J. Puddephatt and T. K. Sham* 545

The P(1s) and P(2p) XAFS Spectra of Elemental Phosphorus, Theory and Experiment. *A. Jürgensen* . . . 548

XANES, EXAFS and RMN Contributions to Follow the Structural Evolution Induced by Alkali-Silica Reaction in SiO_2 Aggregate. *L. Khouchaf, J. Verstraete, R. J. Prado and M. H. Tuilier* 552

EXAFS Study of Pressure-Induced Phase Transition in $SrWO_4$. *A. Kuzmin, R. Kalendarev, J. Purans, J. P. Itié, F. Baudelet, A. Congeduti and P. Munsch* 556

Electrochemical Lithium Intercalation into Transition Metal Oxides. *U. Haake, D. Lützenkirchen-Hecht and R. Frahm* 559

Local Structures of Liquid Semi-Metal Sb Studied by *in-situ* XAFS. *W. Yan, C. Li, S. Wei, Z. Wu, X. Niu, W. Chen, K. Lu and T. Uruga* 562

In situ X-ray Absorption Spectroscopic Study of Oxide Film on Fe Alloy. *J. S. Kim, C. H. Chang and K. Y. Kim* 564

XAFS Analyses of Zinc Compound in Corrosion Product for Magnesium Alloy of Super Plastic Processing. *T. Honma, H. Mori, K. Higashi, H. Okado, K. Maehara, I. Hirosawa and N. Umesaki* 567

X-ray Absorption Studies of Al-Mn System. *L. K. Mehta, S. K. Joshi and A. P. Deshpande* 570

X-Ray K-Absorption Studies of Cobalt (II) Imidazoles. *S. K. Joshi and B. D. Shrivastava* 573

XAFS Study on $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ Cathode Materials for Li-Ion Battteries. *Y. Arachi, H. Kobayashi, S. Emura, Y. Nakata, M. Tanaka and T. Asai* 577

Magnetism

Magnetic moment in the Top Pt Layer of Co/Pt Bilayers. *M. Suzuki, H. Miyagawa, N. Kawamura, H. Muraoka, Y. Inaba, T. Shimatsu, Y. Sonobe, Y. Isohama, N. Nakamura, N. Ishimatsu and H. Maruyama* . 580

CO Induced Spin Reorientation Transition of Co/Pd(111) Studied by XMCD and XPS. *D. Matsumura, T.Yokoyama, K. Amemiya, S. Kitagawa and T. Ohta* 583

Limitations of Integral XMCD Sum-Rules for the Early 3d Elements. *A. Scherz, H. Wende, C. Sorg, K. Baberschke, J. Minár, D. Benea and H. Ebert* 586

Local Structure in Strained Manganite thin Films. *N. M. Souza-Neto, A. Y. Ramos, H. C. N. Tolentino, E. Favre-Nicolin and L. Ranno* 589

Ga Magnetic Polarization in Mn_3GaC under High Pressure Probed by Ga *K*-Edge XMCD. *N. Kawamura, N. Ishimatsu, M. Isshiki, Y. Komatsu and H. Maruyama* 591

Jahn-Teller Dynamic Distortions in $LaMnO_3$ Determined by EXAFS. *J. García, G. Subías, M. C. Sánchez and J. Blasco* 594

XAFS Study of Epitaxial $Co_xTi_{1-x}O_{2-x}$ Anatase. *S. M. Heald, S. A. Chambers and T. Droubay* 597

Temperature Dependence of Magnetic EXAFS for Rare Earth Elements. *H. Wende, A. Scherz, C. Sorg, Z. Li, P. Poulopoulos, K. Baberschke, A. L. Ankudinov, J. J. Rehr, F. Wilhelm, N. Jaouen, A. Rogalev, D. L. Schlagel and T. A. Lograsso* 600

X-Ray Resonant Scattering in Fe_3O_4, $MnFe_2O_4$ and $CoFe_2O_4$ Ferrites. *G. Subías, J. Garcia, M. G. Proietti, J. Blasco, H. Renevier, J. L. Hodeau and M. C. Sánchez* 603

Atomic Structure and the Magnetic Properties of Zr-Doped Sm_2Co_{17}. *B. Ravel and K. Gallagher* 606

Theoretical Analysis of Spin-Dependent Mn K-Edge X-Ray Absorption of MnP. *G. Smolentsev and A. V. Soldatov* 609

Direct Observation of the Fe Substitution Effect on the MCD Spectra of the Dysprosium Iron Garnet Family. *A. Agui, M. Mizumaki, T. Matsushita, N. Kawamura and T. Nakatani* 611

Fluorescence EXAFS Study on Local Structures around Mn and Fe Atoms Doped in ZnO. *H. Ofuchi, Z. W. Jin, T. Fukumura, M. Kawasaki, Y. Matsumoto, T. Hasegawa, H. Fujioka, M. Oshima and H. Koinuma* . 614

Temperature Dependence of X-Ray Magnetic Circular Dichroism in Rare Earth Iron Garnets (Rare Earth = Gd, Dy and Sm). *H. Miyagawa, N. Kawamura and M. Suzuki* 616

X-ray Absorption Fine-Structure Determination of Interfacial Polarization in $SrTiO_3$ Thin Films Grown on Si(001). *J. C. Woicik, F. S. Aguirre-Tostada, A. Herrera-Gomez, R. Droopad, Z. Yu, D. Schlom, E. Karapetrova, P. Zschack and P. Pianetta* 620

XAS Characterization of Growth Parameter Effects for Pulsed Laser Deposited $CoxTi_{1-x}O_{2-\delta}$ Films. *A. Lussier, J. Dvorak, Y. U. Idzerda, S. R. Shinde, S. B. Ogale and T. Venkatesan* 623

XMCD Investigation of Spin Disorder in γ-Fe_2O_3 Nanoparticles at the Fe $L_{2,3}$ Edges. *S. Brice-Profeta, M.-A. Arrio, E. Tronc, I. Letard, Ch. Cartier dit Moulin and Ph. Sainctavit* 626

A Universal Relationship Between Magnetization and the Local Structure in $La_{1-x}Ca_xMnO_3$; a Probe of the Magnetization Process. *L. Downward, F. Bridges, S. Bushart, J. Neumeier and L. Zhou* 629

Mn K-Edge Magnetic EXAFS for Ni-Mn Alloys. *T. Miyanaga, T. Okazaki, R. Maruko, S. Nagamatsu, T. Fujikawa and Y. Sakisaka* 632

XMCD Signals of the High Spin Molecules Fe_8. *I. Letard, Ph. Sainctavit, D. Gatteschi, Ch. Cartier dit Moulin, G. Champion and J.-P. Kappler* 635

Co/Cu/Ni Trilayers Near Their CurieTemperature Studied by XMCD. *C. Sorg, A. Scherz, H. Wende, T. Gleitsmann, Z. Li, S. Rüttinger, Ch. Litwinski and K. Baberschke* 638

XAS Study of $LaMn_{1-x}Ga_xO_3$ Series. *M. C. Sánchez, G. Subías, J. García and J. Blasco* 641

Analysis for Fe-*M* (*M* = Si, Al, Sn) Alloys by Multiple Scattering X-Ray Magnetic Circular Dichroism of Fe K-Edge. *K. Okamoto, S. Nagamatsu, E. V. Voronina, T. Miyanaga and T. Fujikawa* 645

Evolution of Ni Local Structure in $NdNiO_3$ Perovskite Across the Metal-InsulatorTransition. *C. Piamonteze, H. C. N. Tolentino, A. Y. Ramos, N. E. Massa, J. A. Alonso, M. J. Martínez-Lopes and M. T. Casais* 648

Information in Magnetic EXAFS. *A. L. Ankudinov, J. J. Rehr, H. Wende and K. Baberschke* 651

Resonant Photoemission Study of $La_{1-x}Sr_xMnO_3$ Single Crystals. *L. L. Lev, M. B. Tsetlin, M. Leandersson, H. Nylen, I. Lindau, M. N. Mikheeva and A. M. Balbashev* 654

XAFS and XRD Studies on Structures of $Nd_9Fe_{85-x}Mn_xB_6$ Nanocomposites. *S. Yin, S. Wei, G. Xie, Q. Bian, J. Zhang, O. Chen and H. Yang* 658

Catalysis and nano

Temperature Dependence of the Growth of Cerium Oxide Nanoparticles investigated by SAXS and XANES. *J. Zhang, Z. Y. Wu, L. X. Rong and B. Z. Dong* 661

Study on the Thermal Degradation of CeO_2-ZrO_2 Solid Solution by XAFS and XRD. *Y. Nagai, T. Yamamoto, T. Tanaka, T. Nonaka and A. Suda* 664

Study of the Probe Molecule Adsorption on Co-Mo Sulfide Model Catalysts by Means of XANES and FT-IR. *T. Kubota, M. Kawano and Y. Okamoto* 667

In-situ X-ray Absorption Spectroscopy Investigations During the Conditioning Procedure of PtRu Colloid Catalysts. *H. Modrow, G. Köhl, J. Hormes, H. Bönnemann, U. Endruschat and R. Mörtel* 671

Monolayer Dispersive Supported CuO/γ-Al_2O_3 Catalysts Studied by XAFS. *D. Chen, X. Zhang, Y. Hu, Y. Chen, S. Zou and S. Wei* 675

In situ Study of the Crystallisation of Nano-Sized Zinc and Cobalt Aluminate Spinel Catalysts from Ion-Exchanged Zeolite Precursors. *A. M. Beale, G. Sankar, D. G. Nicholson and W. van Beek* 678

Structure of Dioxygen Binding Xerogels Incorporating Cyclams Complexed with $CuCl_2$ Salts. *C. Goulon-Ginet, J. Goulon, A. Rogalev, F. Wilhelm, N. Jaouen, G. Dubois, S. Brandès, G. David, R. Guilard, R. Corriu, D. Cabaret and Y. Joly* 681

EXAFS Study of Electrolytic Nanosolution Confined in Interstitial Nanospaces of Single-Wall Carbon Nanohorn Colloids. *T. Ohkubo, Y. Hattori, H. Kanoh, T. Konishi, H. Sakai, M. Abe, D. Kasuya, M. Yudasaka, S. Iijima, T. Fujikawa and K. Kaneko* 685

EXAFS Characterization of the Local Structure of Fe in Fe-ZSM-5: an Experimental and Theoretical Study. *S. H. Choi, B. R. Wood, J. A. Ryder and A. T. Bell* 688

XAFS Study on the Visible-Light Sensitive Cr-Containing Zeolite Photocatalyst: Mesoporous Cr-HMS Molecular Sieves. *H. Yamashita, K. Yoshizawa, K. Kida, S. Ohshiro and M. Anpo* 691

Annealing Temperature Dependence of C_{60} on Silicon Surfaces: Bond Evolution and Fragmentation as Detected by NEXAFS. *M. Pedio, F. Borgatti, A. Giglia, N. Mahne, S. Nannarone, S. Giovannini, C. Cepek, E. Magnano, G. Bertoni, E. Spiller, M. Sancrotti, L. Giovanelli, L. Floreano, R. Gotter and A. Morgante* 695

EXAFS and XANES Study of Two Novel Pd Doped Sn/SnO_x Nanomaterials. *D. Grandjean, R. E. Benfield, C. Nayral, L. Erades, K. Soulantica, A. Maisonnat and B. Chaudret* 699

Cd and Se Atomic Environments During the Growth of CdSe Nanoparticles in Glass. *T. M. Hayes, P. D. Persans, A. Filin, C. Peng and W. Huang* 703

Ni K- and Au L_3-edge XAFS of $[Au_6Ni_{32}(CO)_{44}]^{6-}$ and a Study of its Transformations in Acetonitrile Solutions. *O. A. Belyakova, Y. Kubozono, S. Kashino and Yu. L. Slovokhotov* 705

Investigation of Size Effects in Magnetoelectric $BiFeO_3$. *S. Chattopadhyay, S. D. Kelly, V. R. Palkar, L. Fan and C. U. Segre* 709

Nucleation and Growth of Copper Nanoparticles on Silicon Surfaces. *A. Singh, K. Luening, S. Brennan, T. Homma, N. Kubo and P. Pianetta* 714

Electronic Characterization of the Single-Wall Carbon Nanotubes: a XANES Study. *Z. Y. Wu, I. Davoli, M. L. Terranova, S. Orlanducci, V. Sessa, M. Abbas, K. Ibrahim, J. Zhong and S. Botti* 717

Structural Stability of Giant Polyoxomolybdate Molecules as Probed by EXAFS. *A. I. Frenkel, S. C. Frankel and T. Liu* 721

In Situ XAFS study on Mo Oxide Catalysts by Molten Salt Preparation. *N. Matsubayashi, K. Sato, M. Imamura, H. Shimada, P. Afanasiev and C. Geantet* 724

XAS and XRD Studies on the Structural Changes of Ni-Raney Catalyst after a Hydrogenation Process. *N. Watanabe, A. Y. Ramos, J. A. M. Ferreira and H. C. N. Tolentino* 727

Investigation of Stress State of Silver Nanoparticles in Silicate Glasses by Means of EXAFS. *M. Dubiel, X. C. Yang and S. Brunsch* 729

Local Structures of Nanocomposite $Co\text{-}C_{60}$ and $Co\text{-}SiO_2$ Thin Films Studied by Fluorescence XAFS. *B. Sheng, D. Chen, J. Fan, W. Liu, X. Zhang, Y. Jiang, W. Yan and S. Wei* 733

EXAFS Study of Fe(3+) Interaction with ZrO_2 and TiO_2 Oxides. *V. V. Kriventsov, D. I. Kochubey, G. Colón, M. C. Hidalgo, J. A. Navio, M. V. Tsodikov and Yu. V. Maksimov* 736

EXAFS Study of Nb Doped $Sr(Co/Fe)O_{3-x}$ Perovskites. *V. V. Kriventsov, D. I. Kochubey, Z. R. Ismagilov, O. Yu. Podyacheva and A. P. Nemudry* 740

Estimating Crystallite Size in Polydispersed Samples using EXAFS. *S. Calvin, C. J. Riedel, E. E. Carpenter, S. A. Morrison, R. M. Stroud and V. G. Harris* 744

XAFS and XRD Studies of $PdO\text{-}CeO_2$ Catalysts on $\chi\text{-}Al_2O_3$. *W. B. Li, Y. Murakami, M. Orihara, S. Tanaka, K. Kanaoka, K.-i. Murai, T. Moriga, E. Kanezaki and I. Nakabayashi* 749

XAS Investigation of Iron Substitution in Triclinic FeAPO-34. *I. Arčon, A. Ristić, N. Novak Tušar, A. Kodre and V. Kaučič* 753

Multiple Scattering Approach to Au L_3-edge XANES of $spr\text{-}Au/Al_2O_3$ Catalyst. *S.-i. Nagamatsu, N. Ichikuni, S. Shimazu, T. Fujikawa, K. Fukuda and T. Uematsu* 756

XANES Study of Carbon Nanotubes Grown without Catalyst. *M. I. Abbas, Z. Y. Wu, K. Ibrahim, S. Botti, R. Ciardi and A. Marcelli* 759

XAFS Study on Active Iron Sites in MCM-41 as a Catalyst for Liquid Phase Oxidation. *T. Shishido, Q. Zhang, Y. Wang, T. Tanaka and K. Takehira* 762

In-Situ XAFS Study of Ag Clusters in Zeolite 4A. *Y. Suzuki, T. Miyanaga, H. Hoshino, N. Matsumoto, and T. Ainai* 765

X-ray Absorption Spectroscopy on Heterogeneous Catalysts at the new XAS Beamline at ANKA. *J.-D. Grunwaldt, S. Hannemann, J. Göttlicher, S. Mangold, M. A. Denecke and A. Baiker* 769

In-Situ X-Ray Absorption Near Edge Structure (Xanes) Spectroscopy of PtRu Colloid Catalysts at Operating Temperature. *B. Brendebach, S. Bucher, J. Hormes, H. Bönnemann, K. S. Nagabhushana, R. Brinkmann and H. Modrow* 773

EXAFS Studies of Bimetallic Ag-Pt and Ag-Pd Nanorods. *D. Lahiri, B. A. Bunker, C. M. Doudna, M. F. Bertino, F. Blum, A. Tokuhiro and J. Terry* 776

An XAFS Study on the Polymer Protected CuPd Bimetallic Nanoparticles – A Novel Heterobond-Philic Structure. *K. Asakura, C. R. Bian, S. Suzuki, W.-J. Chun, N. Watari, S. Ohnishi, P. Lu and N. Toshima* 781

Local Structures of Ultra-Thin Pt Films Probed by Grazing Incidence Fluorescence XAFS. *Z. Xie, I. Kojima, Y. Xie, B. He, D. Chen, T. Liu, T. Hu, X. Zhang and S. Wei* 784

Mo K-edge EXAFS Analysis of Mo/USY Zeolite – Effects of Extra-Framework Aluminum on the Location and Dispersion of Mo Sulfide Catalysts. *K. Sato, N. Matsubayashi, M. Imamura, K. K. Bando and H. Shimada* 787

Characterization of Size Dependent Structural and Electronic Properties of CTAB-Stabilized Cobalt Nanoparticles by X-ray Absorption Spectroscopy. *H. Modrow, N. Palina, Ch. S. S. R. Kumar, E. E. Doomes, M. Aghasyan, V. Palshin, R. Tittsworth, J. C. Jiang and J. Hormes* 790

XAS *In Situ* Cell for Measurements of Mn and Fe Promoted Sulfated Zirconia Catalysts. *R. E. Jentoft, A. H. P. Hahn, F. C. Jentoft and T. Ressler* 794

The Structure of a VO_x/TiO_2 (anatase) Powder Catalyst under Reduction and Oxidation at 623 K. *G. Silversmit, J. A. van Bokhoven, H. Poelman, A. van der Eerden, G. B. Marin, M.-F. Reyniers and Roger De Gryse* 798

XAFS Study on the Local Atomic Structures of Cerium-Oxide Nanoparticles with Surface Coatings. *Z. Wu, J. Zhang, X. Chen, Z. Chen, M. Sun, Z. Wu and L. Guo* 802

Preparation of Mesoporous Silica Supported Nb Catalysts and *in-situ* XAFS Characterization During Carburization Process. *N. Ichikuni, H. Hachiya, K. K. Bando, S. Shimazu and T. Uematsu* 807

XAS Studies on Incorporation of Mn and Co into Silicalite-1. *I. Arčon, N. Novak Tušar, A. Ristić, A. Kodre and V. Kaučič* 810

Quantitative Determination of Platinum Oxidation State by XANES Analysis. *H. Yoshida, S. Nonoyama, Y. Yazawa and T. Hattori* 813

Spontaneous Dispersion of PdO and Generation of Metal Pd cluster in Zeolites Studied by Means of *in situ* DXAFS. *K. Okumura, R. Yoshimoto, S. Yokota, K. Kato, H. Tanida, T. Uruga and M. Niwa* 816

X-ray Absorption Spectroscopy on Cu/ZnO Catalysts Selected by High-Throughput Experimentation Techniques. *J.-D. Grunwaldt, C. Kiener, F. Schüth and A. Baiker* 819

In Situ X-Ray Absorption Fine Structure Studies on the Structure of Ni_2P Supported on SiO_2. *T. Kawai, S. Sato, W.-J. Chun, K. Asakura, K.-K. Bando, T. Matsui, Y. Yoshimura, T. Kubota, Y. Okamoto, Y.-K. Lee and T. S. Oyama* 822

Structural Analysis of Photo-Chemically Anchored Molybdenum Oxide Catalysts by EXAFS. *H. Murayama, N. Ichikuni, K. K. Bando, S. Shimazu and T. Uematsu* 825

In-Situ XAFS Analysis of Dynamic Structural Change of Pd-Pt Nano-Particles Supported on Catalyst Surface Under Sulfidation Conditions. *K. K. Bando, T. Matsui, Y. Ichihashi, K. Sato, T. Tanaka, M. Imamura, N. Matsubayashi and Y. Yoshimura* 828

Monitoring of fast Transformations in Solid State Chemistry and Heterogeneous Catalysis by QEXAFS in the Second Scale. *D. Lützenkirchen-Hecht, J.-D. Grunwaldt, M. Richwin, B. Griesebock, A. Baiker and R. Frahm* 831

XAFS Study on the Local Structure of Zirconium Containing Mesoporous Silicas, Zr-MCM-41 and Their Catalytic Properties. *A. Yamaguchi, M. Yokoyama, A. Suzuki, Y. Iwasawa, H. Sakai, M. Yuasa and M. Abe* 834

Structure and Magnetism of Ni Clusters in AlO_x: Importance of XAS in the Synthesis Optimization. *E. Fonda, D. Babonneau, F. Pailloux, S. R. Teixeira and A. Traverse* 837

Effects of Boron and Phosphorous on Nano-Amorphous Ni-B and Ni-P Alloys Studied by X-ray Spectroscopy. *S. Wei, Z. Jiang, Z. Wei, X. Zhang and S. Zou* 841

Biology

The Manganese Complex of Oxygenic Photosynthesis: Conversion of Five-Coordinated Mn(III) to Six-Coordinated Mn(IV) in the S_2-S_3 Transition is Implied by XANES Simulations. *H. Dau, P. Liebisch and M. Haumann* 844

The Location of Calcium in the Manganese Complex of Oxygenic Photosynthesis Studied by X-Ray Absorption Spectroscopy at the Ca K-Edge. *C. Müller, P. Liebisch, M. Barra, H. Dau and M. Haumann* 847

NEXAFS Study of Amino Acid Analogues Assembled on Gold. *R. M. Petoral Jr. and K. Uvdal* 851

An XAS Study of the Cation Binding Sites in the Purple Membrane of *Halobacterium Salinarum*. *F. Sepulcre, M. Grazia Proietti, M. Benfatto, S. D. Longa, J. García and E. Padrós* 855

Simulation of XANES Spectra for Protein-Bound Metal Centers: Analysis of Linear Dichroism Data. *P. Liebisch, M. Haumann and H. Dau* 859

Investigation of the Local Structure of Fe(II) Bleomycin and Peplomycins using Theoretical Analysis of XANES. *G. Smolentsev, A. V. Soldatov, E. Wasinger, E. Solomon, K. Hodgson and B. Hedman* 862

An Enhanced Electronic State in ZnTPP Induced by Interaction with Solvation: A Multiple-Scattering Calculation of X-ray Absorption Near-Edge Spectra. *T. Liu and L. X. Chen* 864

Biological XAFS at the BioCAT Undulator Beamline 18ID at the APS. *R. A. Barrea, R. Fischetti, S. Stepanov, G. Rosenbaum, E. Kondrashkina, G. B. Bunker, E. Black, K. Zhang, D. Gore, R. Heurich, M. Vukonich, C. Karanfil, A. J. Kropf, S. Wang and T. C. Irving* 867

Methodological Study Using XAS of an Arsenic-Based Antileukemia Treatment. *E. Curis, I. Nicolis, S. Bohic, A. Somogyi, A. Simionovici and S. Bénazeth* 870

First Observation of Natural Circular Dichroism for Biomolecules in Soft X-ray Region Studied with a Polarizing Undulator. *M. Tanaka, K. Nakagawa, A. Agui, K. Fujii and A. Yokoya* 873

Environmental

FOREWORD

Dear participants and other readers of the 12th X-ray Absorption Fine Structure International Conference (XAFS12) proceedings volume. What you are holding in your hands, or reading off your computer screen if you are accessing the electronic version of the proceedings, is the result of a long process. It was initiated in Ako, Japan, already in the summer of 2000 at XAFS11. At that time, Sweden and the Swedish national synchrotron facility, MAX-lab, were chosen to organize the next event in the series of International conferences on X-ray Absorption Fine Structure. After a process of preparations we opened the conference site on the web for electronic submission of abstracts about 6 months before the realization of the event in June 2003. On the way the world had experienced September 11 and a dramatic slowdown in world economics. Given the circumstances at that point we felt uncertain about the possibilities to have a meeting that would reach the size of previous XAFS events. Instead we expected to break the trend of increasing number of participants as documented at previous conferences. Fortunately, we were proven to be wrong.

XAFS-12 was held in late June, 2003 in Malmö, Sweden. More than 450 participants from 30 countries attended the event. The conference accommodated seven plenary lectures, three parallel oral sessions and three poster sessions resulting in some 650 invited and contributed presentations. A breakdown by nation of the submitted contributions is given in Fig. 1.

Among the plenary events the "Lars Hedin Memorial Session" including the lecture of J. J. Rehr (Seattle, USA) highlighted the importance of the longstanding efforts and successes of the late Lars Hedin and his coworkers at the Department of Theoretical Physics, Lund University, for the theoretical description of excited states. Professor Lars Hedin was a member of the XAFS12 organizing committee before he prematurely passed away.

A wide range of topics and areas were covered at the conference, including XAFS applications to materials science, catalysis and nano-science, biology, chemistry, environmental science, and magnetism. The latest developments in theoretical advances related to XAFS, instrumentation, and novel applications of XAFS were presented. Special sessions were also devoted to related phenomena and emerging techniques. More than 350 papers were eventually submitted to the XAFS-12 proceedings. The number of contributed papers was far greater than expected. A summary of how the contributed papers were divided into categories is given in Fig. 2. As one might expect, the largest body is found in the rather generic materials category.

It is our view that the XAFS proceedings have a high value for the community and serves as a good indicator of the present trends and developments. It is our opinion that the volume you are accessing is still another convincing example of the power of XAFS based tools using modern light sources. Amongst the contribution you will find many fascinating examples for future trends for the XAFS technique.

Finally, the organizers of XAFS-12 want to gratefully acknowledge the support from the main conference sponsors: the Royal Swedish Academy of Sciences through its Nobel Institute for Physics, the Swedish Foundation for Strategic Research, the Crafoord Foundation, the University of Lund, the Swedish Research Council, the City of Malmö and the Region of Skåne.

We thank all of you for your commitment to this conference and we look forward to another successful gathering of the XAFS-community during the 13th conference in Stanford, California in 2006.

Ingolf Lindau, Nils Mårtensson, Dimitri Arvanitis, Olof "Charlie" Karis

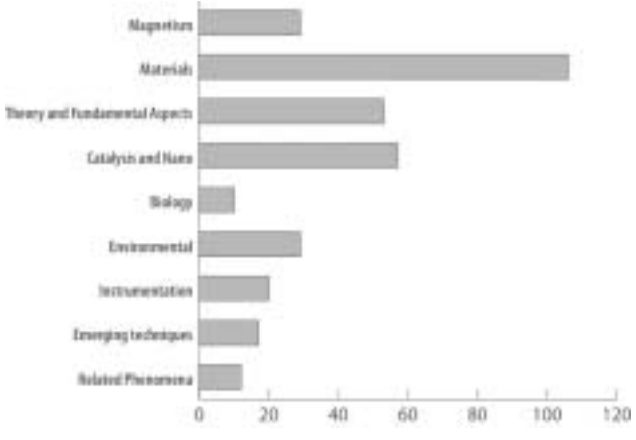

Fig. 2. More than 350 papers were submitted to the XAFS-12 proceedings. Here we give the number of contributions by main category.

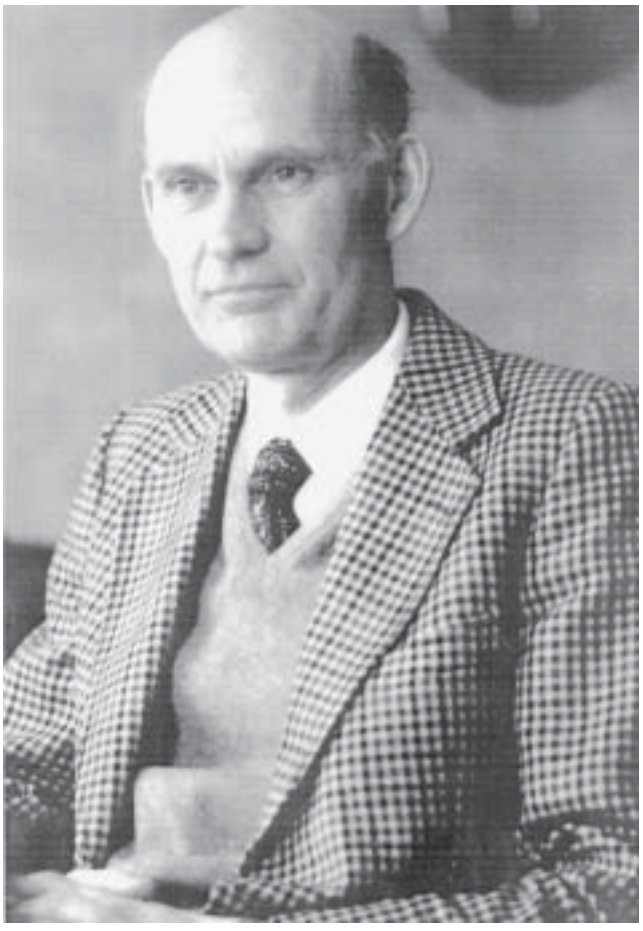

LARS HEDIN

Physica Scripta. Vol. T115, 19–23, 2005

Lars Hedin and the Quest for a Theory of Excited States

J. J. Rehr

Dept. of Physics, Box 351560, University of Washington, Seattle, Washington 98195, USA

Received June 26, 2003; accepted October 14, 2003

PACS number: 7870Dm.

Abstract

The theory of excited electronic states is central to a quantitative understanding of the interaction between light and matter and hence to calculations of various X-ray and optical spectra. Although ground state properties are well described by density functional theory (DFT), that theory is inappropriate for excited states, for which a fully quantitative theory has yet to be developed. No one has contributed more to than Lars Hedin to the quest for such a theory. Here we briefly review a number of his key contributions. One of the most influential is the "GW" approximation for the self-energy of an excited electron. Another is the "blue-electron" approximation for photon and electron spectroscopies. A third, which is relevant to the topics of this conference, is a many-body theory of X-ray spectra based on the "quasi-boson" approximation. This approach is a generalization of the GW approximation which takes into account both extrinsic and intrinsic losses as well as the interference between them, and simplifies the treatment of losses and the core-hole interaction. What makes Hedin's theories stand out is their mathematical elegance and physical robustness, based on ideas conceived before their full implementation was practical. With today's advances in computational power, however, the impact of Lars' work is becoming ever more widely appreciated.

1. Introduction

Lars Hedin [1930–2002] was a key figure in the development of modern theories of excited states. Such developments are crucial to a quantitative understanding of photon and electron spectroscopies. Indeed much of our current computational framework for excited state calculations in condensed matter is derived from Lars' work. To paraphrase Carl-Olof Almbladh and Ulf von Barth, his colleagues at Lund, Hedin's strength as a researcher was marked by his extraordinary ability to see the practical physics in otherwise very complicated theories. Hedin's idea was to try to simplify the basic physics of many-electron systems to a level suitable for computer calculations, and later for comparisons with experiments. A few of Lars' early works are as valid and influential today as they were then. With today's improvements in computers and algorithms, Hedin's GW approximation has become the dominant method for calculating excitation properties in semiconductors and metals.

In this tribute to Lars, I will discuss a few of his major contributions along with some of the history behind them. These include, for example, the "Hedin Equations," the GW approximation for the electron self-energy, the "blue-electron" approximation, and the quasi-boson treatment of electronic excitations. I will focus particularly on Lars' contributions in the field of X-ray spectroscopy. Besides being a central topic of this conference and a personal favorite of my own, it is a topic on which I have had the good fortune to collaborate with Lars since the mid 1990's.

Many of Hedin's ground breaking developments appeared so rapidly in the 1960's that one wonders how he did it and what were the sources that inspired him. Lars provides some of the answers both in his early work [1], and in an unpublished festschrift for Stig Lundqvist [2], a distinguished Swedish condensed matter physicist with whom Lars worked closely at that time. The 1950's and 1960's was a period when the ideas of quantum field theory were beginning to revolutionize condensed matter physics. Feynman diagrams flourished in theoretical papers, explaining everything from electron-scattering to superconductivity in fancy pictographs. But there was a problem. As Lars put it: "Although we now have a wealth of beautiful general theorems, fairly little has been done toward manageable and reliable approximation schemes especially for interacting electrons" [1].

Lars' foray into many-body theory apparently began about 1960. He had gone to Uppsala to do graduate research, first in the quantum chemistry group of Per-Olov Löwdin, one of the world's leading theoretical quantum chemists. Lars also began interacting with Stig Lundqvist and eventually became Stig's first Ph. D. student. Together Lars and Stig gave a seminar series on "Introduction to the field theoretical approach to the many body problem." As Lars remarked, "Stig who was very much the senior and mature physicist did most of the reading of the papers and wrote drafts for our seminars, while I struggled to get the algebra right and tried to understand what it was all about."

2. 1969 Review of Many-body Theory

Like many others, I first learned of Lars' works from his comprehensive 1969 Review article with Stig Lundqvist, "Effects of Electron-electron and Electron-Phonon Interactions on the One-Electron States of Solids" [3]. Part of the article grew from an "intensive collaboration" between Lars, Stig, and their graduate student Bengt Lundqvist, "working out properties" of what John Wilkins termed the "Swedish Electron Gas." This appellation reflects the notable advances by Swedish scientists on the theory of the homogeneous electron gas, which has long been a prototype many-body system. Wilkins was a condensed matter theorist at Cornell, where I did my own graduate work. But he traveled back and forth to Scandinavia regularly to collaborate with Bengt and others and always knew what was going on there. Besides the new physics, the 1969 Review constitutes a superb overview of the concepts used in many-body theories of solids, including Green's function theory, elementary excitations, quasi-particles, etc. It is a model of clarity, and was a godsend to us neophytes trying to make sense of field-theoretical techniques.

Interestingly, much of the final manuscript was completed in less than a month! As Lars described the effort: "This was when solid state physics was still very much in the shadow of nuclear physics in Sweden, and Stig started spending a lot of time on meetings in Stockholm successfully promoting support for solid state physics. At the same time he vigorously pushed our joint efforts on understanding many-body physics and writing the review. I always found it difficult to meet deadlines however much pushed, and when we had dragged delivering our review to [the Solid State Physics editor] Henry Ehrenreich for several years he gave us an ultimatum, 'Deliver by January 1st or the deal is off'. I had agreed with Stig to write a first preliminary sketch. In early December I started on this in earnest and poor Stig read, rewrote,

wrote new drafts and rewrote again in between shuffling back and forth to Stockholm and Nobel activities. We got the article in by January 1, and perhaps it benefited by being written in such a concentrated effort."

3. The Swedish Electron Gas vs Density Functional Theory

The "Swedish electron gas" refers to a Green's function treatment of a uniform system of electrons [1]. The central quantity in the theory is the one-particle Green's function or propagator $G(1,1') = -\mathrm{i}\langle N|T[\psi(1)\psi^\dagger(1')]|N\rangle$, which is the amplitude that an electron added at the 5 dimensional space-spin-time point $1 \equiv \boldsymbol{r}, s, t$ in an interacting N particle system propagates to the point $1'$. Despite its formidable nature one of Hedin's achievements was to tame the approach into a calculable form (i.e., the GW approximation) as benign looking as the Schrödinger equation. In frequency (or energy $E = \hbar\omega$) space, which is convenient for treating spectra, the Green's function is $G(\omega)$ is formally the solution to

$$[\omega - h - \Sigma(\omega)]G(\omega) = 1. \tag{1}$$

Here the one-particle Hamiltonian h includes the kinetic energy $p^2/2m$, the external potential of the nuclei $V_{\rm ext}$, and the Coulomb (or Hartree) potential $V_{\rm Coul} = \int \mathrm{d}^3 r v(\boldsymbol{r} - \boldsymbol{r}')n(\boldsymbol{r}')$, from the average electron charge density $n(\boldsymbol{r})$, and $\Sigma(E)$ is the "self-energy" of an electron due to its interaction with the rest of the system. Thus the homogeneous equation

$$[\omega - h - \Sigma(\omega)]\psi = 0, \tag{2}$$

has the form of a one-particle Schrödinger equation with a self-energy, as first discussed by Schwinger in 1951. Its eigenstates ψ_k and (complex) eigenvalues ω_k have the interpretation of Landau "quasiparticle states" and their energies, respectively. The Green's function approach can be viewed as a mapping of the many-body problem onto a one-particle problem with an effective Hamiltonian $h + \Sigma(\omega)$. All the many-body effects of exchange and correlation are contained in the self-energy $\Sigma(\omega)$.

It is interesting to compare these results with Density Functional Theory (DFT), which was developed by Walter Kohn and collaborators also in the mid 1960's [4]. DFT provided a powerful alternative approach to the problem of many interacting electrons based on a beautiful variational theorem that relates ground state properties of a system to functionals of the electron density. The approach maps the many body problem onto a system of non-interacting electrons with precisely the same density. Thus all ground state properties can be described in terms of eigenstates of a one-particle Schrödinger equation,

$$[\omega - h - V_{\rm xc}]\psi = 0, \tag{3}$$

where h is the above Hartree Hamiltonian, and $V_{\rm xc}([n(\boldsymbol{r})])$ is the exchange-correlation density functional which includes all the many-body effects. I was fortunate to have been one of Walter's postdocs in the mid-1970's, and have always appreciated both the power and simplicity of the method. Lars did too and contributed significantly to the development of DFT. For example, Ulf von Barth and Lars developed the local spin density (LSD) generalization [5]. Although formally exact, the fundamental difficulty with DFT is, as Walter put it, "God only knows what the exact exchange-correlation potential $V_{\rm xc}[n]$ is." Never mind. A variety of approximations exist, which are adequate for ground state properties. Indeed the DFT revolutionized calculations of condensed systems, as recognized by the 1998 Nobel Prize in Chemistry. It's practical advantage (compared e.g., to the Green's function approach) is that the DFT yields a standard one-electron eigenvalue problem which is computationally efficient.

4. The Hedin Equations

The Green's function approach clearly hinges on a suitable approximation for the self-energy $\Sigma(\omega)$, and Lars set out to derive a systematic scheme for its determination. In particular, Lars' treatment is based on an expansion, not in the long range Coulomb potential $v(\boldsymbol{r}, \boldsymbol{r}') = 1/|\boldsymbol{r} - \boldsymbol{r}'|$, but rather on the screened potential W (see below) which leads to more rapid convergence. His solution can be described compactly in a set of four coupled integral equations now referred to as the "Hedin Equations." Since they may be viewed as matrix multiplications over the space-spin-time coordinates, I will drop the indices for notational simplicity except when needed for clarity, i.e.,

$$\Sigma = \mathrm{i}GW\Gamma, \quad W = v + WPv,$$
$$P = -\mathrm{i}GG\Gamma, \quad \Gamma = 1 + \frac{\delta\Sigma}{\delta G}GG\Gamma. \tag{4}$$

The quantities involved are the self-energy $\Sigma(12)$, the screened coulomb interaction $W(12)$, the polarizability (or density response function) $P(12) = \delta n(1)/\delta V(2)$, and the "vertex function" $\Gamma(123)$. These equations are derived in Hedin's *tour de force* paper "New Method for Calculating the One-Particle Green's Function with Application to the Electron-Gas Problem" [1]. In his characteristically non-aggressive style, Lars states that "The results ... are well known to the 'Green's-function people.' The present derivation, however, utilizes only the Schrödinger equation. It constitutes a 'low-brow' version of those parts of the 'high-brow' Green's function theory that we need here." Though their derivation is still not trivial, Hedin does give hints on how to carry out the functional derivatives. The recent review of GW theory by Aryasetiawan and Gunnarsson [6] also gives a clear derivation.

Although the compact structure of the Hedin equations is appealing, a full solution remains a formidable challenge. To simplify the equations, Lars proceeds systematically. To zeroth order in W, $\Sigma = 0$ and the vertex $\Gamma = 1$, and hence to leading order in the screened interaction W one arrives at Lars' famous GW approximation:

$$\Sigma = \mathrm{i}GW, \quad W = v + WPv, \quad P = -\mathrm{i}GG. \tag{5}$$

The physical interpretation of the terms is as follows. The polarizability P is directly related to the dielectric matrix $\epsilon = 1 - Pv$, so that $W = \epsilon^{-1}v$ is the screened coulomb interaction, which is non-local in space and time. Therefore $\Sigma = \mathrm{i}GW$ can be interpreted as a dynamically screened exchange and correlation potential. When the screening becomes negligible, e.g., high densities, $\Sigma = \mathrm{i}Gv \equiv V_{\rm x}$ which is just the non-local Fock exchange. The equations were evaluated in great detail for the uniform electron gas in a beautiful series of papers by Bengt Lundqvist e.g., [7]. Additional terms in the expansions have also been studied, e.g., in studies of the optical potential in atomic scattering with Takashi Fujikawa [8]. For reviews of various aspects of GW theory and its applications, see e.g., Ref. [9] and especially the review by Hedin [10] which focuses on the physical ideas, extensions to spectroscopies, and also generalizations for strongly correlated systems.

Though not universal the GW approximation explicitly incorporates the dielectric response of a given material and

provides a constructive theory. One of the major successes of the GW approach is in the study of excited states. GW calculations, e.g., in Ref. [11, 12], yield band gaps in excellent agreement with experiment in a wide range of materials while the DFT gives substantial errors. Thus the energy dependence of the self-energy shows up clearly in experiment, especially in X-ray spectra. The failure of DFT to predict accurate excitation energies is not surprising since, as Kohn emphasized, the DFT eigenvalues cannot be interpreted as excitation energies. However, Hedin showed that the DFT orbitals are robust – i.e., they possess "orbital stability" [13]. Thus with a given $\Sigma(\omega)$ they can be used to determine the self-energy corrections to the excitation energies $\langle k|\Sigma(\omega_k) - V_{\rm xc}|k\rangle$.

5. Blue Electron Theory

Now I would like to turn to some related aspects of GW theory, and in particular the case of excitation spectra with large energies, as in photoemission. This is a subject on which Lars has contributed extensively, as discussed, e.g., in another big review written with Carl-Olof Ambladh [14]. Through discussions with Stig Lundqvist, Lars developed a way of looking at high energy excited states using *blue electron theory* [2]. As Lars put it: "By a blue electron I understand an electron which to some degree is regarded as distinguishable from the other electrons in the medium, among which its moves. This is clearly in violation of the Pauli principle, but I will try to explore where this idea can lead."

An example of such a blue electron is the ejected electron in photoemission with high kinetic energy compared to the electrons in a solid. When the energy is about 50 eV or higher, the exchange coupling with the solid becomes negligible. In this limit the violation of the Pauli principle is small and one can factor the excited state of the system and the photoelectron, i.e., $|N\rangle \approx |N-1;s\rangle|k\rangle$, where $|N-1;s\rangle$ refers to a particular excited state labeled by s of the "passive" electrons in the system and $|k\rangle$ is the blue electron state. This approach was extensively developed for photoemission, in particular by Witold Bardyszewski and Lars [15]. Another application is the many body theory of XAFS. Since these applications have many common features I will only discuss the latter here.

6. XAFS and the Quasi-boson Approximation

Dramatic progress has been made in the theory of X-ray absorption fine structure (XAFS) over the past few decades [16], and Lars' contributions have played an important role more than once. Inelastic losses are critical to a quantitative theory, since experiment reveals a substantial reduction in XAFS amplitudes compared with ground state calculations.

An important development in X-ray absorption theory was the introduction of a local density approximation for the GW self energy [17]. This is based on a single plasmon-pole approximation of the dielectric function, as discussed in detail by Bengt Lundqvist [7]. Since the GW approximation requires an integral over the dielectric function, its precise form is not crucial. This plasmon-pole self energy is accurate at high energies, and has proved to be adequate for most EXAFS calculations [16]. The imaginary part of the self energy is related to the mean free path $\lambda = k/|\mathrm{Im}\,\Sigma|$ and characterizes the "extrinsic losses," where k is the photoelectron wave number. Moreover, the real part of Σ accounts reasonably well for the observed shifts in peak positions. Another source of amplitude reduction is the "intrinsic loss," from the shake-up and shake-off processes, which give rise to the many-body amplitude reduction factor S_0^2 in the EXAFS formula [18].

However there are problems with these treatments. First they give too much loss. Second, since the excitations caused by extrinsic and intrinsic losses are indistinguishable, *interference* is also possible. Indeed, for photoemission spectroscopy, it had been shown (see e.g., [15, 19]) that the interference is strong near excitation thresholds, where the losses strongly cancel due to the opposite signs of the coupling between the photoelectron and the core-hole to excited states. Physically this reflects the dipole-like behavior or the photoelectron/core-hole pair at low energies, and hence is likely responsible for the surprising weakness of multi-electron excitations in the observed spectra at low energies.

In a remarkable three page paper presented at the 1989 International XAFS Conference in Seattle, Hedin suggested how one might calculate the interference terms [20]. The method uses a generalization of GW theory that incorporates blue electron ideas [21]. Hedin's interest in XAFS was influenced in part by discussions with Giancarlo Strinati who had been working on the Bethe-Salpeter Equation, i.e., the two-particle Green's function approach, and had also done some of first GW calculations [12]. Since Hedin's approach provides an example which incorporates several of his theories, I will summarize the method in some detail below.

From Fermi's Golden rule, the *many-body* formula for X-ray absorption can be expressed in terms of an effective one-particle Green's function as

$$\mu(\omega) = -\mathrm{Im}\,\langle k|d^\dagger G_{\rm eff}(\omega)d|k\rangle,$$

$$G_{\rm eff}(\omega) = \langle\Psi|(\omega - H - h' - V_{\rm es} - V_{\rm sc} + \mathrm{i}\delta)^{-1}|\Psi\rangle, \qquad (6)$$

where d is the dipole operator, H is the Hamiltonian for the solid including all electrons but the (blue) photoelectron, h' is the one-electron Hamiltonian for the photoelectron in the presence of the core-hole, and $V_{\rm es}$ and $V_{\rm sc}$ are the interactions between the photoelectron and the solid, and the solid and the core-hole, respectively. The expectation value $\langle\Psi|\ldots|\Psi\rangle$ integrates over all electron coordinates in the solid. Thus $G_{\rm eff}(\omega)$ is an effective propagator with only the photoelectron coordinates. This propagator takes into account the core-hole interaction, and hence is not equivalent to the usual one-particle Green's function.

Lars often uses limiting cases to check a theoretical formalism. Thus when the interaction $V_{\rm es}$ with the photoelectron is negligible (e.g., at high energies), one can insert a complete set of eigenstates of $H' = H + V_{\rm sc}$ with excitation energies ω_n in Eq. (6) to get an expression as a sum over intrinsic losses,

$$\mu(\omega) = \sum_n |S_n|^2 \mu^{(1)}(\omega - \omega_n),$$

$$G_{\rm eff}(\omega) = \sum_n |S_n|^2 G(\omega - \omega_n), \qquad (7)$$

where $S_n = \langle\Psi|\Psi'_n\rangle$ is a many-body overlap integral, and $\mu^{(1)} = \Sigma_k|\langle c|d|k\rangle|^2\delta(\omega - \epsilon_k)$ is the one-particle Golden rule formula for the X-ray absorption cross-section. Eq. (7) is equivalent to the theory based on the *sudden approximation* with only intrinsic losses [18]. The second limiting case is when the core-hole-solid interaction $V_{\rm sc} = 0$. Then the result for $G_{\rm eff}$ is essentially the GW approximation $G_{\rm eff}(\omega) = [\omega - h' - \Sigma(\omega)]^{-1}$ with only extrinsic losses but including the core-hole interaction.

The treatment of the interference effects is carried out using a "quasi-boson" approximation [7, 15]. The essence of the model is that the dominant excitations of the solid, i.e., plasmons,

electron hole pairs, etc., are bosons. Often only a few such bosons dominate, e.g., plasmons in the case of simple metals. In general the excitations can be represented quantum mechanically by boson (oscillator) operators a_n with energies ω_n and labeled by an index n. Their interactions are represented by terms linear in the boson operators, with coupling constants V^n known as *fluctuation potentials* [19]. For plasmons for example, the fluctuation potentials are simply plane waves and n refers to the plasmon wave number $\boldsymbol{q}$, i.e., $V^q = (2\pi\omega_p^2/q^2\omega_q)^{1/2}\exp(\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r})$. This method has the promise to simplify considerably self-energy calculations since both W and Σ can be represented in terms of fluctuation potentials, e.g., $\Sigma(\omega) \approx \Sigma_n V^n G(\omega-\omega_n)V^n$, and the V_n can be calculated within the random phase approximation (RPA). Thus the quasi-boson model Hamiltonian is

$$H = \sum_n \omega_n a_n^\dagger a_n, \quad h' = \sum_{k>k_F} \epsilon_k c_k^\dagger c_k,$$
$$V_{\mathrm{sc}} = -\sum_n V_{cc}^n (a_n^\dagger + a_n), \quad V_{\mathrm{es}} = \sum_{nkk'} [V_{kk'}^n a_n^\dagger + (V_{kk'}^n)^* a_n] c_k^\dagger c_{k'}. \tag{8}$$

As in all such a shifted oscillator models, the ground states of H and H', with and without a core hole respectively, are simply related by a canonical transformation $|\Psi\rangle = \mathrm{e}^{-S}|\Psi'\rangle$, $S = a/2 - \Sigma_n (V_{cc}^n/\omega_n) a_n'^\dagger$, and the dimensionless strength $a = \Sigma_n (V_{cc}^n/\omega_n)^2$, where a_n' belongs to $H' = \Sigma_n \omega_n a_n'^\dagger a_n'$. Expanding Eq. (6) to second order in V^n, corresponding to the ways of exciting of a single boson n, then gives

$$G_{\mathrm{eff}}(\omega) = \mathrm{e}^{-a}\Bigg[G(\omega) + \sum_n \left(\frac{V_{cc}^n}{\omega_n}\right)^2 G(\omega-\omega_n) - 2\sum_n \frac{V_{cc}^n}{\omega_n} G(\omega-\omega_n) V^n G(\omega)\Bigg]. \tag{9}$$

This key result for $G_{\mathrm{eff}}(\omega)$ gives an expression for the XAS as an expansion in final state one-particle Green's functions. The theory is essentially a generalization of GW theory and makes use of essentially the same ingredients. The first term $G(\omega) \equiv [\omega - h' - \Sigma(\omega) + i\gamma]^{-1}$ is the damped Green's function calculated *in the presence of a core hole*, and yields the standard theory of XAS given by the *final state rule* [22] with only extrinsic losses. The second term accounts for the intrinsic losses, $S_n = V_{\mathrm{cc}}^n/\omega_n$ being the many-body overlap integral. The third term comes in with a minus sign and accounts for the interference.

The results can be interpreted in terms of the spectral function $A_{\mathrm{eff}} = -(1/\pi)\mathrm{Im}\, G_{\mathrm{eff}}$, which describes the energy distribution of the photoelectron. For the plasmon-pole model, for example, this consists of a asymmetrical quasi-particle peak and a broad satellite separated by the plasmon energy ω_p. The effect of the interference terms is to increase the strength of the quasi-particle peak at $\omega = E_k$, and to decrease the strength of the satellites. Remarkably the satellite strength cancels completely at the excitation thresholds! This can be seen by looking at the residues of the poles of $G(\omega-\omega_n)G(\omega)$. Thus, in addition to the intrinsic amplitude $V_{\mathrm{cc}}^n/\omega_n$ the amplitude of the satellite excitations has a competing contribution of opposite sign from the extrinsic losses,

$$S_n(\omega) = G(\omega)V^n - \frac{V_{\mathrm{cc}}^n}{\omega_n}, \tag{10}$$

which vanishes at the plasmon excitation threshold $\boldsymbol{q} = 0$. Precisely the same *cancellation theorem* applies in photoemission [15]. This also explains why the quasi-particle approximation is accurate at low energies and satellite excitations can be neglected, consistent with the *adiabatic approximation*. Thus Lar's model naturally explains the transition from the the sudden to adiabatic limits.

I had spent the spring of 1995 in Lund working on this model, but it took several more years to develop the theory to a semi-quantitative level [23]. A key result, using Eq. (9) and Eq. (6), is many-body expression for the XAS as a convolution of the final state one-electron spectrum $\mu^{(1)}$ [defined below Eq. (7)] with an asymmetric, energy dependent spectral function $A_{\mathrm{eff}}(\omega,\omega')$,

$$\mu(\omega) = \int \mathrm{d}\omega'\, A_{\mathrm{eff}}(\omega,\omega')\mu^{(1)}(\omega-\omega'). \tag{11}$$

This may be viewed as an energy dependent broadening of $\mu^{(1)}$ by the spectral function A_{eff}, i.e., $\mu(\omega) = \langle\mu^{(1)}(\omega)\rangle$. As discussed above, the amplitudes of the quasi-particle peak and the satellite contributions are energy dependent: in the adiabatic limit, the satellite contribution is small and the quasi-particle amplitude tends toward unity, while at high energies (compared to ω_p) the interference becomes small and the theory crosses over to the sudden limit dominated by intrinsic losses. Eq. (11) implies that XAFS spectrum $\chi = \langle\chi^{(1)}\rangle$ is similarly broadened, since it is linear in μ. The effect of such broadening is a decreased and phase shifted XAFS amplitude,yielding the energy dependent amplitude reduction factor $S_0^2(\omega)$, in reasonable agreement with experiment [23].

The last topic I worked on with Lars, just after midsummer 2002, dealt with the comparison between the two-particle Bethe-Salpeter equation and the one-particle final state rule (FSR), for treating core-hole interaction effects in deep-core X-ray spectra. Despite their apparent differences, Lars had suggested that the methods are rather similar. Recent work in collaboration with Eric Shirley and Aleksi Soininen has corroborated Lars' suggestion [24]. The main difference is that the FSR treats screening of the core-hole self-consistently while BSE uses linear response, but these differences often have little effect numerically. Moreover, the use of the quasi-boson approach to calculate satellite excitations suggests how both the FSR and the BSE can be improved, leading to a more complete many-body treatment of X-ray spectra.

Acknowledgments

This paper is dedicated to Lars Hedin whose works and encouragement have been an inspiration. We also thank Bob Albers, Alexei Ankudinov, Carl-Olof Almbladh, Witold Bardyszewski, Chuck Fadley, Takashi Fujikawa, Eric Shirley, Giancarlo Strinati, and John Wilkins for comments and suggestions, and especially Hillevi Hedin for her gracious hospitality all these years. This work was supported in part by US DOE Grant DE-FG03-97ER45623 and facilitated by the DOE CMSN.

Abstract

The theory of X-ray absorption near edge structure (XANES) is complicated due to the difficulty of treating chemical, many-body, and core-hole effects. To address these problems we introduce a full potential, real space Green's function approach for calculations of both local electronic structure and X-ray spectra. Our approach includes inelastic losses as well as screened core-hole and local field effects. The latter are due to the screening of the X-ray electric field. The approach is illustrated in calculations for periodic solids and for small molecules. Calculations for the K-edge absorption of Si crystals show significant improvements in the XANES compared with that calculated with spherical, muffin-tin potentials. However, for systems of high symmetry like the S K-edge in the SF_6 molecule, we find that the non-spherical corrections are small. Instead, local atomic displacements are responsible for additional XANES peaks. Local field effects are shown to be important at the diamond K-edge, which effectively counteract the core-hole interaction.

1. Introduction

An X-ray photon is absorbed in matter by promoting one of the core electrons into an unoccupied photoelectron state of a molecule or solid. Thus if the resulting core-hole and photoelectron did not interact, the X-ray would serve as a direct probe of the energy position of the unoccupied states. However, several many body effects contribute to X-ray absorption: self-energy, core-hole interaction, local field effects, and multi-electron excitations. Their relative importance varies depending on material, edge and energy with respect to a given edge.

Neverless, the dominant features of the absorption spectrum can usually be calculated using the *standard model* [1] developed for EXAFS calculations. The model uses 1) overlapping self-consistent muffin-tin potentials constructed from the spherically symmetric density around each atom; 2) the final state rule to account for the core-hole interaction, i.e., the potentials are calculated in the presence of a static, fully screened core-hole; and 3) a local Hedin-Lundqvist self-energy is used to account for energy level shifts and inelastic losses during propagation of the photoelectron. This standard theory is usually so successful that it can been used even for a quantitative analysis of XANES for structure determinations [2].

In this paper we demonstrate that several effects not fully included in this standard model can sometimes play an important role, and therefore should be included in XANES calculations. For example, we find that non-spherical charge densities and potentials in a full potential calculation resolves the double peak structure at the K-edge white line of crystalline Si. The complicated structure at the S K-edge of the SF_6 molecule can be explained if one accounts for the vibrational motion of the molecule (i.e., the vibronic interactions). Local field effects are shown to be important for the diamond K-edge calculation, where they counteracts the transfer of oscillator strength to the edge region due to the core-hole interaction.

2. Full Potential Multiple scattering approach

Originally multiple scattering theory was developed for the muffin-tin potential. It's generalization for the "full potential" was suggested by Lloyd and Smith [3] in 1972, and independently by Williams and Morgan in 1974 [4]. The full potential multiple scattering theory for XANES calculations was first suggested by Natoli [5] to account for the effects of non-spherical potentials. Later Foulis *et al.* [6] demonstrated that both full potential and self-consistency are essential to understand the spectral features at the Cl K-edge of the Cl_2 molecule.

Our implementation of the full potential multiple scattering theory (MST) mostly follows the above cited references. However, we have introduced several modifications. First, instead of non-overlapping cell potentials, which have jumps at the Voronoi polyhedra boundaries, we use the overlapping "fuzzy" Voronoi polyhedron construction suggested by Becke [7]. One defines cell functions $w_n(\vec{r})$ which smoothly go from 1 inside Voronoi cell to 0 outside, so that the sum over all cell functions $\Sigma_n w_n(\vec{r}) = 1$ for all spacial points. Using these cell functions we separate total potential into the cell potentials:

$$V_n(\vec{r}) = w_n(\vec{r}) V_{tot}(\vec{r}). \tag{1}$$

Thus potential changes smoothly across the boundary, which results in fewer spherical harmonics being needed in calculations. In the second step we find regular and irregular solutions of the Schrödinger equation in each cell,

$$(H - E)\Psi_L(\vec{r}) = 0, \qquad (H - E)H_L(\vec{r}) = 0. \tag{2}$$

Due to the non-spherical potential these are expressed as a sum over all angular momenta e.g., $\Psi_L(\vec{r}) = \sum_{L'} \Psi_{LL'}(r) Y_{L'}(\hat{r})$. They are normalized so that at large distances ($r \to \infty$)

$$\Psi_{nL}(\vec{r}) \to j_L(\vec{r}) + \sum_{L'} h_{L'}(\vec{r}) t_{nL',nL}, \tag{3}$$

$$H_{nL}(\vec{r}) \to h_L(\vec{r}), \tag{4}$$

where for convenience we have defined $j_L(\vec{r}) = i^l j_l(kr) Y_{lm}(\hat{r})$, $h_L(\vec{r}) = i^l h_l(kr) Y_{lm}(\hat{r})$, and $\bar{j}_L(\vec{r}) = i^{-l} j_l(kr) Y^*_{lm}(\hat{r})$. Notice that for complex wavevector k, $\bar{j}_L(\vec{r}) \neq j_L(\vec{r})^*$. Thus the t-matrix is found from normalization of the regular solution, and unlike the spherically symmetric case, t has off diagonal matrix elements.

Thus the full multiple scattering (FMS) part of calculations, which is the most time consuming part of the FEFF8 XAS code, [1] remains practically the same for full potential calculations,

$$G^{FMS}_{iL,jL'} = G^0 (I - TG^0)^{-1}, \tag{5}$$

where we have suppressed the matrix indices for $T_{iL,iL'} = t^i_{LL'}$ and the free propagator $G^0_{iL,jL'}$. Finally, one can calculate the total Green's function as a sum over central atom and scattering parts,

$$G^c(\vec{r},\vec{r}',E) = -2k\sum_L H_{cL}(r_<)\bar{\Psi}_{cL}(r_>), \tag{6}$$

$$G^{sc}(\vec{r},\vec{r}',E) = -2k\sum_{L,L'} \Psi_{cL}(\vec{r})G^{FMS}_{cL,cL'}\bar{\Psi}_{cL'}(\vec{r}\,'), \tag{7}$$

where $\bar{\Psi}$ is also a Solution of Schrödinger equation but normalized differently at large distances: $\bar{\Psi}_L \to \bar{j}_L(\vec{r}) + \sum_{L'} t_{LL'}\bar{h}_{L'}(\vec{r})$.

However, the above *standard* MST expression for the Green's function is not useful at large distances since there the regular solution grows exponentially, spurriously leading to exponential growth of electron density for molecules or for spacial points above the surface of a solid. Traditionally this problem has been avoided by using empty cells and neglecting the leakage of charge of "filled" and empty cells. In this paper, however, we do not use empty cells, but still limit the use of the standard expression to within small spheres around each nucleus. For the region outside we use electron density approximated by the alternative, well-behaved expression,

$$G^c - G^0 = -2k[\bar{\Phi}_L H_L + \bar{j}_L(H_L - h_L)], \tag{8}$$

$$G^{sc}(\vec{r},\vec{r}',E) = -2k\sum_{iL,jL'} \Phi_{iL}(\vec{r})G^{FMS}_{iL,jL'}\bar{\Phi}_{jL'}(\vec{r}\,'), \tag{9}$$

where $\Phi_{iL} = \Psi_{iL} - j_L$ and $\bar{\Phi}_{iL} = \bar{\Psi}_{iL} - \bar{j}_L$ exponentially decay at high distances for energies below interstitial level or when the energy has a nonzero imaginary part. This is important for calculations of the total charge density using MST, especially for molecules. However for X-ray absorption from deep core hole levels, the standard expression does not have a problem at large distances due to the finite core-hole dimension. The standard expression is also much easier to use for calculations, due to the absence of the site off-diagonal matrix elements of G^{FMS}.

Knowledge of the Green's function then allows us to calculate various physical quantities. The density of states and electron densities are determined by its imaginary part, and are needed in self-consistent calculations. The X-ray absorption is given by

$$\mu(\omega) \propto \sum_{iLL'} M_{iL}[\delta_{LL'} + \mathrm{Im}\, G^{FMS}_{iL,iL'}]\bar{M}_{iL'}, \tag{10}$$

where the dipole matrix elements coupling with the X-ray field to the initial state i and final Ψ_L are $M_{iL} = \langle i|\vec{\epsilon}\cdot\vec{r}|\Psi_L\rangle$ and $\bar{M}_{iL} = \langle\bar{\Psi}_L|\vec{\epsilon}\cdot\vec{r}|i\rangle$.

We demonstrate the importance of the full potential in the XANES for Si crystals (Fig. 1). The full potential code (solid) clearly reproduces the double peak structure of the white line in the experimental data [11] (dots), while muffin-tin code FEFF8 (dashes) gives primarily a single peak of about the same width. Thus the double peak structure can be understood as the additional splitting of the unoccupied bands due to the non-spherical, and hence anisotropic part of potential due to the strong directional bonds in Si.

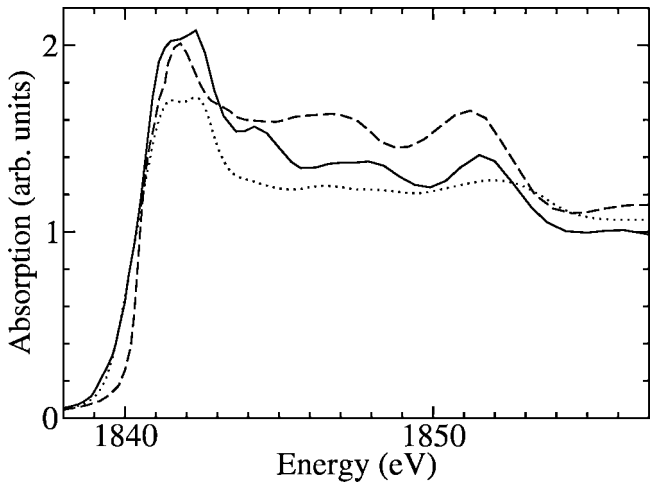

Fig. 1. K-edge absorption of Si crystal. The full potential (solid) calculations with 329 atom clusters reproduce the double peak structure of the white line in experimental data (dots). In contrast, muffin-tin calculations (dashes) with 849 atom clusters have a single dominant peak.

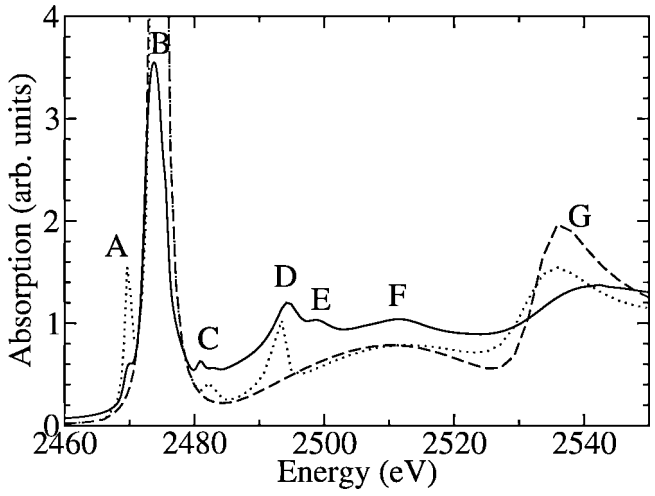

Fig. 2. S K-edge absorption of SF_6 molecule. Full potential calculations for S in the center of octahedron (dashes) and for S shifted by (0.1,0.1,0.1)Å (dashes) versus experiment (solid). This shift is reasonable to describe vibronic coupling in SF_6.

3. Vibronic coupling

Next we want to demonstrate the applicability of our full potential code to molecules. We chose the K-edge of SF_6 molecule as an example, since surprisingly the standard MST calculation lacks many of the peaks observed in experiment. Thus in the work of Tyson *et al.* [12] only 3 XANES peaks out of 7 (B, F and G on Fig. 2) are reproduced by MST calculations. This is even more surprising since the L_2 and L_3 edges of SF_6 are well reproduced [13]. However, we found that even our full potential code gives only 3 peaks for the perfect octahedron structure. Thus we found that to explain the experimental data at S K-edge, it is important to consider vibronic coupling effects. Since in the ground state, this molecule is a perfect octahedron, some transitions are forbidden by the dipole approximation. However, atomic displacements continually break the symmetry, and in actual calculations one has to average calculated XANES over various distorted atomic configurations. Fujikawa [14] has suggested a general treatment of vibrations for X-ray absorption calculations. In general it requires one to know the vibrational Hamiltonian for the excited state. If we neglect the difference of vibrations in ground and excited states, the X-ray absorption is given as an average over possible initial atomic displacements,

$$\mu(\omega) = \langle\mu(\omega,\vec{Q})\rangle, \tag{11}$$

where $\vec{Q}$ describes the displacement of an atom (or atoms) from its equilibrium position. One obtains the same expression assuming the atoms don't move significantly during the transition. If one

expands $\mu(\omega, \vec{\boldsymbol{Q}})$ in powers of Q, assuming small dependence of X-ray absorption on atomic positions we obtain to leading order,

$$\mu(\omega) = \mu(\omega, Q) + \frac{\delta^2 \mu(\omega, \vec{\boldsymbol{Q}})}{\delta Q_i \, \delta Q_j} \langle Q_i Q_j \rangle, \tag{12}$$

where the first order terms cancel since $\langle Q_i \rangle = 0$. Thus the leading correction to the absorption at the equilibrium position is connected with the Debye-Waller factors. Thus for SF_6 the typical displacement is about 0.05 Ångström [12].

In Fig. 2 we also show calculations performed for configurations where the S atom is displaced by (0.1,0.1,0.1) Å from its equilibrium position at the origin. We simply used the amplitude which is consistent with measured Debye-Waller factor for this molecule. As one can see this shift reproduces 6 peaks out of 7 in the correct positions, and even gives reasonable agreement with experiment [12] in their intensities. The intensity of 3 additional peaks (A,C,D) scales as a square of the distortion amplitude. This still did not produce peak E, which may be due to a different type of distortion or possibly to some other source like multi-electron excitations. Even though we do not perform an average over all possible displacements, it is clear from Fig. 2 that some ensenble averaging may be important more generally, and may have significant effect on calculated XANES spectrum. Indeed, this should be essential for structural XANES analysis, since the assumption of perfect octahedral equilibrium positions, even with thermal or structural Debye Waller factors $\exp(-2k^2\sigma^2)$ fails to account the observed XANES.

This calculation clearly demonstrates that especially for symmetric equilibrium positions, atomic motion may lead to additional peaks due to vibronic coupling to states for which dipole transitions are forbidden for the equilibrium geometry. Such coupling can be reproduced by averaging XANES using quantum molecular-dynamics simulations. Even simple shifts of the order of typical Debye-Waller factors may reveal some forbidden transitions. However, appropriate averaging may be necessary to get the right intensities. These findings are consistent with an earlier interpretation of the spectral features in SF_6 K-edge XANES as a vibronically induced coupling, by Zimkina and Vinogradov [15]. Here we are able to support such an interpretation quantitatively.

4. Local Field Effects and Core-hole interaction

Local field effects were used by Zangwill and Soven to describe the screening of X-ray field within an absorbing atom. This effect arises since the external electric field of the X-ray polarizes the electron cloud around the nuclei, which creates an induced screening electric field and hence modifies the transition matrix elements. From another point of view, the local fields can be shown to arise from the non-local exchange term in the photoelectron-hole interaction.

Local fields must be distinguished from the core-hole interaction which can lead to excitons in dielectrics and edge singularities in metals. However, these two effects are directly connected to the direct and exchange terms in the interaction kernel in time dependent density functional theory (TDDFT).

The TDDFT [16, 18, 19] provides an efficient formalism to include simultaneously local field effects and the core-hole interaction in calculations of response functions. The TDDFT was originally introduced for atoms within the local density approximation (LDA), an approach also referred to as the TDLDA [16]. It has since been extended to many other systems [17, 19]. Moreover, the TDDFT equations are similar to the Bethe-Salpeter equation (BSE) [20, 21, 22, 23, 24], which provides a systematic many-body framework for treating local field effects. The main difference between the TDDFT and the BSE lies in the structure of the exchange-correlation kernel $f_{xc}(\omega)$ in the TDDFT and the screened core-hole interaction in the BSE. In addition the single-particle states in the BSE are taken to be quasiparticle states which account for self-energy effects.

Within all of these approaches, the XAS (or cross-section) $\mu(\omega)$ can be expressed as an integral over the *non-interacting* response function $\chi_0(\vec{r}, \vec{r}\,', \omega)$ and the screened X-ray field $\phi(\vec{r}, \omega)$,

$$\mu(\omega) = -\frac{4\pi\omega}{c} \int \mathrm{d}\vec{r} \, \mathrm{d}\vec{r}\,' \phi^*(\vec{r}, \omega)[\mathrm{Im}\, \chi_0(\vec{r}, \vec{r}\,', \omega)]\phi(\vec{r}\,', \omega),$$

$$\chi_0(\vec{r}, \vec{r}\,', \omega) = \sum_{ij} (f_i - f_j) \frac{\psi_i^*(\vec{r})\psi_i(\vec{r}\,')\psi_j^*(\vec{r}\,')\psi_j(\vec{r})}{\omega + E_i - E_j + \mathrm{i}0^+}. \tag{13}$$

Here f_i are Fermi occupation numbers (1 or 0), and the sums run over all one-electron eigenstates $\psi_i(\vec{r})$ of the ground state Hamiltonian.

Remarkably it has been proved that Eq. (13) is equivalent to an analogous expression with ϕ replaced by the external X-ray field ϕ^{ext} and χ_0 by the full response function $\chi = [1 - \chi^0 K]^{-1}\chi^0(\omega)$ [16]. However, the form in Eq. (13) has the advantage of putting all screening effects into the effective transition operator $\phi(\omega)$. The field $\phi(\omega)$ consists of the external X-ray field coupling the electrons $\phi^{ext} \equiv \hat{\boldsymbol{\epsilon}} \cdot \vec{r}$ (in the dipole approximation) plus an induced local field. In matrix form this is given by

$$\phi(\omega) = \epsilon^{-1}(\omega)\phi^{ext}(\omega), \qquad \epsilon(\omega) = 1 - K(\omega)\chi^0(\omega). \tag{14}$$

The kernel $K(\vec{r}, \vec{r}\,', \omega)$ characterizes the particle-hole interaction and contains direct and exchange parts, i.e., $K(\vec{r}, \vec{r}\,', \omega) = V(\vec{r}, \vec{r}\,') + f_{xc}(\vec{r}, \vec{r}\,', \omega)$ where $V = 1/|\vec{r} - \vec{r}\,'|$ is the bare Coulomb interaction, which accounts for the local field effects. The $f_{xc}(\vec{r}, \vec{r}\,', \omega)$ represents the screened core-hole interaction, which is approximated by a local function. Thus within TDLDA $f_{xc}^0(\vec{r}, \vec{r}\,') = \delta(\vec{r} - \vec{r}\,')\delta v_{xc}[\rho(\vec{r})]/\delta\rho$ avoids the non-locality of BSE and is obtained from the ground-state LDA exchange-correlation potential $v_{xc}[\rho]$. This often works well at low energies, e.g., for optical spectra. For the X-rays one in general needs a dynamic model [25].

The TDLDA approach fits well with the the RSMS formalism used in FEFF8 [25]. Carrying out the integrations over χ_0, Eq. (13) becomes

$$\sigma(\omega) = \frac{4\pi e^2 \omega}{c} \sum_{v,LL'} \tilde{M}_{vL}(\omega)[\delta_{L,L'}(E) + G_{LL'}^{FMS}]\tilde{M}_{vL'}(\omega), \tag{15}$$

where $E = \omega + E_v - E_F$ is the photoelectron energy and E_v the energy of the occupied (or valence states). The screening of both the X-ray field and the photoelectron-core hole interaction are included implicitly in the renormalized dipole matrix elements $\tilde{M}_{vL}(\omega) = \langle R_L|\phi|v\rangle$. Here $R_L(\vec{r}, E)$ are normalized scattering states calculated with the absorbing atom ground state potential, and $G_{LL'}^{FMS}(E)$ contains the fine structure due to scattering by the environment [1]. The calculation of renormalized matrix elements within a local screening approximation is achieved by a small matrix inversion [25]. Note that by replacing ϕ with ϕ^{ext} in Eq. (5), the screened matrix elements $\tilde{M}_{vL}$ become bare dipole matrix elements $M_{vL} = \langle R_L|\hat{\boldsymbol{\epsilon}} \cdot \vec{r}\,|i\rangle$, and one recovers the independent electron formula, equivalent to Fermi's Golden Rule. Since the strength of the XAS is a measure of the screening response, the

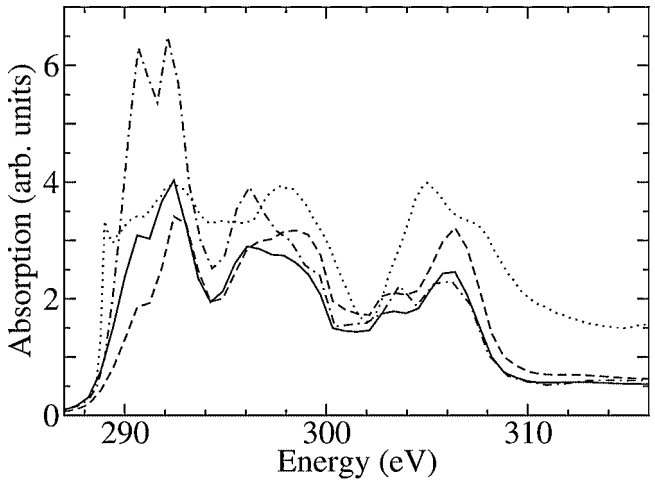

Fig. 3. K-edge absorption of diamond. Experiment (dots) is compared to calculations with the initial, ground state potential without a core-hole (dashes), with the fully relaxed core-hole potential (dash-dots), and with the adiabatic TDLDA kernel (solid).

independent-electron approximation should become increasingly valid away from the edge region. Several kernels were compared for the transition metals L_3/L_2 branching ratio [25]. However, for the diamond K-edge calculations the adiabatic TDLDA kernel is appropriate since there is only one edge.

In Fig. 3 we show calculations for the K-edge of diamond with the TDLDA approach (solid) that includes both the core-hole interaction and local field effects. It is compared to experiment [26] (dots) and a calculation with the final state rule (dash-dots), that includes core-hole interaction and neglects local field effect, and for the initial, ground state potential (dashes) which neglects both core-hole and local field effects. As one can see the ratios of the first 3 peak intensities differ significantly among the calculations. If one takes into account that the experimental data has a roughly linear background, the TDLDA calculation seems to be the best to reproduce the relative intensity of the peaks. All of our calculations miss the excitonic peak right at the edge (which may require bigger clusters), but the consequent double peak structure again is best described by TDLDA calculations. This suggests that local field effects are important in this case and have an amplitude comparable to that of the core-hole interaction. Both final state rule (Fig. 3) and BSE calculations [21] overestimate the strength of the white line suggesting that the white line sensitive both to the screening of the core-hole interaction and the local fields. Notice that core-hole effects tends to bring oscillator strength closer to the edge, while the local field effect tends to move it away from the edge. In practice, there are cases where either of the effects dominates, which means that simultaneous treatment of both is essential.

5. Conclusions

The *standard* theory of X-ray absorption originally developed for the EXAFS region, is usually accurate even for XANES calculations [1]. This theory makes use of spherically symmetric densities and potentials, a fully screened core-hole potential, and inelastic losses and energy shifts based on the Hedin-Lundqvist self-energy approximation. However, this standard theory sometimes breaks down for XANES calculations, as illustrated by several examples. Non spherical corrections are needed to resolve the Si K-edge double peak white line, which illustrates the sensitivity of XANES calculations to the details of the potential construction beyond the spherical approximation. Vibronic coupling or average over possible initial atomic displacements needs to be included for the SF_6 K-edge absorption calculation and hence in other cases where local distortions are important. And finally, local field effects and the screening of the core-hole interaction are important and may change relative intensities of the peaks in XANES significantly, especially for energies below 1 keV, as demonstrated by diamond K-edge calculations. Thus extensions of the standard XANES theory are generally needed for reliable structural XANES analysis. Our examples show that such a theory should include non-spherical potentials, vibronic, local field, and core-hole interaction effects.

Abstract

X-Ray Absorption Near Edge Structure (XANES) spectroscopy is a powerful method to study the local structure around an absorbing site of various types of matter. Analysis of the spectrum can give both electronic and structural information on the site around the absorbing atom. In this paper we present some recent theoretical advances that allow a complete quantitative analysis of the XANES energy region in term of structural parameters. Some examples will be presented in details with a complete discussion of the strengths and limitations of the method when applied to real systems.

1. Introduction

X-ray absorption spectroscopy (XAS) is one of the most powerful methods to obtain structural and electronic information on the local environment of an excited atom. During the past ten years, much theoretical and computational effort has been made that has led to the development of *ab-initio* methods for XAS calculations in arbitrary systems [1]. In the high-energy region (typically from 50–100 eV above the rising edge) several approximations can be made to reduce the complicate many-body photo-absorption process in that of a photoelectron scattering in an effective potential. This allows a quantitative analysis of the extended X-ray-absorption fine-structure (EXAFS) region of the XAS spectra. The EXAFS technique has found many applications ranging from chemistry to molecular biology, including liquid and solid-state problems in condensed-matter physics.

The situation is different concerning the low-energy part of the X-ray absorption cross section extending up to around 50–100 eV above the threshold, the so called XANES (X-ray absorption near-edge structure) region. This part is very sensitive to the geometrical details of the absorbing site (overall symmetry, distances and bond angles), so that, in principle, an almost complete recovery of the geometrical structure within 6–7 Å from the absorbing site can be achieved from the experimental data with atomic resolution. However, the quantitative analysis of the full XAS spectrum, including the edge, is a complex many-body problem that requires an adequate treatment and the need for heavy time-consuming algorithms to calculate the absorbing cross section including all multiple-scattering (MS) contributions of any order, the so-called full MS approach. Due to these difficulties, the analysis of the pre-edge and first part of the XAS spectra (up to 50–100 eV) has been exploited so far only on qualitative ground, by comparison with model compounds or as an aid for EXAFS studies or more advanced investigations, such as the ones based on the analysis of contributions related to correlation functions of orders higher than two [2].

Recently some of us have proposed [3] and applied to several systems [4, 5] a new method, called MXAN, to perform a quantitative analysis of the XANES energy range, i.e. from the edge up to 200 eV. In this paper we present details of the method and some results obtained for some test cases with the aim to validate the method and define its potentiality and limitation.

2. The MXAN procedure

The method is based on the comparison between experimental data and many theoretical calculations performed by varying selected structural parameters starting from a plausible ansatz for the structure, i.e. from a well defined initial geometrical configuration around the absorber. The calculation of XANES spectra related to the hundreds of different geometrical configurations needed to obtain the best fit of the experimental data is done in a reasonable time and the optimization in the space of parameters is achieved by the minimization of the square residual function in the parameter space.

The calculations are performed within the so-called full MS approach, i.e. the inverse of the scattering path operator is computed exactly, avoiding any "*a-priori*" selection of the relevant MS paths. The MXAN procedure uses the set of programs developed by the Frascati theory group [1, 5]; in particular VGEN, a generator of muffin-tin potentials, and the CONTINUUM code for the full MS cross section calculation. The optimization in the space of the parameters is achieved using the MINUIT routines of the CERN library by minimizing the square residual function

$$S^2 = n\frac{\sum_{i=1}^{m} w_i[(y_i^{\mathrm{th}} - y_i^{\mathrm{exp}})\varepsilon_i^{-1}]^2}{\sum_{i=1}^{m} w_i} \qquad (1)$$

where n is the number of independent parameters, m the number of data points, y_i^{th} and y_i^{exp} the theoretical and experimental values of absorption, ε_i the individual errors in the experimental data set, and w_i is a statistical weight. For w_i = constant = 1, the square residual function S^2 becomes the statistical χ^2 function. A typical fit involves an experimental energy range of about 150–200 eV from the rising edge and the application to several test cases shows that the best-fit solution is independent from the minimization strategy and from the starting conditions.

The MXAN method is based on the muffin-tin (MT) approximation for the shape of the potential and the use of the concept of complex optical potential, based on the local density approximation of the self-energy of the excited photoelectron. The MT radii are chosen according to the Norman criterion with some percentage of overlapping and the potential is recalculated at each step of the minimization procedure keeping fix the overlapping factor. The effects of the non-MT corrections will be discussed in some details later in this paper, but evidence exists that their

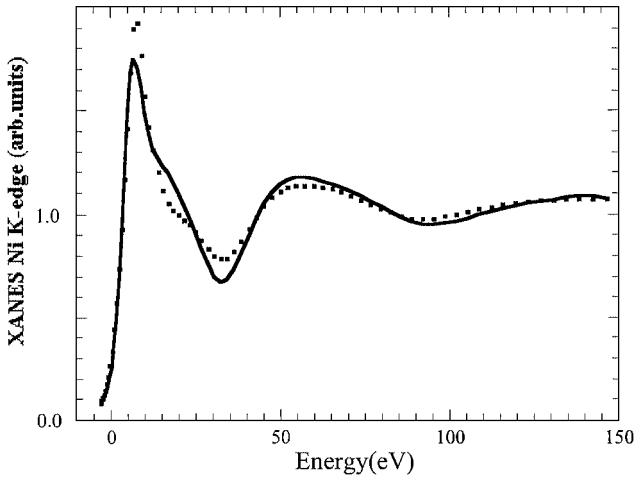

Fig. 1. Comparison between the experimental data (dotted line) and the best-fit calculation (solid line) of the Ni K-edge spectrum of the Ni^{2+} aqua ion. In this case the full complex HL potential has been used.

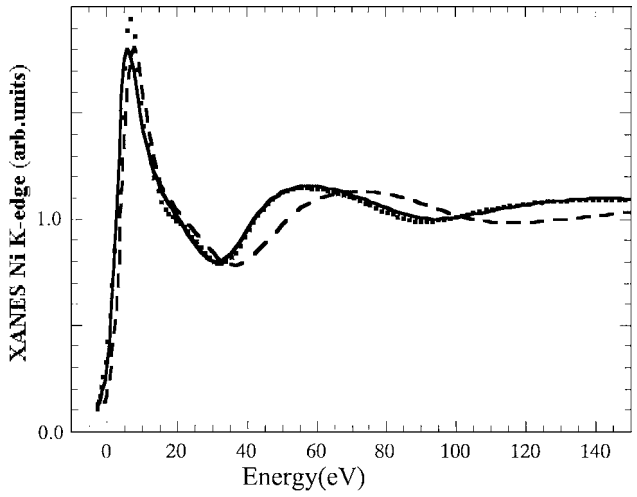

Fig. 2. Comparison between the experimental (dotted line) and best-fit calculation (solid line) of the Ni K-edge XANES spectrum of Ni^{2+} aqua ion. The dashed line corresponds to the calculation associated to the starting structure.

relevance is confined within the first 20–30 eV from the edge [6, 7] with very weak influence on the structural determination due to the relatively large energy range used in the fit. In this way the geometrical arrangements restrain the numerical results of the fitting procedure.

The self-energy is calculated in the framework of the Hedin-Lundqvist (HL) scheme [1]. The use of the full complex HL potential introduces a relevant over damping at low energies in the case of covalent molecular systems as shown in Fig. 1 where we report a comparison between the experimental data related to Ni^{2+} ion in water and the calculation, at the best fit condition, obtained by using the full complex HL potential. H atoms are included in the calculation. In this case the best-fit structure corresponds to an octahedron with an oxygen-metal distance of 2.04(2) Å in good agreement with the more recent EXAFS results.

Note that we obtain the correct geometry despite the presence of relevant discrepancies between experimental data and the best-fit calculation in the first 40 eV. For the experimental details see references [8].

In order to have a full access to the structural information contained in the low-energy part of the XANES spectrum, we have developed a phenomenological approach to calculate the inelastic losses based on the convolution of the theoretical spectrum, calculated by using only the real part of the HL potential, with a suitable Lorentzian function having an energy dependent width of the form $\Gamma_{tot}(E) = \Gamma_c + \Gamma_{mfp}(E)$. The constant part Γ_c includes the core hole lifetime and the experimental resolution, while the energy dependent term represents all the intrinsic and extrinsic inelastic processes. The $\Gamma_{mfp}(E)$ function is zero below an onset energy E_s (which in extended systems corresponds to the plasmon excitation energy) and begins to increase from a value A_s following the universal functional form of the mean free path in solids. Both the onset energy E_s and the jump A_s are introduced in the $\Gamma_{tot}(E)$ function via an arctangent functional form to avoid discontinuities and to simulate the electron-hole pair excitations. Their numerical values are derived at each step of computation (i.e. for each geometrical configuration) on the basis of a Monte Carlo fit, similarly to the procedure used in optimisation by simulated annealing [9].

Using this procedure the agreement between the experimental data and the best fit theoretical curves becomes good in the whole energy range, small discrepancies remaining in the intensity of the resonance at 15 eV as shown in Fig. 2. The best fit corresponds to an octahedral symmetry with an oxygen-metal distance of 2.03 ± 0.03 Å in good agreement with the value obtained by the GNXAS analysis using the EXAFS energy region [5, 8]. The dashed line corresponds to the calculation associated with the starting putative structure that is an elongated octahedron.

Applications of this approach to different systems produce the same type of agreement between experimental data and best-fit calculations confirming the reliability of our phenomenological approach to the inelastic losses treatment in the XANES spectroscopy. To clarify this important point we report in Fig. 3 the behavior of the $\Gamma_{tot}(E)$ function for Ni^{2+} ion in water from the edge up to 80 eV. This function, starting from the value $\Gamma_c = 1.70$ eV, which is in good agreement with the core-hole lifetime ($\Gamma_{c-h} = 1.44$ eV) plus the experimental resolution, increases smoothly up to the value E_s that is the onset of the plasmon-like excitations for the considered charge density. Hereby after it follows the universal form with the size increased by the A_s value.

This phenomenological approach can be justified on the basis of a multi-channel multiple scattering theory [10]. In the sudden

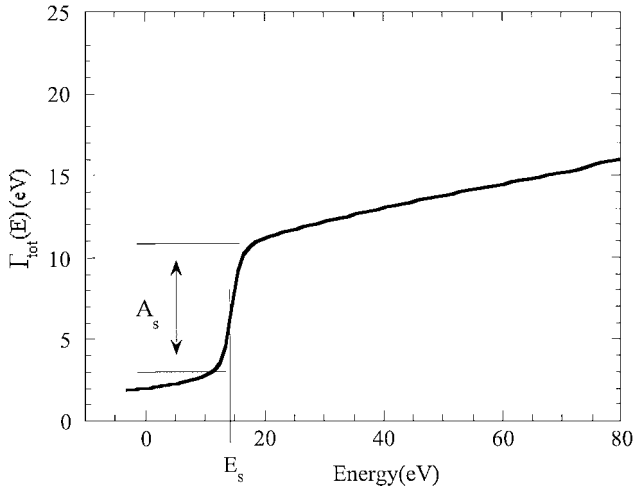

Fig. 3. Behaviour of the energy dependent width $\Gamma_c(E)$ of the Lorentzian function used in the convolution procedure to account for the inelastic losses. It refers to Ni^{2+} in water and the parameters T_c, E_s and A_s are derived on the basis of simulated annealing Monte Carlo search.

limit, the net absorption is given by a sum over all the possible excited states of the (N-1)-electron system [1, 10]. By assuming that the channels coming from the excitation of the N-1 electrons are near in energy, the total absorption is given by a convolution of the one-particle spectrum, calculated with the full-relaxed potential, with a spectral function $A(\omega)$ representing the weight of the other excited states. Hence the total XAS cross-section can be written as

$$\mu = \sum_n \mu_n \xrightarrow[\Delta E \to 0]{} \int \mu(\omega - \omega')A(\omega')\mathrm{d}\omega' \tag{2}$$

where the "ansatz" is made that the spectral function $A(\omega)$ is well approximated by a Lorentzian function with the energy dependent width $\Gamma_{\mathrm{mfp}}(E)$ previously defined. Moreover, it is possible to demonstrate that in the case of dominance of only one electronic channel (the elastic one), the corresponding Green's function G_0 obeys a Dyson-like equation with a suitable complex optical potential $\Sigma^{\mathrm{opt}}(r, r'; E)$ that, with some approximation (locality, homogeneous systems...) is equivalent to a "real" calculation convoluted by a Lorentzian function of suitable energy dependent width [10]. Therefore the $\Gamma_{\mathrm{tot}}(E)$ function is characterized by parameters which have a clear physical meaning and they are not free to assume any value, but are varied in a well defined interval. Obviously, when contributions from one or more of these excited states become relevant, they must be considered explicitly in the calculations.

We also note that the shape of the $\Gamma_{\mathrm{mfp}}(E)$ function is similar to the inverse lifetime of the quasiparticles Γ_{k} derived in the GW_0 scheme, without the sharp onset at the plasmon excitation energy to account for the interference between the intrinsic and extrinsic inelastic losses [11].

Note that the MXAN method introduces as a total four non-structural parameters. Applications to several test cases indicate that their influence on the structural reconstruction is weak and it reduces to an increase of a few percent of the error in the structural parameters determination [12].

The use of the MXAN procedure to the analysis of potassium ferrocyanide (III) in water allowed us to shed light on the relevance of non-MT corrections on the quantitative structural determination. Due to its high symmetry and to the shortness of the cyanide bond length this molecular system has often been used as a test case for any XANES calculations, but a good reconstruction of the experimental data has never been achieved. A thorough analysis of the Fe K-edge XANES is presented in a paper in these proceedings [13], here we just want to stress that the non-MT corrections are small even in this case and do not affect the structural determination. In fact we observe that it is possible to write a MS theory, which does not use the MT approximation for the shape of the potential, having the same formal structure of the usual MS theory by adding some suitable quantities to the scattering matrix and propagators [14].

In this way the total photo-absorption cross section is proportional to

$$\sigma_t \approx \mathrm{Im}(T + H)^{-1} \tag{3}$$

where $T = (T_{\mathrm{a}})^{-1} + \Delta T$ and $H = H_{MT} + \Delta H$. Here $(T_{\mathrm{a}})^{-1}$ and H_{MT} are the usual MS quantities calculated within the MT approximation. The corrections are proportional to the interstitial volume. Indicating $\Delta = \Delta T + \Delta H$ we can expand the total cross section σ_{t} in series using Δ as a parameter:

$$\sigma_t \approx \mathrm{Im}\left\{ \sum_{n=0} (-1)^n [T_a^{-1} + H_{MT})^{-1}\Delta]^n (T_a^{-1} + H_{MT})^{-1} \right\}. \tag{4}$$

In this way σ_{t} becomes:

$$\sigma_t \approx \sigma_{MT} + corr(E; V_{\mathrm{int}}). \tag{5}$$

In other words the total non-MT cross section can be written as the sum of the cross section calculated in the MT approximation and corrections that decrease with the energy and depend on the potential in the interstitial volume. For these reasons the corrections are usually small for molecular systems with high symmetry. In fact a full potential calculation does not improve dramatically the agreement between theory and the potassium ferrocyanide experimental data [13].

3. Conclusions

In conclusion, we have presented a new method for a quantitative analysis of XANES spectra based on a fitting procedure in the framework of full multiple scattering calculations. In this way we achieve a full access to the whole XANES energy range allowing complete structural determination of the local geometry around the absorber. The MXAN method has been proven to provide reliable structural results confirming the validity of the application of the full MS scheme in the framework of the MT approximation. The results of the present investigation represent a step forward in understanding the role that the XANES technique can play in providing quantitative structural information on chemical systems.

Abstract

We consider screening of the core-hole potential experienced by the ejected electron in core-excitation processes. This potential affects near-edge structure strongly, but it appears difficult to consistently obtain reliable screened core-hole potentials without substantial computation. Screening effects have both atomic and solid-state (or molecular/cluster) contributions. We emphasize aspects that must be true of "correct" screening models, in an attempt to circumvent the need to carry out full-scale random-phase approximation (RPA) or self-consistent-field calculations of the screening. We present and discuss three spectra computed with RPA and model screened potentials, suggesting ideas to be considered in future work developing screening models.

1. Introduction

Core-excitation spectra provide information about structural properties and electronic states of molecules, clusters, and solids. Depending on the probe [e.g., X-ray absorption (XAS), inelastic X-ray scattering (IXS), or inelastic electron scattering (EELS)], a core-excitation spectrum provides information about unoccupied electron states in the form of a partial density of states (PDOS). This is weighted by matrix elements, perturbed by the final-state core-hole potential and complicated by vibrational and many-body effects on spectra.

High-resolution near-edge spectra are highly detailed and informative, but are also most strongly affected by core-hole effects. These effects have been treated in multiple-scattering work [1]–[2], supercell calculations [3], and the Bethe-Salpeter equation [4]. Because the core-hole effects influence near-edge spectral features so strongly, it is important to calculate the screened core-hole potential experienced by the excited electron accurately, and reliable means to do so appear to require substantial calculations.

Here we consider aspects of models for core-hole screening. We review salient aspects of traditional or "orbital-based" screening calculations, such as the random-phase approximation (RPA), which are based on self-consistent field calculations and perturbation theory. We then propose two screening models that are "density-based," which require only the total electron density as input and so are computationally much more efficient. This is an especially important consideration in complex systems, where orbital-based calculations tend to scale more poorly with system size. We present results obtained using three screening models (RPA and two density-based models) for F, O and Mg 1s edges in solid LiF and MgO. We show theoretical screening effects and concomitant absorption spectra, so one can estimate how a screening model affects a spectrum. We discuss the results and provide some possible suggestions intended to aid development of efficient yet accurate screening models in future work.

2. Orbital-based (numerical) screening calculations

Most practical numerical calculations of electronic structure begin with self-consistent-field (SCF) calculations, where one-electron orbitals solve a Schrödinger-like equation. We shall refer to all such calculations as being *orbital-based*. These calculations are usually numerically intensive because of the need to use supercells or sum over large numbers of virtual electron states. As an key example, in density-functional theory, one has (in Hartree atomic units)

$$\left[-\tfrac{1}{2}\nabla^2 + V_{\rm ext} + V_{\rm H} + V_{\rm xc}\right]\psi_i(\mathbf{r}) = \epsilon_i\psi_i(\mathbf{r}), \tag{1}$$

where the potential has contributions $V_{\rm ext}$, accounting for atomic nuclei or pseudopotentials, $V_{\rm H}$, which is the Hartree potential, and $V_{\rm xc}$, which is the "exchange-correlation potential" that approximately describes exchange and correlation effects. We have

$$V_{\rm H}(\mathbf{r}) + V_{\rm xc}(\mathbf{r}) = \int {\rm d}^3\mathbf{r}'\,\frac{n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} + \frac{\delta E_{\rm xc}}{\delta n(\mathbf{r})}, \tag{2}$$

where n is the total electron density because of occupied electron levels, given by

$$n(\mathbf{r}) = \sum_i^{\rm occ.} |\psi_i(\mathbf{r})|^2\,. \tag{3}$$

$E_{\rm xc}$ is the total exchange-correlation energy. The eigenvalues $\{\epsilon_i\}$ qualitatively mimic electron-level energies in atoms, molecules and solids.

Core-hole screening in SCF calculations can be determined by computing $V_{\rm H} + V_{\rm xc}$ when a core level on the "central site" is occupied and unoccupied and subtracting the difference. This can be difficult in an extended systems because of system size, but one can also calculate the same screening effects perturbatively in linear-response theory. The perturbed density is given by

$$\begin{aligned}\Delta n(\mathbf{r}) &= \int {\rm d}^3\mathbf{r}'\chi^0(\mathbf{r},\mathbf{r}';\omega=0)\Delta V_{\rm tot}(\mathbf{r}') \\ &= \int {\rm d}^3\mathbf{r}'\chi(\mathbf{r},\mathbf{r}';\omega=0)\Delta V_{\rm C}(\mathbf{r}').\end{aligned} \tag{4}$$

$\Delta V_{\rm C}$ is the unscreened potential of a core hole. Here, the *irreducible* polarization function $\chi^0(\mathbf{r},\mathbf{r}';\omega=0) = \delta n(\mathbf{r})/\delta V_{\rm tot}(\mathbf{r}')$ describes the induced change in density because of the change in the total potential,

$$\Delta V_{\rm tot}(\mathbf{r}) = \Delta V_{\rm C}(\mathbf{r}) + \Delta V_{\rm H}(\mathbf{r}) + \Delta V_{\rm xc}(\mathbf{r}). \tag{5}$$

The function χ^0 may be computed in one step, because it involves perturbation of the one-electron Schrödinger equation for independent electrons, suggesting that it is easier to model than the *reducible* polarization, $\chi(\mathbf{r},\mathbf{r}';\omega=0) = \delta n(\mathbf{r})/\delta V_{\rm C}(\mathbf{r}')$. The density is perturbed by a potential to which it contributes,

according to the integral equation,

$$\chi(\mathbf{r},\mathbf{r}';\omega) = \chi^0(\mathbf{r},\mathbf{r}';\omega) + \int \mathrm{d}^3\mathbf{r}'' \times \int \mathrm{d}^3\mathbf{r}''' \chi^0(\mathbf{r},\mathbf{r}'';\omega)\frac{\delta V_{\mathrm{tot}}(\mathbf{r}'')}{\delta n(\mathbf{r}''')}\chi(\mathbf{r}''',\mathbf{r}';\omega). \quad (6)$$

One can consider the response to a static potential, ΔV_{C}, by setting angular frequency $\omega = 0$, and this equation ignores ω-dependence of the kernel, $\delta V_{\mathrm{tot}}(\mathbf{r}'')/\delta n(\mathbf{r}''')$. Omitting exchange-correlation contributions to the kernel yields the time-dependent Hartree or random-phase approximation (RPA). Including these contributions yields a time-dependent density-functional-theory (TDDFT) calculation. In practice, these calculations give similar results for core-hole screening (as physics is dominated by the Hartree-potential effects in atomic core regions), and similar results are found in supercell SCF calculations [3].

3. Interplay of core and valence screening

The ejected electron involved in a core excitation basically witnesses the average screened potential of the core hole. Screening is done by core electrons localized on the central site and valence electrons with extended wave functions. One can consider screening by these two categories of electrons in turn. A deep core hole causes other core electrons to "contract" toward the atomic nucleus. This contraction is weakly affected by valence electrons and an atom's environment. We may rewrite Eq. (4) as

$$\Delta n(\mathbf{r}) = \int \mathrm{d}^3\mathbf{r}'\chi(\mathbf{r},\mathbf{r}';\omega=0)\Delta V_{\mathrm{C}}(\mathbf{r}') \approx \int \mathrm{d}^3\mathbf{r}'\chi_{\mathrm{V}}(\mathbf{r},\mathbf{r}';\omega=0)\Delta W_{\mathrm{C}}(\mathbf{r}'), \quad (7)$$

where χ_{V} is the polarizability if only the valence electrons are permitted to relax, and ΔW_{C} is ΔV_{C} screened by core electrons. ΔW_{C} can be obtained in atomic-structure calculations.

4. Density-based (model) screening calculations

Orbital-based screening calculations can scale poorly with system size. Moreover, short-range screening of a core hole, say on the scale of one or two atomic radii, should depend mostly on the central site's local enviroment, but most of the effort expended in an orbital-based calculation may be devoted to more remote regions of one's system. Density-based screening models may help address these issues. Just as for orbital-based screening calculations, density-based screening calculations can focus on computing χ or χ^0, which are related by Eq. 6. Any viable model for χ or χ^0 should obey all known constraints such as sum rules, some of which are cited here. First, χ or χ^0 should assume the "correct" value in the "homogeneous limit," which is the uniform electron gas in metallic systems, and which has reasonable counterparts in insulators, such as the Levine-Louie model dielectric function [5]. (This points to a shortcoming for such dielectric functions, because an insulator must intrinsically be a non-uniform system on the atomic scale, must possess an intrinsically non-metallic one-electron density matrix $\rho_1(\mathbf{r},\mathbf{r}')$, etc. It appears difficult to ascertain all of the ramifications of this for model dielectric functions, and how these ramifications may best be addressed. Perhaps the zero-moment sum rule for Im χ^0 may be of use:

$$\frac{1}{\pi}\int_0^\infty \mathrm{d}\omega\,\mathrm{Im}\,\chi^0_{\mathrm{L}}(\mathbf{r},\mathbf{r}';\omega) = \tfrac{1}{2}|\rho_1(\mathbf{r},\mathbf{r}')|^2 - \langle n(\mathbf{r})\rangle\delta^3(\mathbf{r}-\mathbf{r}'). \quad (8)$$

Here χ^0_{L} denotes the Lindhard polarizability or its analogue in a real material, and this sum-rule is easily derived using completeness.)

Kramers-Kronig relations and the f-sum rule are well know results, giving

$$\mathrm{Re}\left\{\begin{array}{c}\chi\\ \chi^0\end{array}\right\}(\mathbf{r},\mathbf{r}';\omega=0) = \frac{2}{\pi}\int_0^\infty \frac{\mathrm{d}\omega}{\omega}\,\mathrm{Im}\left\{\begin{array}{c}\chi\\ \chi^0\end{array}\right\}(\mathbf{r},\mathbf{r}';\omega) \quad (9)$$

and

$$\int_0^\infty \mathrm{d}\omega\,\omega\int \mathrm{d}^3\mathbf{r}\int \mathrm{d}^3\mathbf{r}'\,\mathrm{Im}\left\{\begin{array}{c}\chi\\ \chi^0\end{array}\right\}(\mathbf{r},\mathbf{r}';\omega)f(\mathbf{r},\mathbf{r}') = -\frac{\pi}{2}\int \mathrm{d}^3\mathbf{r}\,n(\mathbf{r})\left[(\nabla_{\mathbf{r}}\cdot\nabla_{\mathbf{r}'})\,f(\mathbf{r},\mathbf{r}')\right]_{\mathbf{r}'=\mathbf{r}}. \quad (10)$$

Here, $f(\mathbf{r},\mathbf{r}')$ can be any well-behaved function, and in reciprocal space we have the simplified formula in a periodic crystal,

$$\int_0^\infty \mathrm{d}\omega\,\omega\mathrm{Im}\left\{\begin{array}{c}\chi\\ \chi^0\end{array}\right\}(\mathbf{G}+\mathbf{q},\mathbf{G}'+\mathbf{q};\omega) = -\frac{\pi}{2}\tilde{n}(\mathbf{G}-\mathbf{G}')(\mathbf{G}+\mathbf{q})\cdot(\mathbf{G}'+\mathbf{q}). \quad (11)$$

(Note that the "Im" is restricted as defined by Zhang *et al.* [6].) There are also related constraints for certain limits, i.e.,

$$\lim_{\mathbf{Q}\to\infty}\chi^0(\mathbf{Q},\mathbf{Q};\omega=0) = \lim_{\mathbf{Q}\to\infty}\chi(\mathbf{Q},\mathbf{Q};\omega=0) \sim -\frac{4\tilde{n}(0)}{Q^2} \quad (12)$$

and

$$\lim_{\mathbf{r}\to\mathbf{r}'}\chi^0(\mathbf{r},\mathbf{r}';\omega) \sim -\frac{n(\mathbf{r})}{\pi\,|\mathbf{r}-\mathbf{r}'|}. \quad (13)$$

Other constraints can be found as well, such as through relating the ω^0, ω^1 and ω^{-1} moments of $\mathrm{Im}\chi^0(\mathbf{r},\mathbf{r}';\omega)$ using the Cauchy-Schwarz inequality. More stringent constraints and/or bounds on the polarizability would also be of use to the authors and others, if such properties could be stipulated.

However, we have found that satisfying these constraints – other than the one involving $\rho_1(\mathbf{r},\mathbf{r}')$, which might prove to be a paradigmatic challenge for screening models – is not sufficient to ensure that a screening model leads to accurate core-excitation spectra. Instead, we present two bulk models that have proved most successful in our work.

Our models are inspired by the Levine-Louie (LL) dielectric function [5], which describes screening in a homogeneous insulating system, obeying Eqs. (9–13) for that case. Having the correct value of $\epsilon(q\to 0;\omega=0)$, this model exhibits reasonable behavior of $\epsilon^{-1}(q,\omega=0)$ for intermediate q, though its results differ from RPA results for $\epsilon^{-1}(\mathbf{Q},\mathbf{Q};\omega=0)$ in real materials. The RPA results include local-field effects and concomitant effects of non-plane-wave character of Bloch functions. Incorporating these effects better into a model dielectric function is desirable.

Hybertsen and Louie introduced local-field effects in the LL model [7], but in a way that appears to have potential to violate Eq. (11). We note the following way to include local-field effects into the polarizability and dielectric response. Defining $B^0(q,\omega) = \chi^0_{\mathrm{LL}}(q,\omega)/q^2$ and $B(q,\omega) = \chi_{\mathrm{LL}}(q,\omega)/q^2$, with real-space counterparts $\tilde{B}^0(r)$ and $\tilde{B}(r)$, one may introduce the

model polarizability,

$$\left\{\begin{matrix}\chi_M\\ \chi_M^0\end{matrix}\right\}(\mathbf{r},\mathbf{r}';\omega) = -\nabla\cdot\nabla'\left(\frac{n(\mathbf{r})+n(\mathbf{r}')}{2\bar{n}}\right)\left\{\begin{matrix}\tilde{B}\\ \tilde{B}^0\end{matrix}\right\}(|\mathbf{r}-\mathbf{r}'|,\omega). \tag{14}$$

Noting

$$\int_0^\infty \mathrm{d}\omega\,\omega\,\mathrm{Im}\left\{\begin{matrix}B\\ B^0\end{matrix}\right\}(q,\omega) = -\frac{\pi\bar{n}}{2} \tag{15}$$

for all q, inserting the above formula into Eq. (10) and integration by parts ensures fully satisfying Eqs. (10–11). Here $\bar{n}$ is the average valence electron density in a bulk system.

Use of χ_M allows direct evaluation of $\epsilon^{-1}(\mathbf{Q},\mathbf{Q}';\omega)$, and its form allows computation of the dynamical part of a GW self-energy to be an $O(N_\mathrm{G}\log_2 N_\mathrm{G})$ rather than $O(N_\mathrm{G}^2)$ process. Use of χ_M^0 requires evaluation and inversion of $\epsilon(\mathbf{Q},\mathbf{Q}';\omega)$. In principle, this can give more accurate results, although the χ_M^0 that is used should yield the correct macroscopic dielectric properties only *after* local-field effects are included by inverting ϵ, suggesting that our present χ_M^0 may tend to underestimate screening effects. In a different context, if something analogous to χ_M^0 were similarly constructed and used when it involved averaging of the mesoscopic polarizability on a superatomic length scale that was smaller than all other critical dimensions in one's system, it could lead to correct treatment of polarizabilities and screening in cases of objects with a variety of shapes, surfaces, image-charge effects, etc.

5. Screened potentials and concomitant spectra

Figures 1–3 illustrate core-hole screening effects and near-edge spectra for F, O and Mg 1s edges in LiF and MgO. Theoretical results were obtained as in Ref. [4], with self-energy effects computed according to Ref. [8]. The plane-wave cutoffs used for band-structure and self-energy or screening calculations were as found in Ref. [9], ensuring that peak positions in spectra are converged to better than 0.1 eV, and peak amplitudes to with a few percent. Brillouin-zone sampling in Bethe-Salpeter calculations (see Ref. [4]) employed 4096 **k**-points in the full Brillouin zone on a regular grid, shifted according to Ref. [10]. Tests using denser grids indicated that spectral features could change by at most a few percent of the largest spectral features. The self-energy effects shift and Lorentz-broaden spectral features. Additional broadening was also included to match the measured width of the lowest-energy spectra feature, with data taken from Refs. [11] and [12]. The energy scale for each edge was shifted to align this feature using RPA screening with its experimental counterpart.

Three types of screening were considered: orbital-based RPA screening, and density-based model screening involving χ and χ^0 as discussed above. ΔW_C and associated valence screening effects are shown in the lower panel of each figure. In the F(1s) and O(1s) cases, the χ and χ^0 models respectively overestimate and underestimate screening effects at the nucleus, whereas both screening models underestimate screening effects at intermediate distances (around 1 a_0 to 2 a_0), and achieve the correct behavior of $(1-1/\epsilon_\infty)/r$ at long-range. This leads to gross exaggeration of core-hole effects at both near-edges by the χ^0 model, as compared to a more accurate description of core-hole effects by the χ model, slightly underestimating them in LiF, and slightly overestimating them in MgO. Note that the results for MgO and LiF are quite analogous, as both anions assume noble-gas configurations in

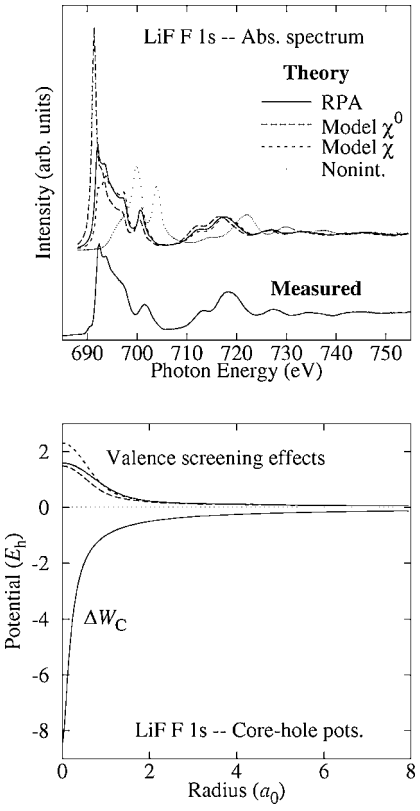

Fig. 1. Contributions to the core-hole potential (lower panel) and absorption spectra (upper panel) for the F 1s edge in LiF. In the lower panel, ΔW_C is the core-screened core-hole potential. Valence screening effects are shown as computed three ways according to the legend in the upper panel. Atomic units are used, with the energy unit being the Hartree energy, $E_\mathrm{h} \approx 27.2114\,\mathrm{eV}$. In the upper panel, corresponding theoretical absorption spectra are shown using the same legend, and a theoretical spectrum that omits core-hole effects is shown to illustrate the total magnitude of core-hole effects (labeled "Nonint."). A measured spectrum cited in the text is shown for comparison.

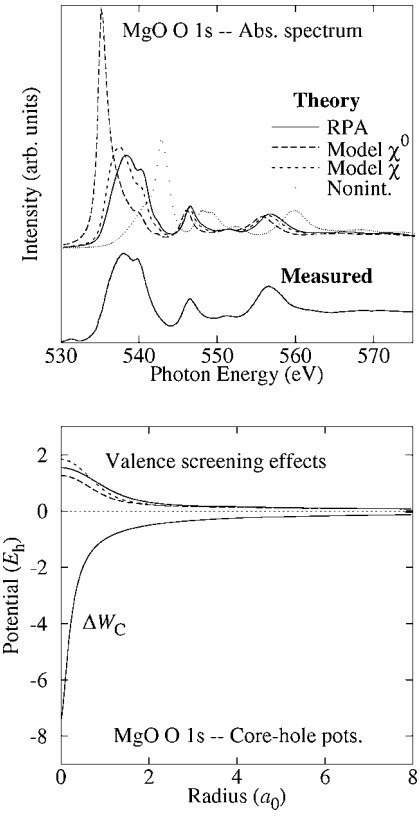

Fig. 2. Same as for Fig. 1, but for the O 1s edge in MgO.

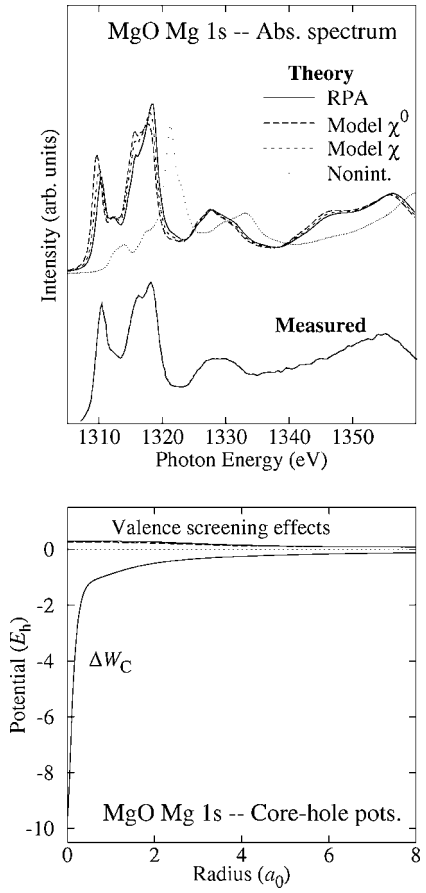

Fig. 3. Same as for Fig. 1, but for the Mg 1s edge in MgO.

these rocksalt-structure solids. Meanwhile, valence screening effects are very modest in the case of a Mg 1s hole in MgO, which is not surprising in view of the nominal Mg^{2+} configuration. Core-hole effects appear similar for all types of screening, with RPA results underestimating the effects the most. In all three cases, note that the qualitative change in spectral features because of core-hole effects vastly improves agreement with experiment, with the best overall agreement achieved with RPA screening.

6. Discussion

The vastly different spectra found in Figs. 1–2 are disconcerting in view of the modest difference in valence screening effects compared to the absolute size of the total core-hole potential. In diamond, screening effects are about 80%, so that they must be treated exceptionally well to obtain an accurate total screening potential. Often, differences between results found using χ and χ^0 models and RPA results in solids are borne out in atomic calculations. Thus, atomic calculations might help improve density-based screening models in a corrective sense, if issues such as identifying appropriate reference configurations and boundary conditions are resolved. Also, the spherically symmetrical component of screening effects can be only weakly affected by non-spherical site symmetry, suggesting simplifications to explore. As mainly short-range screening effects are treated poorly in density-based screening models, the models may be helpful for long-range screening, whereas atomic-like calculations that exploit simplifications afforded by spherical symmetry may be most helpful for correcting χ or χ^0 model results at short distances. These possibilities are currently being investigated.

Abstract

A many-body relativistic XAFS theory has been developed on the basis of quantum electrodynamic Keldysh Green's function approach. To obtain photon absorption rate we calculate the time derivative of the projected photon Green's function whose self-energy includes relativistic electron Green's functions. For retarded and advanced electron Green's functions we can apply a useful expansion in terms of correlated quasi-nonrelativistic Green's functions.

1. Introduction

Many-body XAFS theory has been developed on the basis of many-body scattering theory [1–3] and Keldysh Green's function theory [4, 5] in the framework of non-relativistic theory. As is well known, the influence of relativistic effects increases with atomic number Z. So far several relativistic XAFS theoretical approaches have been proposed, however all of them are in one-electron theoretical framework. Here we discuss a many-body relativistic XAFS theory based on quantum electrodynamic Keldysh Green's function approach [6]. As a simple application we obtain a sound theoretical background for the current relativistic one-electron XMCD theory written in terms of many-body optical potential. The present approach also provides us a tool to analyse XAFS spectra irradiated by high intensity X-rays by applying renormalization of photon Green's functions.

2. Relativistic Keldysh Green's Functions

We now define the nonequilibrium photon Green's function $D^{\mu\nu}$ by use of the functional derivative with respect to external current j_ν^{ext}

$$\frac{4\pi}{c}D^{\mu\nu}(1,2)=\frac{\delta\langle A^\mu(1)\rangle}{\delta j_\nu^{ext}(2)} \tag{1}$$

which satisfies the equation [6]

$$\Box D^{\mu\nu}(1,2)-\partial^\mu\partial_\lambda D^{\lambda\nu}(1,2)-\int_c \mathrm{d}3\Pi^\mu{}_\lambda(1,3)D^{\lambda\nu}(3,2) = \delta_c(1-2)\delta^{\mu\nu}, \tag{2}$$

where $\int_c$ means the time integration on the closed path and delta function δ_c on the closed path is defined as

$$\delta_c(t_1-t_2)=\delta(t_1-t_2)\ t_1,t_2\ on-leg = -\delta(t_1-t_2)\ t_1,t_2\ on+leg. \tag{3}$$

The functional derivative in eq. (1) yields a useful expression of the photon Green's funciton

$$D^{\mu\nu}(1,2)=\frac{\mathrm{i}p_2}{4\pi}\langle T_c[\delta A^\mu(1)\delta A^\nu(2)]\rangle \tag{4}$$

where p_1 is 1 when t_1 is on + leg (from ∞ to $-\infty$), and -1 when on − leg (from $-\infty$ to ∞), T_c is the path-ordering operator on the Keldysh contour and $\delta A^\mu(1)=A^\mu(1)-\langle A^\mu(1)\rangle$. Here we define the photon selfenergy

$$\Pi^\mu{}_\nu(1,2)=\frac{4\pi}{c}\frac{\delta\langle j^\mu(1)\rangle}{\delta\langle A^\nu(2)\rangle}. \tag{5}$$

We also define the one-electron Green's function

$$\mathrm{i}G(1,2)=\langle T_c[\psi(1)\bar\psi(2)]\rangle,\qquad \bar\psi(2)=\psi^\dagger(2)\gamma^0 \tag{6}$$

which satisfies the Dyson equation

$$\left\{c\gamma_\mu\left(p^\mu+\frac{1}{c}\langle A^\mu(1)\rangle\right)-c^2\right\}G(1,2)-\int_c \mathrm{d}3\Sigma(1,3)G(3,2) = \delta_c(1-2). \tag{7}$$

Two different self energies Π and Σ are closely related in terms of the vertex function Γ_ν defined by

$$\Sigma(1,2)=cp_1\gamma_\mu\int_c \mathrm{d}3\,\mathrm{d}4G(1,3)\Gamma_\nu(32,4)D^{\nu\mu}(4,1^+),$$

$$\Pi^\mu{}_\nu(1,2)=c\,\mathrm{tr}\left[\gamma^\mu\int_c \mathrm{d}3\,\mathrm{d}4G(1,3)\Gamma_\nu(32,4)G(4,1^+)\right],$$

$$\Gamma_\nu(34,2)=-\frac{4\pi\mathrm{i}}{c}\frac{\delta G^{-1}(3,4)}{\delta\langle A^\nu(2)\rangle}. \tag{8}$$

Useful approximations can be obtained from a closed set of intergro-differential equations, Hedin's equations. For this purpose the vertex function Γ_ν is written by use of Σ

$$\Gamma_\nu(12,3)=-\frac{4\pi\mathrm{i}}{c}\left[\gamma_\nu\delta_c(1-2)\delta_c(1-3)-\frac{\delta\Sigma(1,2)}{\delta\langle A^\nu(3)\rangle}\right]. \tag{9}$$

The first order approximation for the electron and the photon selfenergies are given by

$$\Sigma^{(1)}(1,2)=-4\pi p_1\mathrm{i}\gamma_\mu G(1,2)\gamma_\nu D^{\nu\mu}(2,1^+) = \Sigma_l^{(1)}(1,2)-4\pi p_1\mathrm{i}\gamma_i G(1,2)\gamma_j D^{ji}(2,1^+), \tag{10}$$

$$\Pi^{\mu(1)}{}_\nu(1,2)=-4\mathrm{i}\pi\,\mathrm{tr}[\gamma^\mu G(1,2)\gamma_\nu G(2,1^+)]. \tag{11}$$

The longitudinal part of $\Sigma^{(1)}(1,2)$ is just a "GW" term

$$\Sigma_l^{(1)}(1,2)=\mathrm{i}p_1\gamma_0 G_l(1,2)\gamma_0 W(2,1^+), \tag{12}$$

where G_l is the longitudinal Green's function defined by eq. (14) and the transverse part $\Sigma_t^{(1)}(1,2)$ (the second term of eq. (10)) can contribute to electron-photon interaction. In the approximation $\Sigma^{(1)}=\Sigma_l^{(1)}+\Sigma_t^{(1)}$, we have neglected the transverse-longitudinal coupling terms such as D^{0i}, which should be small enough in the Coulomb gauge [6]. Up to the first order skeleton selfenergy, the electron Green's function G can be writtenin the matrix notation

*Electronic address: tfujikawa@faculty.chiba-u.jp

($\Sigma_l^{(1)}$ and $\Sigma_t^{(1)}$ are abbreviated as Σ_l and Σ_t)

$$G = G_0 + G_l\Sigma_t G_l + G_l\Sigma_t G_l\Sigma_t G_l + \cdots \tag{13}$$

where G_l is longitudinal electron Green's function

$$G_l = G_0 + G_0\Sigma_l G_l. \tag{14}$$

In the QED approach one-electron Green's function $G_l(1,2)$ can be assumed to be only dependent on the time difference $t_1 - t_2$, and we can define the spectral representation of $G_l(1,2)$. As the advanced g^a and the retarded Green's function g^r satisfy the closed Dyson equations on the contour from $-\infty$ to ∞, these Green's functions have simple expression in the energy space by use of the Hartree potential V_H as a 4×4 matrix

$$g_l(\varepsilon) = \begin{pmatrix} \varepsilon - V_H - \Sigma_{11} & -c\sigma\cdot\boldsymbol{p} - \Sigma_{12} \\ -c\sigma\cdot\boldsymbol{p} - \Sigma_{21} & \varepsilon + 2c^2 - V_H - \Sigma_{22} \end{pmatrix}^{-1} \tag{15}$$

where $\Sigma_{ij} = \Sigma_{ij}(\varepsilon)$ is the 2×2 (i, j) submatrix of the longitudinal selfenergy $\Sigma_l(\varepsilon)$. After some algebra we can rewrite the relativistic Green's function g_l in terms of the quasi-nonrelativistic one-electron Green's function g_{11},

$$g_l(\varepsilon) = (1 - X)^{-1} \begin{pmatrix} g_{11} & g_{11}Q \\ Qg_{11} & Qg_{11}Q + 1/2c^2 \end{pmatrix} \tag{16}$$

where

$$X = \begin{pmatrix} g_{11}Q\Sigma_{21} & X_{12} \\ X_{21} & X_{22} \end{pmatrix}, \qquad Q = \sigma\cdot\boldsymbol{p}/2c,$$

$$\begin{aligned} X_{12} &= g_{11}\{\Sigma_{12} - Q(\varepsilon - \Sigma_{22})\}, \\ X_{21} &= \left(Qg_{11} + \frac{1}{2c^2}\right)\Sigma_{21}, \\ X_{22} &= Qg_{11}\Sigma_{12} - \left(Qg_{11}Q + \frac{1}{2c^2}\right)(\varepsilon - \Sigma_{22}). \end{aligned} \tag{17}$$

The quasi-nonrelativistic one-electron Green's function g_{11} satisfies the Dyson equation for the selfenergy Σ_{11}

$$g_{11} = g_{11}^0 + g_{11}^0\Sigma_{11}g_{11}. \tag{18}$$

Up to the relativistic order g_{11}/c^2, $g_l(\varepsilon)$ is given by

$$g_l(\varepsilon) = \begin{pmatrix} g_{11} + \delta g_{11} & g_{11}Q \\ Qg_{11} & Qg_{11}Q + 1/(2c^2) \end{pmatrix}, \tag{19}$$

$$\delta g_{11}(\varepsilon) = g_{11}Q\Sigma_{21}g_{11} + g_{11}\Sigma_{12}Qg_{11} + g_{11}Q(\Sigma_{22} - \varepsilon)Qg_{11}. \tag{20}$$

In the relativistic "GW" approximation for $\Sigma_l^{(1)}$ shown by eq. (12), each of submatrix $\Sigma_l^{(1)}(\varepsilon)_{ij}$ is given with aid of the approximation (19),

$$\begin{aligned} \Sigma_{11}(1,2) &= \mathrm{i}\{g_{11}(1,2) + \delta g_{11}(1,2)\}W(2,1^+), \\ \Sigma_{12}(1,2) &= \mathrm{i}g_{11}(1,2)QW(2,1^+), \\ \Sigma_{21}(1,2) &= \mathrm{i}Qg_{11}(1,2)W(2,1^+), \\ \Sigma_{22}(1,2) &= \left\{Qg_{11}(1,2)Q + \frac{1}{2c^2}\right\}W(2,1^+). \end{aligned} \tag{21}$$

We notice that Σ_{11} has finite contribution even in the nonrelativistic limit $c \to \infty$, whereas other selfenergies have no contribution in that limit. We see that Σ_{12}, Σ_{21} are in the order of Σ_{11}/c, Σ_{22} is in the order of Σ_{11}/c^2.

3. Relativistic Many-Body XAFS Theory

To obtain the photoabsorption rate of the photon state $(\boldsymbol{k}, \alpha)$ is obtained by

$$w(\boldsymbol{k}\alpha) = -\frac{\mathrm{d}}{\mathrm{d}t}\langle n_{\boldsymbol{k}\alpha}(t)\rangle|_{t=0}. \tag{22}$$

We should note that $w(\boldsymbol{k}\alpha)$ has contribution from absorption, emission and scattering and so on. In the Heisenberg operator $n_{\boldsymbol{k}\alpha}(t) = a^\dagger_{\boldsymbol{k}\alpha}(t)a_{\boldsymbol{k}\alpha}(t)$, the time t in $a^\dagger_{\boldsymbol{k}\alpha}(t)$ has to be on $+$ leg, whereas that in $a_{\boldsymbol{k}\alpha}(t)$ on $-$ leg to keep the order of the operators. First we should represent $\langle n_{\boldsymbol{k}\alpha}(t)\rangle$ in terms of transverse photon Green's function $D^{>ij}$. By use of the polarization vector $\mathrm{e}^i(\boldsymbol{k}\alpha)$ and plane wave $\phi_{\boldsymbol{k}}(\boldsymbol{r}) = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r})/\sqrt{V}$, we can obtain

$$\begin{aligned} &\mathrm{i}\mathrm{e}^i(\boldsymbol{k}\alpha)^*\mathrm{e}^j(\boldsymbol{k}\alpha)\int \phi^*_{\boldsymbol{k}}(\boldsymbol{r}_1)D^{>ij}(1,2)\phi_{\boldsymbol{k}}(\boldsymbol{r}_2)\,\mathrm{d}\boldsymbol{r}_1\,\mathrm{d}\boldsymbol{r}_2 \\ &= \frac{c^2}{2\omega_k}\langle a_{-\boldsymbol{k}\alpha}(t_1)a^\dagger_{-\boldsymbol{k}\alpha}(t_2) + a^\dagger_{\boldsymbol{k}\alpha}(t_1)a_{\boldsymbol{k}\alpha}(t_2) \\ &\quad + a^\dagger_{\boldsymbol{k}\alpha}(t_1)a^\dagger_{-\boldsymbol{k}\alpha}(t_2) + a_{-\boldsymbol{k}\alpha}(t_1)a_{\boldsymbol{k}\alpha}(t_2)\rangle \end{aligned} \tag{23}$$

which contains $\langle n_{\boldsymbol{k}\alpha}(t_1)\rangle$ in the limit $t_2 \to t_1$.

The next job is to systematically calculate $D^>$ starting from the Dyson equation $D = D^0 + D^0\Pi D^0 + D^0\Pi D\Pi D^0$. Of course the free photon Green's function never contribute to the photoabsorption processes. The greater part of the second term of the above Dyson equation is given by use of the Langreth rule [7],

$$(D^0\Pi D^0)^> = D^{0>}\Pi^a D^{0a} + D^{0r}\Pi^> D^{0a} + D^{0r}\Pi^r D^{0>} \tag{24}$$

where for the matrix product AB we do not use time integration on Keldysh contour but from $-\infty$ to ∞

$$(AB)(1,2) = \int_{-\infty}^{\infty}\mathrm{d}t_3\,\mathrm{d}x_3 A(1,3)B(3,2).$$

To obtain the photoabsorption rate we calculate the time derivative of eq. (24) which yields the following formula by using infinitly small positive η to take causality into account

$$\begin{aligned} &\frac{\mathrm{d}}{\mathrm{d}t}\int_{t,t'\to 0} D^0(t - t_1)\Pi(t_1 - t_2)D^0(t_2 - t')\mathrm{e}^{\eta(t+t')}\mathrm{d}t_1\,\mathrm{d}t_2 \\ &= 2\eta\int\frac{\mathrm{d}\varepsilon}{2\pi}D^0(\varepsilon)\Pi(\varepsilon)D^0(\varepsilon). \end{aligned} \tag{25}$$

From now on we focus our attention to the lowest order contribution in regard to D^0, that is, the term $D^0\Pi D^0$, which gives golden rule expressions. Substituting explicit formulas of free photon Green's functions into eq. (25), we obtain the photon absorption rate neglecting other contributions

$$\begin{aligned} &\frac{\mathrm{d}}{\mathrm{d}t}\langle n_{\boldsymbol{k}\alpha}(t)\rangle \\ &\approx 2\eta\int\frac{\mathrm{d}\varepsilon}{2\pi}\mathrm{e}^i(\boldsymbol{k}\alpha)^*\mathrm{e}^j(\boldsymbol{k}\alpha)\langle\phi_{\boldsymbol{k}}|(D^0\Pi D^0)^>(\varepsilon)|\phi_{\boldsymbol{k}}\rangle \\ &\approx \frac{\mathrm{i}c^2}{2\omega_k^2}\langle d_i(-\boldsymbol{k}\alpha)|(\Pi^r - \Pi^a - \Pi^>)_{ij}(\omega_k)|d_j(-\boldsymbol{k}\alpha)\rangle\langle\eta_{\boldsymbol{k}\alpha}\rangle \end{aligned} \tag{26}$$

where we define

$$d_i(\boldsymbol{k}\alpha;\boldsymbol{r}) = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r})\mathrm{e}^i(\boldsymbol{k}\alpha)/\sqrt{V}.$$

From the first line to the second, we pick up all terms contributing to the photoabsorption. We thus obtain a fundamental relativistic formula for the X-ray absorption rate of the photonstate $(\boldsymbol{k}\alpha)$

neglecting unimportant factor,

$$I(\boldsymbol{k}\alpha) = -\mathrm{Im}[\langle d_i(\boldsymbol{k}\alpha)|\Pi^{>}_{ij}(\omega_k)|d_j(\boldsymbol{k}\alpha)\rangle]\langle n_{\boldsymbol{k}\alpha}\rangle. \quad (27)$$

To closely compare this with the one-electron theory, we further introduce GW approximation for Π as shown by eq. (11) where G's are approximated by the longitudinal part g_l. For g_l (g^a_l or g^r_l) we can use the expansion in terms of quasi-nonrelativistic Green's function g_{11} as shown by eq. (16), which yields

$$\begin{aligned} I(\boldsymbol{k}\alpha) = -\mathrm{Im}\sum_p |S_p|^2(&\langle\varphi_c|\Delta^* g^{>}_{11}(\varepsilon_p+\omega_k)\Delta|\varphi_c\rangle \\ &+\langle\varphi_c|\Delta^*\delta g^{>}_{11}(\varepsilon_p+\omega_k)\Delta|\varphi_c\rangle \\ &+\langle\varphi_c|\Delta^* g^{>}_{11}(\varepsilon_p+\omega_k)Q\Delta|\chi_c\rangle \\ &+\langle\chi_c|\Delta^* Q g^{>}_{11}(\varepsilon_p+\omega_k)\Delta|\varphi_c\rangle + \cdots)\langle n_{\boldsymbol{k}\alpha}\rangle. \end{aligned} \quad (28)$$

where $|\varphi_c\rangle$ and $|\chi_c\rangle$ are the large and small components of the core function c. The first term of eq. (28) has finite contribution even in the nonrelativistic limit ($c \to \infty$), whereas the other terms vanish in that limit. In the energy region well above the Fermi energy, $I(\boldsymbol{k}\alpha)$ is written in terms of scattering Green's function g_{sc} under the influence of the optical potential. This formula can be compared with that derived within relativistic one-electron theoretical framework [8].

4. Concluding Remarks

In this work a relativistic QED theory for XAFS analyses is discussed on the basis of Keldysh Green's functions, which goes beyond relativistic one-electron theory. In the same way we can discuss resonant and loss effects in XAFS. Because of restricted space, detailed discussion on these effects cannot be shown here.

Abstract

The combination of X-ray absorption spectroscopy (XAS) with UV-Vis and Raman spectroscopies or with Differential Scanning Calorimetry (DSC) has been recently carried out on the D44 beamline of DCI-LURE. The different set-ups used to perform such combinations are described and examples of combined investigations belonging to different field of materials science (coordination chemistry, sol-gel and catalysis) are presented.

1. Introduction

The use of complementary techniques in Materials Science is a well-established prerequisite for accessing a deeper structural description of a given material. The recent emergence of a combination of techniques using synchrotron radiation facilities appears as a significant progress for the understanding of materials processing. Indeed this approach which offers a simultaneous access to different kinds of information for the same material has great advantages with respect to separate experiments in order to eliminate errors due to differences in sample environment, thermal history, ageing, temperature, sample preparation. Even more important is the possibility to resolve ambiguities in the understanding of materials processing by allowing an accurate determination of the order of occurrence of the chemical and physical events by the different techniques.

The community using synchrotron radiation scattering techniques was pioneer in the development of such approach with the combination of Small or Wide Angle X-ray Scattering (SAXS/WAXS) or X-ray Diffraction (XRD) with Differential Scanning Calorimetry (DSC) [1–5], SAXS or WAXS with Raman spectroscopy [3, 6, 7] and SAXS with Fourier Transform-Infrared spectroscopy (FT-IR) [8]. Besides the combination of X-ray Absorption Spectroscopy (XAS) with X- Ray Diffraction (XRD) for which a lot of concrete combined studies are published [9–11], examples of combination of XAS with conventional physico-chemical characterisation techniques like DSC [12, 13] or FT-IR [14] are rather scarce. One of the possible reasons may be the non-triviality to design versatile cells with windows, substrate materials and sample conditioning suitable for the two techniques in a large range of X-ray energy and experimental conditions (temperature, controlled atmosphere . . .). Namely, a problem to overcome when performing simultaneous experiments with XAS is that of the difference in optimum sample thickness for the two techniques. For example, several orders of magnitude for optimum thickness exist for performing FT-IR and XAS or SAXS experiments in the transmission mode [8, 14]. This problem forces the experimentalist to adapt the detection mode of techniques, e.g. to use the attenuated total reflection method for the FT-IR experiment [8, 14]. Furthermore, whereas scattering techniques can adapt the photon energy for minimising absorption from cell windows and from the sample itself, this possibility is not available for the combination with XAS for which the X-ray energy is determined by the threshold energy of the element of interest.

Another complication arising for measuring complementary data simultaneously to XAS data comes from the difficulty of setting the apparatuses around the same sample. However, the advent of innovative designs for the extra instruments has recently helped solving this technical limitation. The main innovation for spectroscopic techniques is the use of intense sources, of efficient optical fibres and high-sensitive detector systems allowing a miniaturisation of the spectrometer, which is not at the expense of the data quality (resolution and detection limit). Such development will be extensively illustrated in this paper with the combination of XAS with UV-Vis and with Raman spectroscopies. To the best of our knowledge, these spectroscopies have never been combined with XAS. UV-Vis spectroscopy uses ultraviolet and visible electromagnetic radiation to energetically promote valence electrons in a molecule to an excited energy state. Besides characteristic bands used as fingerprints of chromophores in a molecule, this technique is also powerful to provide electronic information such as oxidation state or optical band gap. Raman scattering measurements, like infrared absorption, are used to obtain information about the structure and properties of molecules from their vibrational transitions. This technique is very well suited for the combination with XAS because both have a lot of common specificities. Namely, both can be used for many types of samples (liquid, solid or gas) under operating conditions and in time-resolved measurements.

Finally we have also developed a DSC set-up allowing combination with XAS in transmission mode. DSC is a technique determining the variation in the heat flow given out or taken by a sample when it undergoes a change of structure or chemical composition under temperature change in a controlled atmosphere. Therefore thermally induced processes can be accurately followed. The device described herein allows to work in a larger temperature range and in a wider energy range than devices previously combined with XAS [12, 13]. An example of combined DSC and XAS study will be presented.

2. Combined processing techniques

XAS experiments were performed at the DCI source at LURE, on the D44 beamline. Examples of combination presented herein were carried out in transmission mode using ionisation chambers filled with suitable gases. Fe, Co and Zn K edge data were recorded using a Si(111) double crystal monochromator whereas Mo K-edge measurements were done using a Ge(400) monochromator. The beam size on the sample was adjusted to ≈5 mm horizontally and 1 mm vertically. The monochromator allows step by step acquisitions ranging between 6 to 20 minutes depending on the energy range, energy step and data acquisition time (typically 1 or 2 s).

We describe in the following the different technical solutions used to perform the combined experiments presented in Section 3. The versatility of some of them has been tested on several systems and will be mentioned.

The differential scanning calorimeter used was a commercial Setaram DSC 111 apparatus based on the Calvet heat-flux principle. This apparatus is a performant laboratory DSC instrument characterised by a high sensitivity (5–10 μW). The sample of interest and an inert reference are each positioned at the centre of two horizontal juxtaposed alumina tubes (internal diameter ≈7 mm) inserted into the silver calorimetric block. The temperature difference arising from thermal activity is balanced by two independent compensatory heaters surrounding the samples. Due to the specific design of this apparatus, a quantitative measurement of the change in enthalpy is possible. Two kapton windows seal both extremities of alumina tubes in order to work under controlled atmosphere. The available operating temperatures are between −120 °C and 830 °C with heating rates from 0.01 to 30 °C min^{-1}. A photon beam (lateral size ≈4–5 mm) passes through the tube containing the sample of interest. The sample is pressed as a pellet (≈6 mm diameter) inside a platinum tube and sandwiched in a vertical arrangement by two coaxial Pt tubes. The sample so-inserted in the Pt-tube is set at the centre of the alumina tube. On one hand, the Pt tube ensures a good thermal conduction towards the sample. On the other hand, its length (≈26 mm) is sufficient to avoid contamination of the alumina tube by direct contact at the melting temperature of the sample.

The UV-Vis-near IR spectrophotometer is a commercial Varian Cary 50 dual beam apparatus working in the 190–1100 nm wavelength range with approximately 1.5 nm fixed spectral bandwidth. Scan rates up to 400 nm/s are available making this apparatus powerful for time-resolved experiments. The pulsed Xenon lamp source is narrow and very intense and the Si diode detectors are unaffected by room light. These specifications make this apparatus suitable to be fitted with a fibre optic coupler allowing a flexible arrangement for combined measurements with XAS. The reduction of transmittance of 2 m length fibre optic probes (Hellma) compared to the direct beam is about 41% in the 220–1100 nm range. At this time, the UV-Vis set-up is only equipped for solution analysis in transmission for both techniques but it could be upgraded for solid characterisation by means of diffuse reflectance accessory. The main problems to solve for characterising simultaneously liquid media by XAS and UV-Vis are the windows and the thickness of the cell. On one hand, the use of commercial cuvettes made of quartz suprasyl or fused silica, well adapted for UV-Vis, must be thrown out for XAS measurements below 15 keV and replaced by plastic like polystyrene (PS) or polymethylmethacrylate (PMMA) cuvettes. On the other hand, the suitable thickness is extremely dependent on the system of interest, *i.e.* concentration and solvent. So it is well known that for a given thickness, organic and aqueous media do not absorb the same amount of X-ray photons at a given energy. Then versatile technical solutions must be based on cells with variable optical path as the cell [15] developed by Graseby Specac Co working with controlled optical path up to 6 mm and using thin Mylar, polypropylene or polyethylene windows (between 10 to 50 μm). For example this cell is very well suited for combinations at energies ranging from the Cr-K (5989 eV) to the Zr-K (17998 eV) edges.

The Raman spectrometer is a commercial modular Raman spectrometer (Model HL5R of Kaiser Optical Systems, Inc.). It incorporates a small but high-powered near IR laser diode working at 785 nm, a high sensitive Charge Coupled Device (CCD) detector providing fast and simultaneous full spectral collection of Raman data from 100 to 3450 cm^{-1}, holographic Notch filters. The average resolution is 2 cm^{-1}. The use of excitation light in the near-IR region allows minimising possible strong fluorescence originating from the sample which could cover the weak Raman signal. The laser beam is incident on the sample through a laser probe made of a probehead and of a single optical fibre for the excitation by the laser and of another one for the collection of the scattered Raman signals. Both fibres are packed in a common sheath of 10 m length. The probehead can be equipped with non-contact or immersion optics with different fixed focal lengths. The choice of the optics depends on the studied system and on the geometry of the cell. On one hand, the Raman scattering signal arising from windows (liquid cell or windows of controlled atmosphere chambers) can be minimised by adjusting the focus point of the optics away from the optical window. On the other hand, for studying solutions, immersible optics can be used with long focal length for transparent media and short focal length for opaque solutions or turbid media. This flexibility for the focal length of the Raman optics makes appreciably easy the design of the sample environment to study systems under constraints. Therefore, a lot of systems were recently investigated by combined XAS and Raman spectroscopies. Among them we can mention the study of ionic conduction into $K(CF_3SO_3)$-doped polyelectrolytes at the potassium K-edge (3609 eV) [16], the study of the thermally induced electron transfer of an Prussian Blue analogue $Na_{1.5}Co_4[Fe(CN)_6]_{3.2}.13H_2O$ [17] at the iron and cobalt K-edges (7112 and 7709 eV, respectively) and the study of hydrolysis-condensation of $SnCl_4.5H_2O$ in ethanolic medium at the tin K-edge (29200 eV) [18]. In this paper, we present results obtained on Mo-based heterogeneous catalysts. Solids are prepared as self-supporting pellets where possible, or by diluting the powder prior to pelletizing, in γ alumina that is suitable for both techniques (low absorption for XAS and very weak Raman signal with limited fluorescence). The sample thickness was adapted to the XAS constraints.

3. Experimental results

3.1. *Combined XAS and DSC measurements on the dehydration study of a cyanide-bridged Fe(III) and Co(II) ferromagnetic chain (Coll. Laboratories 2 and 4)*

The combination of XAS and DSC measurements was performed to study the thermal dehydration of the cyanide-bridged iron(III)–cobalt(II) double zigzag ferromagnetic chain, $[Fe^{III}(bpy)(CN)_4]_2[Co^{II}(H_2O)_2].4H_2O$, where bpy is the 2,2′-bipyridine. The occurrence of slow relaxation of the magnetisation

when the applied magnetic field is set to zero allows to classify this system among the few first «linear nano-magnets» [19]. But unexplained occurrence of two rates of relaxation has been observed. Two hypotheses were proposed to account for this phenomenon, both based on a mixture of species: the fully hydrated chain mixed either with a dehydrated form of the initial molecule or with a species implying photoinduced electron transfer. Indeed the single crystal XRD structure of the fully hydrated chain [19] shows that two kinds of water molecules are involved in the structure: two are linked to the cobalt ion and four are hydration water molecules linked through van der Waals forces and hydrogen bonds to the two coordinated water molecules. The metal atoms are six-coordinate: two nitrogen atoms from bpy and four cyanide carbon atoms around Fe and four cyanide nitrogen atoms and two water molecules around Co. No similar XRD data were available in the operating conditions of measurement of relaxation rates using a SQUID (Superconducting quantum-interference device). Nevertheless it was evidenced by XAS that structural changes [20] occur by submitting the fully hydrated chain to primary vacuum as that encountered in SQUID apparatus, but, no change in the oxidation state of the two metallic ions occurs. This first set of results binds us to study carefully the thermal dehydration processes of the system by a combined DSC-XAS study.

Figure 1 shows a DSC curve recorded under nitrogen atmosphere at a heating rate of 5 °C min^{-1} on a pellet of sample (≈8 mg of product) suitable for the combination of XAS. Two intense endothermic peaks well defined over about 30 °C and centred at ≈66 °C and 168°C were observed in agreement with thermogravimetry analysis (TGA). Figure 2 shows XANES spectra recorded at the Co K edge during isothermal processes performed with the DSC apparatus between RT and 180 °C. The conditions (duration and temperature) of isothermal treatment chosen as a function of DSC data are indicated in Figure 1. XANES data at both edges were collected at each isothermal treatment temperature whereas EXAFS data were only recorded at RT, 66 °C and 168 °C. First, we observe during isothermal treatments at different temperatures between RT and 180 °C a continuous decrease of the intensity of the white line with a concomitant increase of the intensity of the preedge indicating

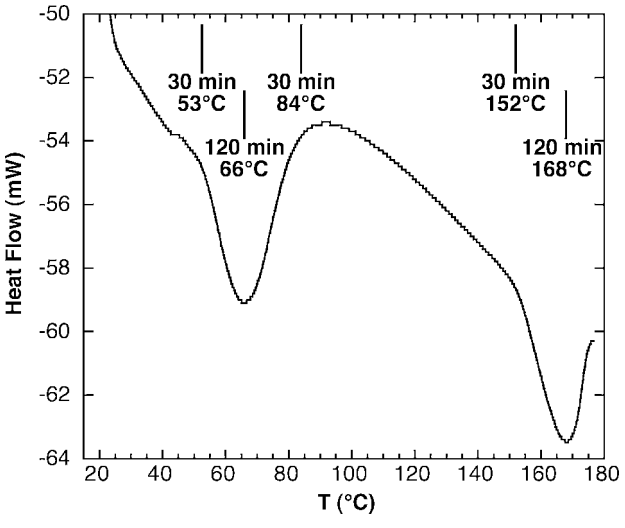

Fig. 1. DSC scan for the $[Fe^{III}(bpy)(CN)_4]_2[Co^{II}(H_2O)_2].4H_2O$ sample obtained at a heating rate of 5 °C min^{-1} under N_2 atmosphere. The temperatures of the isothermal EXAFS and XANES measurements at the Fe and Co K edges are indicated by vertical bars. Isothermal treatments were done either for 30 or 120 min.

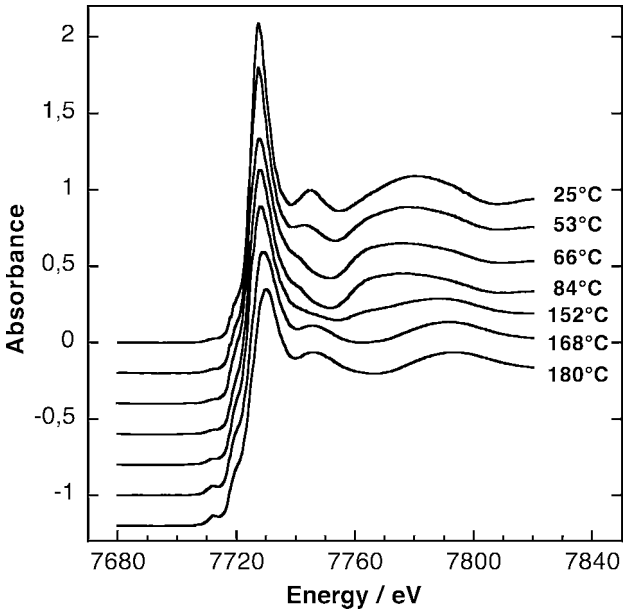

Fig. 2. XANES spectra recorded at the Co K edge during the isothermal heating of the $[Fe^{III}(bpy)(CN)_4]_2[Co^{II}(H_2O)_2].4H_2O$ sample from RT to 180 °C under N_2 atmosphere.

a change of the regular octahedral symmetry of the fully hydrated chain towards a more distorted one at higher temperatures. Second, the intensity of the resonance at ≈7745 eV decreases after the first endothermic event and increases again after the second one. Finally a non monotonous shift of the position of the first EXAFS oscillation has been evidenced: first a shift at lower energy from RT to 84 °C followed by a shift at higher energy from 84 °C to 180 °C. The structural changes were solved by FeFF7 calculations done to simulate the Co and Fe K-edges EXAFS spectra recorded in the same set of experiments [20]. The first endothermic peak is associated to the loss of the four hydration molecules affecting the overall structure around Co, with in particular a change of the Co-NC-Fe angle from 167° (RT XRD data) to 140° (FeFF7 simulations for 84 °C data). The second endothermic event is related to the loss of the two coordinated-water molecules leading to a tetra-coordinated symmetry for Co and a decrease of the Co-N distances (from 2.11 Å in the RT-XRD structure to 2.04 Å in the FeFF7 simulations for 180 °C data) as suggested by XANES measurements. Furthermore the Co-NC-Fe angular arrangement, which is well known to be strongly affected by multiple scattering events due to its quasi-linearity, undergoes again a change from 140° to 167° (FeFF7 simulations for 180 °C data) explaining the overall non monotonous change observed in resonances above the white line energy (Fig. 2).

Finally the comparison of the XANES spectra recorded during the dehydration processes of the $[Fe^{III}(bpy)(CN)_4]_2[Co^{II}(H_2O)_2].4H_2O$ chain with the XANES spectrum of the pumped sample under primary vacuum allows to conclude that the change in the magnetisation relaxation of the chain is assigned to structural changes around Co due to the departure of hydration water molecules.

In this study, DSC curve and XAS data were not recorded simultaneously for two reasons: the compulsory DSC heating rate and the limiting step by step scanning mode of the D44 experiment which obliges, at the moment, to record the XAS data during isothermal treatment. But no technical limitations for the DSC111 Setaram apparatus hinder its use on a time-resolved or dispersive XAS experiment, as done recently on the dispersive D11 beamline at LURE for studying phase transitions in lead

carboxylate liquid crystals [21]. Nevertheless, DSC and XAS measurements were performed in sequence, strictly under the same conditions: same pellet as in DSC, same oven geometry and same reference temperature, which is essential for the accuracy of the correlation between thermodynamic and structural changes.

3.2. *Combined in-situ XAS/UV-Vis measurements to study the formation of ZnO nanoparticles (Coll. Laboratory 5)*

During the past years considerable interest has been paid to the preparation of II-VI semiconductor nanometer-sized colloids by sol-gel routes [22]. Indeed these materials present a phenomenon of quantum confinement by excitons as primary particles are smaller than 7 nm offering potential applications in many technologies, such as solar energy conversion or optoelectronic devices. The control of the particles formation, and in this case of the nanoparticle size, is of prime importance on the optimisation of the properties of the final materials. Generally speaking, this task can be achieved by XAS investigation of the structure of precursors involved in the hydrolysis-condensation processes, and of the different building blocks during the solid-state growth. Nevertheless, our expertise in this field shows also that the use of XAS alone often does not allow to unravel the mechanisms of hydrolysis-condensation of cations and must be combined to complementary techniques, as reported for Ce [23], Cr and Zn [24] and Ga [25] cations.

For quantum dot colloids, UV-Vis spectroscopy is routinely used to determine their particle sizes [22] because the presence of exciton levels in the 250 to 500 nm wavelength range. In this context, we have developed at LURE a methodology to follow the kinetics of formation of II-VI semiconductor colloidal suspensions by combining XAS and UV-Vis. This approach is illustrated for ZnO nanoparticles preparation.

The colloid synthesis follows the previously reported procedure [26] based on the preparation in ethanolic medium of $Zn_4O(CH_3COO)_6$ precursors [27] from zinc acetate solution and subsequent hydrolysis-condensation induced by LiOH addition and thermal activation at moderate temperature (between 20 and 70 °C). XAS and UV-Vis spectra were recorded simultaneously on the same precursor solution heated at 60 °C by using a thermostated cell with optical path adjusted at 6 mm [15], and equipped with polypropylene windows of 10 µm thickness. Besides the determination of local order around Zn and of the particle sizes during the colloidal formation, the motivation of the combined investigation was also to clarify the occurrence of a Zn-based hydroxy double salt phase, $Zn_5(OH)_8(OCOCH_3)_2.2H_2O$ (labelled hereafter Zn-HDS) observed as final solid mixed with ZnO and zinc acetate phases [26]. In particular, we had interest to determine if the formation of the Zn-HDS phase was concomitant to the ZnO formation or arose from the reaction of ZnO with zinc acetate during ageing of the colloidal suspension before extraction of solids.

Figure 3 displays optical UV absorption spectra recorded during heating of solution whereas Figure 4 shows the corresponding Zn-K edge EXAFS spectra. The formation of ZnO colloidal particles is evidenced in UV-Vis by the presence of a pronounced HOMO-LUMO transition at ≈331 nm. For comparison, ZnO bulk crystals have an absorption band edge at 388 nm whereas 3 nm colloidal particles present an excitonic transition peak at ≈320 nm. In this example, the particle size determined by UV-Vis spectroscopy is around 4 nm. We note an increase of the intensity of the excitonic peaks but no shift of the

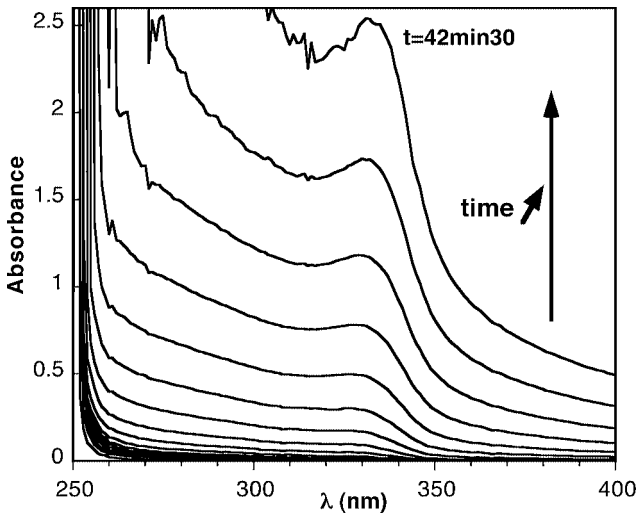

Fig. 3. Temporal evolution of the optical absorption spectra recorded during the formation of ZnO quantum dots by heating of a precursor solution at 60 °C in presence of LiOH. One UV-Vis spectrum was recorded every 2 min 30.

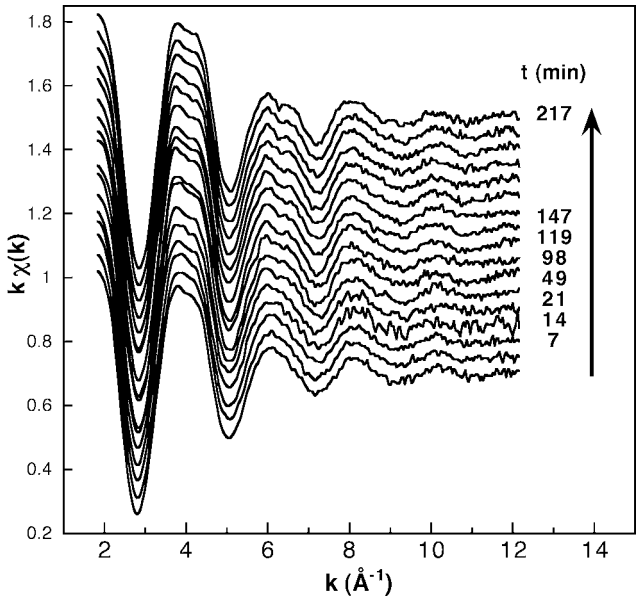

Fig. 4. Temporal evolution of the Zn-K edge EXAFS spectra recorded simultaneously with the UV-Vis spectra presented in Fig. 3. The data acquisition time for one EXAFS spectrum was 7 min.

absorption onset to longer wavelength indicating that the nearly monodisperse size of particles is constant at the early stage of ZnO formation. The observed change of EXAFS spectra is also associated to the formation of ZnO colloidal particles in solution. At the end of the process (at 217 min), the EXAFS spectrum presents features in phase with the characteristic oscillations measured on ZnO bulk crystals but with damped intensities. The damping of EXAFS oscillations is not only due to the nanocrystalline size of ZnO particles but also to the fact that the solution is a mixture of different species, here ZnO and precursors. It is noteworthy that due to the mixture of species, EXAFS appears less sensitive than UV-Vis to evidence the formation of ZnO nanoparticles. Indeed, the splitting of the first and second EXAFS oscillations characteristic of the ZnO formation is only obvious after 98 min of heating, whereas the excitonic UV peak is defined after 20 min. Nevertheless, XAS is also powerful to reveal that the formation of Zn-HDS is not concomitant to the formation of ZnO particles for 217 min of heating at 60 °C.

The complementarity of information available by both techniques is well illustrated with this study. The difference in sensitivity can be useful for unravelling complex kinetic formation pathway, but also for interpreting deeply XAS data. Indeed, structural parameters related to ZnO colloids can be constrained from the particle size available by UV-Vis, making the EXAFS analysis procedure more reliable and accurate in the determination of structural parameters related to a mixture of species.

3.3. *Combined in-situ XAS/Raman measurements: rehydration of a calcined Mo/Al_2O_3-SiO_2 supported catalyst (Coll. Laboratory 6)*

In situ studies of heterogeneous catalyst preparation, activation and reactivity has tremendously benefit from the advent of combined experiments such as XRD and (quick)EXAFS [9–11]. Hence, it is currently recognised that most of the effort on catalyst characterisation has to be directed toward the combination of spectroscopic techniques [28] since information available from synchronised spectroscopic measurements may lead to the establishment of structure-reactivity relationships essential for improving the molecular engineering of new catalytic materials. In this communication, we show the first *in situ* molecular-scale characterisation of heterogeneous catalysts by simultaneously combining EXAFS with Raman spectroscopy.

We have investigated the room-temperature hydration of a calcined 5 wt% Mo/ASA supported catalyst (ASA stands for an amorphous silica alumina containing 25 wt% Al_2O_3 and 75 wt% SiO_2) which is a potential candidate for the hydro-desulfurisation of petroleum feedstocks. The catalyst was prepared by impregnation of ammonium heptamolybdate and calcination at 500 °C (more details on the sample preparation will be given elsewhere [29]). This study is aimed at showing that drastic changes in Mo speciation can occur when exposing the catalyst to water vapour after calcination. It will be shown that these changes can be related to the dissolution of the oxide support [30]. The sample-holder containing a self-supported pellet of the catalyst was put into a rectangular aluminium cell in which a stream of water-saturated oxygen gas was allowed to flow at room temperature. A geometry similar to conventional fluorescence XAS experiment was adopted for Raman signal detection. The sample-holder orientation was set to 45° with respect to incident X-rays in order to allow the simultaneous recording of the Raman signal from the direction perpendicular to the X-rays. The Raman probehead was located outside the sample cell at ≈7.5 cm from the sample and the window through which the Raman signal was collected was a thin polypropylene foil (20 µm). Laser and X-rays impinged the sample at the same position. Each Raman spectrum corresponds to an integration time of 10 s. In order to compare Mo-K edge EXAFS and Raman spectra in the same temporal frame, 200 Raman spectra were averaged while 4 EXAFS spectra were recorded.

Figure 5 displays selected Raman spectra and Figure 6 shows the corresponding Fourier Transforms (FT). The time nomenclature given in these figures corresponds to the duration of the hydration step. The spectrum recorded at "0 h" corresponds to the sample before flowing water-saturated oxygen through the cell whereas spectra recorded at "*n* h" are related to samples that were submitted to *n* hours of hydration. The Raman (liquid-state) and EXAFS (solid-state) spectra of the aluminomolybdate ion $[Al(OH)_6Mo_6O_{18}]^{3-}$ (labelled hereafter $AlMo_6$) are given for comparison. The Raman spectrum of the "0 h" sample

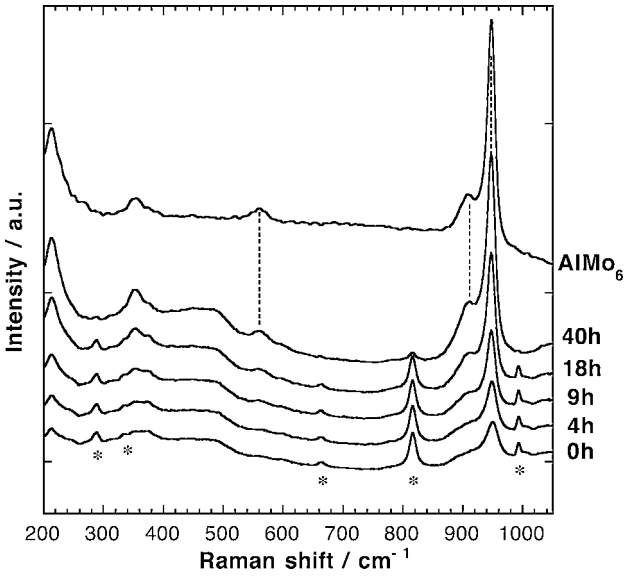

Fig. 5. Temporal evolution of the Raman spectra recorded during the RT-rehydration of a calcined Mo/Al_2O_3-SiO_2 supported catalyst. The Raman spectrum of the aluminomolybdate ion (liquid state), labelled $AlMo_6$, is presented for comparison. Stars indicate the position of characteristic bands of MoO_3.

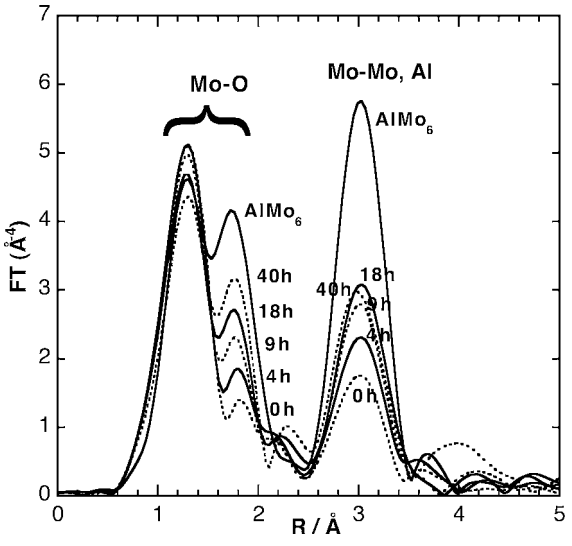

Fig. 6. Temporal evolution of the FT of the Mo K-edge EXAFS spectra recorded simultaneously with the Raman spectra shown in Fig. 5. The FT of the EXAFS signal for $AlMo_6$ entities (solid state) is also reported.

exhibits the characteristic lines of MoO_3 at 817 and 995 cm^{-1} together with a broad band centred at ≈950 cm^{-1} characteristic of surface isopolymolybdic entities [31]. Note that the relative band intensities for MoO_3 and the isopolymolybdic species does not reflect the relative amount of each phase. Indeed, MoO_3 is a strong Raman scatterer and the bands that are related to MoO_3 correspond to a small amount of oxide. Raman spectra obtained after exposure to moisture show *i*) a sharpening and increase of the band at about 950 cm^{-1} and *ii*) the appearance of a shoulder at 910 cm^{-1} along with a weak band at about 560 cm^{-1}. All of these bands are clear spectroscopic signatures for the formation of $AlMO_6$ entities (see the liquid-state Raman spectrum of $AlMO_6$) and ref. [31]. Hence, Raman results clearly evidence that exposing the calcined sample "0 h" to prolonged moisture leads to an almost total disappearance of the MoO_3 phase and initial isopolymolybdic entities whereas the formation of $AlMO_6$ entities becomes evident. At the same time, EXAFS data show a change of the first and

second coordination sphere around Mo that can be related to the above structural changes since the "40 h" spectrum can be satisfactorily fitted with $AlMo_6$ crystallographic data. As a matter of fact this study reveals for the first time that despite the dominant presence of silica in the ASA oxide support, silicomolybdic acid is not formed by exposing the sample to extensive moisture at RT as reported before for Mo/SiO_2 catalyst [32]. It is noteworthy again that XAS or Raman results alone would be very difficult to interpret. On one hand, the mixture of MoO_3 and isopolymolybdic entities in the "0 h" sample can not be revealed by XAS alone due to the very low amount of MoO_3 in the mixture. On the other hand, although the "40 h" sample can be satisfactorily reproduced by FeFF7 simulations based on the $AlMo_6$ crystallographic structure, the addition of a Mo-Al contribution to simulate the second intense peak of the FT could be considered, without the support of Raman results, as a fitting trick since a rather satisfactory fit is already achieved by considering Mo-Mo contributions only. More quantitative analysis of this combined XAS-Raman study will be given in a forthcoming paper [29].

This study shows again the benefit that XAS can get when combined with complementary techniques, in particular with vibrational spectroscopies. That leads a lot of teams to vigorously work on the design of suitable cells for such combination [28]. As an example, effort was devoted recently to design a common cell usable for XAS and synchrotron-based far-IR and for conventional mid-IR in laboratory [33]. Unfortunately, one has to change the windows for using the cell in separate experiments. This can be a drawback for catalyst characterisation, as already mentioned in the introduction. As regards vibrational spectroscopy, it is worth noting some advantages of the Raman technique as compared to IR spectroscopy. First, as shown herein, the Raman signal is not affected by absorption of Al_2O_3 and SiO_2 oxide supports contrary to IR for which strong IR absorption is observed below $\approx 1000\,cm^{-1}$. Furthermore, the Raman signal arising from alumina and silica is very weak. Second, in contrast to IR spectroscopy, Raman spectroscopy can provide information from aqueous solution during materials processing because water gives a very weak Raman signal in the metal-oxide vibration range. Finally the design of cells for simultaneous *in situ* characterisation suitable for XAS and Raman spectroscopies is easier than for combination of XAS and IR. Indeed we have to optimise the cell for XAS constrains only since Raman signal can be recorded on the same sample through a glass or plastic window. All these advantages make Raman spectroscopy a promising technique for combination with XAS.

4. Conclusion and perspectives

We have successfully developed a new experimental approach for studying materials processing based on the simultaneous combination of XAS with techniques routinely applied in materials science, such as DSC, UV-Vis or Raman spectroscopies. The potential of such an approach has been demonstrated with different examples. Besides the access to complementary information, we can summarise the advantages of such combination: *i*) elimination of artefacts introduced by the use of separate experiments (sample history and environment, ageing, temperature control...), *ii*) increase of the accuracy in the time correlation between different physical and chemical events and *iii*) improvement of the reliability of XAS analysis. All the combined techniques are based on robust and versatile devices which are laboratory equipment.

Whereas the combination with spectroscopic methods (UV-Vis, Raman) presented above are a totally innovative approach, the combination of XAS with DSC has already been reported in the past [12, 13]. However we have carefully considered the main directions mentioned as further development by these pioneering reports for offering to the materials science community an improved XAS-DSC set-up. In particular, the temperature range of −60 °C–375 °C accessible in [12, 13] has been extended from −120 °C to 830 °C offering new possibilities for the study of solid-state reactions. On the other hand, the geometry of the device allows the use of kapton windows for the crossing of X-rays allowing to work at lower energy than Br K-edge (13474 eV). So combined DSC- XAS measurements between RT and 550 °C on glassy systems [34] at the Fe (7112 eV) and Ni (8333 eV) K edges have been recently carried out using this set-up. Similar experiments on hydrocalumite intercalated with oxochromium entities [35] will soon be carried out at the Cr K-edge (5989 eV).

The improvement to the UV-Vis/XAS combined set-up could be directed towards the possibility of studying solid systems and not only liquid media as now. The design of an *in situ* cell allowing to study materials at high temperatures with both Raman and XAS is a prerequisite for further developing the combination of spectroscopic techniques.

In fact the main weakness of previous combinations was not related to the use of complementary techniques but to the performance of the D44 beamline and DCI source (acquisition time, photons flux available at the sample position and beam size). The advent of third generation synchrotron radiation sources with high brilliance will clearly offer new possibilities for such combined experiments. As a matter of fact, all the combined apparatuses which are suitable for time-resolved experiments presented above will be installed on the future SAMBA (acronym for "Spectroscopies Applied to Materials Based on the Absorption") beamline dedicated to X-ray absorption spectroscopy at SOLEIL. The SAMBA beamline is fully described in a contributed paper of this conference [36] and will offer the possibility to record high-quality Quick-EXAFS data in few seconds.

Finally the advent of microfocus beamlines dedicated to XAS should also gain great benefit from the developments in MicroRaman spectroscopy. Indeed the size of the laser spot being of the same order of magnitude as a microfocused X-ray beam, both techniques could be combined in order to obtain complementary information about the heterogeneity of samples. The field of applications of such combination is very large from environmental science to materials science. Such a combination will soon be tested on the LUCIA beamline (acronym for "Line for Ultimate Characterisation by Imagery and Absorption") which will be first built at the SLS before being installed at SOLEIL.

Abstract

Extended X-ray absorption fine structure (EXAFS) data were measured at three temperatures (20 K, 80 K and 300 K) above the L_3-edge of polycrystalline α-tantalum. The data analysis is based on a recently developed Bayesian approach and uses the FEFF8 code results. Besides the temperature dependence of the lattice constant we obtain a separation of the Debye-Waller parameters into structural and thermal contributions. The latter are well described by a force-field model with two force parameters. *A posteriori* errors and cross correlations between the model parameters are calculated, taking the errors of the input EXAFS function as well as systematic uncertainties of the model into account. Lattice-dynamical observables determined independently are compared with the results of our force-field model using the parameters from the fit of our EXAFS data.

1. Introduction

EXAFS measurements have been performed on a commercially available tantalum foil at 20 K, 80 K, and 300 K. In order to analyze the absorption functions $\mu(k_l)$, measured at wave numbers k_l, $l = 1,\ldots,L$, in terms of a set of model parameters $\boldsymbol{x} = \{x_n\}$ we use a Bayesian approach [1]. The objective of this approach is (I) to determine the subspace **R** of the total model-parameter space **Q** in which the data determine the result of the fit, (II) to find a natural scaling of the model parameters, which makes their errors comparable and error cross-correlations meaningful, and (III) to obtain most probable *a posteriori* values for the model parameters and their errors and error correlations. The method requires the repeated solution of the direct problem of calculating $\boldsymbol{\chi}(\boldsymbol{k})$ from given model parameters $\boldsymbol{x}$. For the electronic part of the direct problem we use the FEFF8 code [2] results and for the lattice-dynamical part the iterative procedure introduced by Poiarkova and Rehr [3] and presented in detail by Krappe and Rossner [1].

For the solution of the inverse problem of inferring model parameters **x** together with their uncertainties from given EXAFS data $\boldsymbol{\mu}(k_l)$, we apply Bayes' theorem. It requires to specify (I) the overall efficiency $A(k)$ to normalize the measured absorption coefficient to the atomic background absorption coefficient computed by FEFF, (II) *a priori* values for the model parameters, (III) errors for the experimental input $\mu(k_l)$, and (IV) an estimate of the uncertainties connected with the truncation of the infinite multiple-scattering series for $\boldsymbol{\chi}(k_l)$ and the muffin-tin and local-density approximations in FEFF, and with the restriction of the electron and lattice dynamics to finite clusters surrounding the absorbing atom.

With the ansatz

$$\sigma_j^2 = (\sigma_j^{therm})^2 + (\sigma_j^{struct})^2 \tag{1}$$

for the Debye-Waller (DW) parameters and assuming that the structural contributions σ_j^{struct} do not change with temperature, a consistent set of force-field parameters can be determined to account for the thermal contribution to the DW parameters σ_j^{therm}.

2. Experimental setup

We used a tantalum foil of 5 µm thickness from Goodfellow Corporation with 99.9% Ta. No heat treatment in vacuum was performed on the sample. EXAFS measurements were carried out at beam line E4 of HASYLAB at DESY, using a Si(111) double crystal monochromator. To reduce the higher harmonic content of the beam, the monochromator was detuned to approximately 50% of the maximal transmitted X-ray intensity. The width of the vertical slit was opened up to 1 mm resulting in an estimated energy resolution of ≈2 eV. All data were taken in transmission mode and collected around the L_3-edge of Ta (9.61–10.85 keV). Energy calibration was accomplished by assigning the position of the first inflection point of the tantalum absorption-spectrum to 9.881 keV. We used nitrogen gas at atmospheric pressure in the ion chambers before and behind the sample. For each of the three measurements at 20 K, 80 K, and 300 K three scans were collected to improve statistics.

3. Data analysis

The fitting procedure of Ref. [1] has been extended to include a correction $\Delta\mu_0(k)$ to the embedded-atom absorption-coefficient $\mu_0^{\mathrm{FEFF}}(k)$. Similar to Klementev [5] the correction term is expressed as cubic-spline function with N_p support points k_p. In addition, a k dependent overall efficiency $A(k) = \bar{\mu}(k)/\bar{\mu}_0^{FEFF}(k)$ of the experimental set-up is introduced, where $\bar{\mu}$ is the measured absorption coefficient $\mu(k)$ after preedge-background subtraction and after averaging in k to remove the EXAFS wiggles, and $\bar{\mu}_0^{FEFF}$ is the similarly averaged μ_0 from FEFF. We then represent $\mu(k)$ by

$$\mu(k) = A(k)(\mu_0^{FEFF}(k) + \Delta\mu_0(k))(\chi(k) + 1). \tag{2}$$

A thorough discussion of this procedure is given in a forthcoming paper [4]. The set of model parameters x_n consists of the amplitudes $\Delta\mu_0(k_\mathrm{p})$ at the support points k_p, the many-body correction to the scattering amplitude, ${S_0}^2$, the reference energy E_0 in the expression $k^2 = 2m\hbar^{-2}(h\nu - E_0)$, the lattice constant a, assuming that the half-path lengths R_j are related to the lattice constant by the geometry of the ideal bcc lattice, the multiplicity number of the first shell, N_1, the (projected) DW parameters of the single and multiple-scattering paths, considered in the multiple-scattering series, σ_j^2, $j = 1,\ldots,J$, and the third cumulant of the first single-scattering path, $C_{3,1}$. Alternatively, instead of fitting the total DW

*e-mail: rossner@hmi.de

parameters of all scattering paths we use a force-field model to express the thermal contribution to the $\sigma^2{}_j$ in terms of nearest and next-nearest neighbor central-force constants $\kappa_s, s = 1, 2$. The following bootstrap procedure is used to separate the thermal from the structural contribution to $\sigma^2{}_j$: We start with the 300 K data and determine spring constants $\kappa_1{}^{(1)}$ and $\kappa_2{}^{(1)}$, assuming that

$$\sigma_j^2 = (\sigma_j^{therm}(T = 300\,\mathrm{K};\ \kappa_1{}^{(1)}, \kappa_2{}^{(1)}))^2. \tag{3}$$

We then determine $\sigma^2{}_j$ from the 20 K data and define

$$(\sigma_j^{struct})^2 = \sigma_j^2 - (\sigma_j^{therm}(T = 20\,\mathrm{K}; \kappa_s{}^{(1)}))^2. \tag{4}$$

New spring constants $\kappa_s{}^{(2)}$ are determined by fitting

$$(\sigma_j^{therrm}(T = 300\,\mathrm{K}; \kappa_s{}^{(2)}))^2 = \sigma_j^2 - (\sigma_j^{struct})^2 \tag{5}$$

to the 300 K data and the cycle is repeated. Convergence is typically achieved after 3–5 cycles.

In our fitting procedure we use a cluster size of $I = 10$ shells ($R_{\max} = 9$ Å) in FEFF and $I = 19$ shells ($R_{\max} = 12$ Å) in the lattice-dynamics calculation. As *a priori* values for the model parameters we use $\Delta\mu_0(k_p) = 0, k_p = 1, \ldots, 14, S_0{}^{(0)} = 1$, $E_0{}^{(0)} = 9884$ eV (the peak position of the white line); the $R_j{}^{(0)}$ are calculated from a lattice constant $a = 3.30$ Å, assuming an ideal bcc structure; from the same assumption the $N_j{}^{(0)}$ were derived; the $(\sigma_j{}^{(0)})^2$ are obtained from the Debye model with a Debye temperature of 240 K, and all third cumulants were set to $C_{3,j} = 0$. In FEFF8 the option of a self-consistent potential was used with a cluster of 65 atoms within a sphere radius of 7 Å, a Hedin-Lundqvist exchange correlation potential with a constant imaginary part of 0.75 eV, a maximum number of 6 legs in multiple-scattering paths, a 4% cutoff of the mean amplitude relative to the largest path amplitude, and a radial grid parameter of 0.01 for atomic background computations. The normalized absorption functions for Ta at 20 K, 80 K, and 300 K are shown in Fig. 1. The experimental data are represented by dots with error bars and the final fits are shown by solid lines. All experimental data points to the left of the dotted line at 3.2 Å are disregarded because the multiple-scattering series converges too poorly for the chosen cluster size in this range of k-values. Truncation and model errors are determined as in Ref. [1].

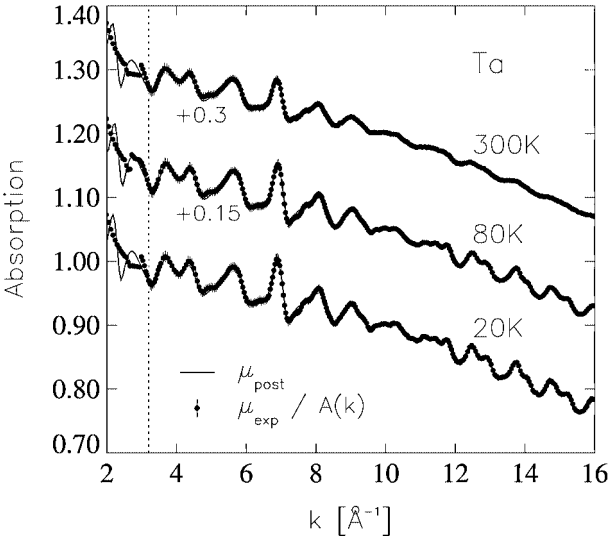

Fig. 1. The absorption coefficients $\mu(k)$ of the experimental data for Ta at 20 K, 80 K, and 300 K after preedge-background subtraction and normalization to μ_0^{FEFF} (dots with error bars) and the corresponding *a posteriori* values (solid line).

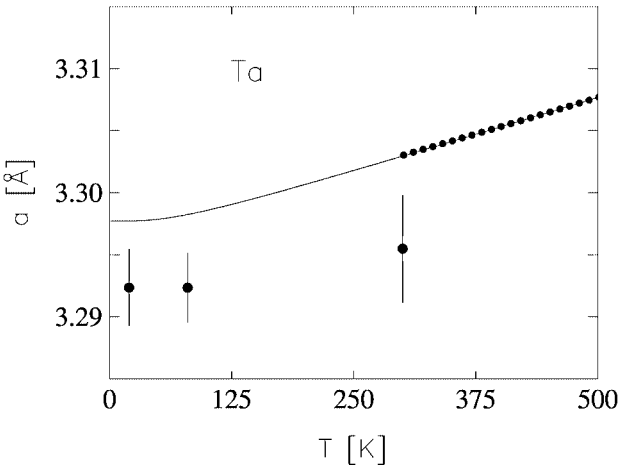

Fig. 2. Temperature dependence of the lattice constant a, extracted from the fits (solid points with error bars), results of Ref. [5] (small dots), and extension of these results to lower temperatures (line).

4. Discussion of results

The lattice constants obtained from the fit for the three temperatures are shown in Fig. 2. There seem to be no measurements of the lattice constant of Ta below room temperature. We have therefore extrapolated the measured lattice constants and thermal expansion coefficients from Amonenko *et al.* [6] at 500 K to lower temperatures using the temperature-integrated form of the Grüneisen formula [7] with the assumption that the Debye model is valid with a Debye temperature of 248 K and that the temperature dependence of the compression modulus can be neglected in the extrapolated temperature range. The extrapolation is also shown in Fig. 2 for a rough comparison with our data which are, as usual, about one order of magnitude less accurate than the X-ray diffraction data of Amonenko *et al.* [6]. Still larger uncertainties are due to the fact that neither for our probe nor for the one of Amonenko *et al.* were the degree of oxidation and the gas load of the lattice accurately determined.

More interesting is the result on the lattice dynamics. A consistent description of the DW parameters at all three temperatures is obtained with a temperature-independent contribution $\sigma_j^{\mathrm{struct}}$ and a thermal part $\sigma_j^{\mathrm{therm}}$ derived from a force-field model with only nearest and next-nearest neighbor central-force constants κ_1 and κ_2. A fit of the same quality is obtained with a Debye model for $\sigma_j^{\mathrm{therm}}$, using a Debye temperature of 248 K. The contributions to the DW parameters are shown in Fig. 3 for all 72 scattering paths. We find that even at 20 K the $\sigma^2{}_j$ depends primarily on the vibrational structure. The 'melting' of the EXAFS oscillations for long path lengths is shown by the first 10 path numbers which represent single scattering paths plotted with increasing paths lengths. The figure further demonstrates the sensitivity of $\sigma^2{}_j$ to displacement-displacement correlations which are absent in the unprojected DW parameter measured in diffraction experiments [8]. Especially $\sigma^2{}_{65}$ of the multiple-scattering path number 65, where all scattering centers are aligned and follow the sequence A-B-C-B-A-B-A, is more than twice as high as $\sigma^2{}_{66}$ with a sequence A-B-C-D-C-B-A for the aligned atoms.

A two-parameter force-field model can of course not describe the whole phonon dispersion-relations, in particular in the elastic limit. We calculated the unprojected densities of phonon states ρ_0 for a 19-shell cluster with 411 atoms and a 28-shell cluster with 749 atoms by a recursion method in analogy to the one used for the

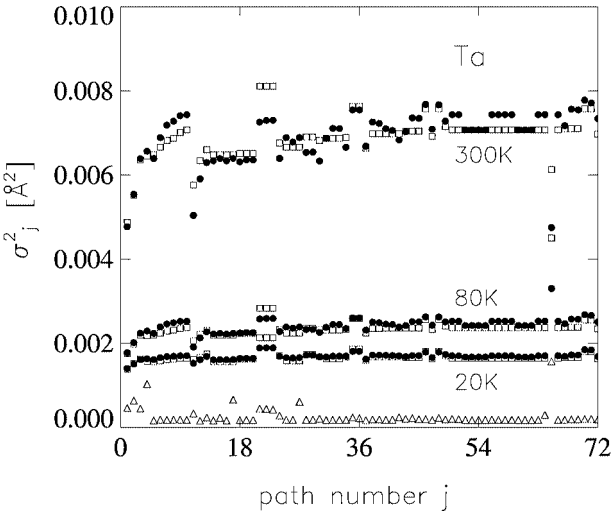

Fig. 3. Thermal DW parameters for 20 K, 80 K, and 300 K (open and filles circles) and structural DW parameters (open triangles) for all scattering paths. The thermal DW parameters derived from a force-field model are represented by filled circles and those derived from a Debye model ($\Theta_{\mathrm{Debye}} = 248$ K) are shown by open circles. Path numbers 1–10 represent single scattering paths, path numbers 11–72 number multiple scattering paths.

projected level densities and described in the appendix. The result for the 28-shell cluster is shown in Fig. 4 in comparison with the state density in the Debye model, and in a Born-von Karman model [9, 10] using the same 28-shell cluster. In this model 19 parameters were fitted to reproduce the measured phonon-dispersion curves. The unprojected DW exponent 2W divided by the recoil frequency ν_R of the free ion is shown as function of the temperature in Fig. 5. for two cluster sizes in our force-field model and for the Born-von Karman parameters [10] in the infinite lattice. The figure indicates that with increasing cluster size $2W/\nu_R$ decreases towards the values of the infinite lattice result. Projected DW parameters are less influenced by the low-frequency properties of the projected state density ρ_R because the latter vanishes much faster for $\nu \to 0$. This is seen analytically in the Debye model, where $\rho_0(\nu)$ vanishes as ν^2, but $\rho_{\mathrm{R}}(\nu)$ as ν^4 for

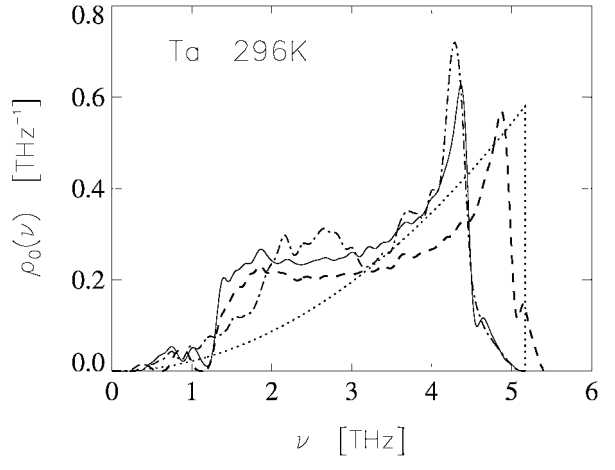

Fig. 4. Comparison of unprojected densities of phonon states for a cluster with 749 atoms using Woods' parametrization of the dynamical matrix and calculating its eigenvalues by a standard library routine (dashed dotted line), using Woods' parametrization and our recursion method (solid line), using our two spring constants in combination with the recursion method (dashed line), and using the Debye model (dotted line).

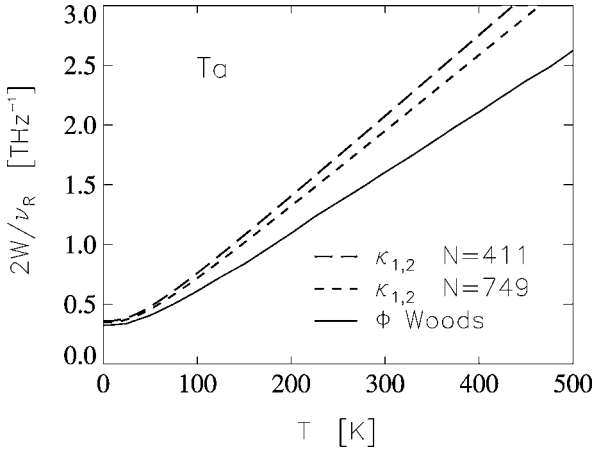

Fig. 5. The unprojected DW exponent 2W divided by the recoil frequency ν_{R} of the free ion plotted as function of the temperature for the Born-von Karman parameters in an infinite lattice [9] (solid line) and for our force-field model using two cluster sizes of 411 atoms (long dashed line) and 749 atoms (short dashed line).

small ν. For force-field models this effect is shown in Fig. 6 and also seen in the numerical results of Sevillano *et al.* [8].

The fitted values of the parameters including the corrections $\Delta\mu_0(k_l)$ to the FEFF results for $\mu_0(k)$ are shown in table I together with their *a posteriori* errors. The corrections $\Delta\mu_0(k_l)$ are zero within one standard deviation of the *a posteriori* errors. Also the unharmonicity parameter $C_{3;1}$ vanishes within these limits.

5. Conclusions

The introduction of an energy-dependent overall detection efficiency enables us to determine empirical corrections to the embedded-atom absorption-coefficient from FEFF in a simultaneous fit with the lattice constant, the structural contribution to the DW parameter and a pair of spring constants describing the essential features of the lattice dynamics in a cluster surrounding the absorbing atom. A bootstrap procedure was used to separate the thermal from the structural contribution to the total DW parameters. The thermal contribution has been described by a force-field model with only two central force

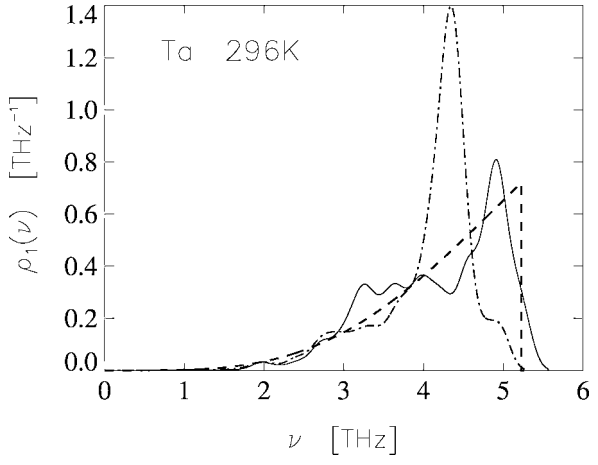

Fig. 6. Comparison of densities of phonon states projected onto the first single scattering path for a cluster with 749 atoms using our recursion method in combination with Woods' parametrization [8] (dashed dotted line) as well as our two spring constants (solid line). The Debye model results are represented by the dashed line.

constants and the projected and unprojected densities of phonon states were compared with results of a 19-parameter Born-von Karman model, fitted to neutron diffraction data. We find good agreement of the projected state densities from EXAFS and neutron diffraction data, and still rather fair agreement for the unprojected quantities when the finite cluster size probed in EXAFS is taken into account.

Appendix I: Calculation of unprojected Debye-Waller parameters in a force-field model

In the following we show that a variant of the iteration method proposed by Poiarkova and Rehr [3] to evaluate the projected phonon level-density and the projected Debye-Waller parameters can be used to obtain also the total level density. Following our presentation of the iteration method in Section II of Ref. [1] one has to substitute the projected density of states $\rho_j(\omega)$ in Eq. (5) of Ref. [1] by the total density of vibrational states

$$\rho_0(\omega)\,\mathrm{d}\omega = \sum_\gamma \delta(\omega - \omega_\gamma)\,\mathrm{d}\omega = -\frac{1}{\pi}\mathrm{Im}\,tr\left(\frac{1}{z - \Phi + \mathrm{i}\varepsilon}\right)\mathrm{d}z =: \omega_0(z) \tag{6}$$

with $z = \omega^2$. Calling the determinant of the matrix $(z\delta_{vv'} - \langle v|\Phi|v'\rangle)$ again D_{-1} and $A_{vv'}$ its cofactors, we find

$$\mathrm{tr}\left(\frac{1}{z - \Phi}\right) = \frac{1}{D_{-1}}\sum_v A_{vv} = \frac{1}{D_{-1}}\partial_z D_{-1}. \tag{7}$$

As in Ref. [1] we introduce the determinants D_v of the tridiagonal matrices obtained from $(z\delta_{vv'} - \langle v|\Phi|v'\rangle)$ by removing rows and columns 0 to v and find the recursion relation

$$D_v = (z - a_{v+1})D_{v+1} - b_{v+2}^2 D_{v+2}, \tag{8}$$

with $v = -1, 0, \ldots$, or

$$D_{v+1}/D_v = \frac{1}{z - a_{v+1} - b_{v+2}^2 D_{v+2}/D_{v+1}}. \tag{9}$$

The basis states $|v\rangle$ are generated by the dynamical matrix Φ with the Lanczos algorithm, starting with a vector $|0\rangle$. It should be stressed that Φ has to be symmetrized when used in this context.

The convergence of the recursion (9) implies that D_{-1} is a minimal solution of the recursion (8) according to a theorem by Pincherle [11, 12]. To obtain an approximation to the minimal solution, we use Miller's algorithm in a version proposed by Gautschi [12]. Defining

$$r_v = \frac{D_{v+1}(z)}{D_v(z)}, \quad v = -1, 0, \ldots, N, \tag{10}$$

Eq. (9) becomes

$$r_v = (z - a_{v+1} - b_{v+2}^2 r_{v+1})^{-1}, \quad v = N-1, N-2, \ldots, -1, \tag{11}$$

which is solved backwards, starting with $D_{N+1} = 0$, $D_N = z - a_N$, $b_{N+1}^2 = 0$, and $r_N = 0$. In terms of the set of ratios r_v an approximation to $D_{-1}(z)$ is given by

$$D_{-1} = (z - a_N)\left(\prod_{v=-1}^{N-1} r_v\right)^{-1}. \tag{12}$$

The zeros of D_{-1} may be called z_v, $v = 0, \ldots, N_0$. The state density $\omega_0(z)$ is then given by $\sum_{v=0}^{N_0}\delta(z - z_v)$, the weight factors w_v being all equal to 1 in this case. In principle any start vector $|0\rangle$ could be used in the Lanczos algorithm, e.g. the vector $\{1, 0, \ldots, 0\}$.

As discussed already by Haydock and Te [13] the convergence of the iteration method is much faster for the projected level density and the projected DW parameters than for the unprojected density. In fact we found that N had to be of the order of the number of degrees of freedom in the cluster to get acceptable results. The method is therefore suitable to calculate the phonon level-density of finite clusters of up to a few Å size, where calculations in Fourier space are not suitable.

Abstract

X-ray Magnetic Circular Dichroism became mature and is used in a large variety of applications. Taking advantage of the element-specificity of XAS, a variety of important problems was addressed: e.g. magnetism and magnetic profiles at interfaces of nanostructures, induced magnetism at chemisorbed molecules, enhanced 2D spin-fluctuations in coupled ultrathin ferromagnet films, the revival of orbital magnetic moments and its relative alignment to the spin moment, limitations for the applicability of the integral XMCD sum rules, separation of dipolar (E1) and quadrupolar (E2) contributions in the XMCD. An equally important progress in the fundamental understanding is the symbiosis of theory and advanced experiments. In all examples given the combination of both was very successful. Theory can 'switch on and off' various effects, i.e. L_3-L_2 edges, dipol-quadrupolar effects, layer selective magnetic moments, multiple vs. single scattering. This serves for a better understanding of magnetism on an atomic scale.

1. Introduction

In 1988 at the XAFS V conference Gisela Schütz and coworkers reported their first results on X-ray magnetic circular dichroism (XMCD). They pointed out that X-ray absorption spectroscopy (XAS) is the most appropriate technique to study selectively almost every element in the periodic table. They demonstrated that by taking the difference spectra between right and left circular polarization ($\mu^+ - \mu^-$) one was sensitive to study *spin densities* [1]. This opened a complete new field to study magnetic materials. Clearly, Mössbauer effect and nuclear magnetic resonance are also element-specific, for example the spin-polarization/induced magnetism at Cu in the vicinity of Mn in MnCu alloys has been detected by NMR long time ago – the so-called RKKY-oscillations. However, it is obvious that the XAS via the various K-, L-, M-edges is not only sensitive to most of the elements but also probes different parts of the electron density (s-, p-, d-shells). Years later at XAFS IX in 1996 Jo Stoehr pointed out that these new discoveries would have a major impact on information technology and material science [2]. He also demonstrated that by employing the so-called *integral sum-rules* XMCD is able to probe separately the orbital and the spin magnetism, μ_L and μ_S [3]. Again, μ_L and μ_S have been determined long time ago since the early days of Charles Kittel by measuring the g-factor in ferromagnets via magnetic resonance and yielding $\mu_L/\mu_S = (g-2)/2$ [4]. However, one has to admit that by virtue of XMCD the field of atomic magnetism in solids has been re-activated and makes enormous progress in experiment as well as in theory.

The research grew enormously and spread out addressing almost all fields in material science nowadays. Only few examples can be mentioned here: ferromagnetic ultrathin multilayers exchange coupled via nonmagnetic spacers like Co/Cu/Ni form in- and out-of-plane magnetic domains which were recently studied by element-specific and magnetic microscopy [5]. The magnetic coupling between ferro- and antiferromagnetic films and its exchange bias field like at Co/NiO interfaces are enormously important for storage media. Recently, it has been shown that at such an interface one will not have an intact Co metal and NiO interface but rather oxygen interdiffuses into Co leading to metallic Ni areas at the interface [6]. Molecules like CO on ferromagnetic Ni surface are hybridized and see a spin-polarization resulting in a magnetic moment at the oxygen atom [7]. For small clusters of few atoms of Fe, Co, or Ni almost the full orbital moments survive. (They are not quenched like in solids.) This was shown twice by groups from Lausanne: years back for the gas phase [8], and recently for clusters on surfaces [9].

In this work we will not review the full variety of technological applications but focus on another aspect of this highly active research field, namely the fact that new external parameters in magnetic nanostructures can be used to manipulate the magnetism and serve for a better understanding of fundamentals. It seems to be an accidental coincidence that in the same period of time when the XMCD grew up also the theory made progress in *ab initio* calculations. Clearly, magnetism is only a relativistic correction in total energy calculations. Out of a $\approx$ eV total energy per particle only a few μeV are of magnetic origin. In some cases it may therefore not be sufficient to treat spin-orbit coupling as a perturbative part of the Hamiltonian adding small corrections. It may be rather important to treat the system fully relativisticly.

In the real structure and experiment there are two important 'knobs' to manipulate the magnetism: (*i*) Via the *finite size effect* one can shift the Curie temperature T_C of ferromagnets from its bulk value almost down to zero. E.g., just by varying the thickness of a Co film and a Ni film one can move $T_C^{Co} < T_C^{Ni}$. Such a manipulation is impossible in bulk systems. (*ii*) Special growth recipes for nanostructures enable to prepare crystallographic structures not available in the bulk, e.g. pseudomorphic growth of Ni/Cu(100) produces tetragonal Ni or Co/Cu(111) trigonal Co. Both are not available in bulk structures. However, these small perturbation from cubic fcc or bcc structures are very important for reactivation of orbital magnetism. Changes of the crystallographic structure by ≈ 0.05 Å change the magnetic anisotropy energy (MAE) by 10^2–10^3 [10]. Selected examples for prototype studies in experiment and theory are: In Sec. 2 we discuss the effects of spin-fluctuations in two-dimensional (2D) nanostructures by virtue of element-specific magnetization profiles for Ni and Co exchange coupled films. Sec. 3 gives examples of combined theory and experiment to study the layer-resolved magnetic profile at interfaces of ferromagnets/nonmagnetic metals. In Sec. 4 we disentangle the XMCD at L edges of Rare Earths with assistance of theory to separate dipolar and quadrupolar contributions. Most of the experimental analysis of XMCD spectra take the intensity of the XMCD signal as a measure of the magnetization, i.e. the area

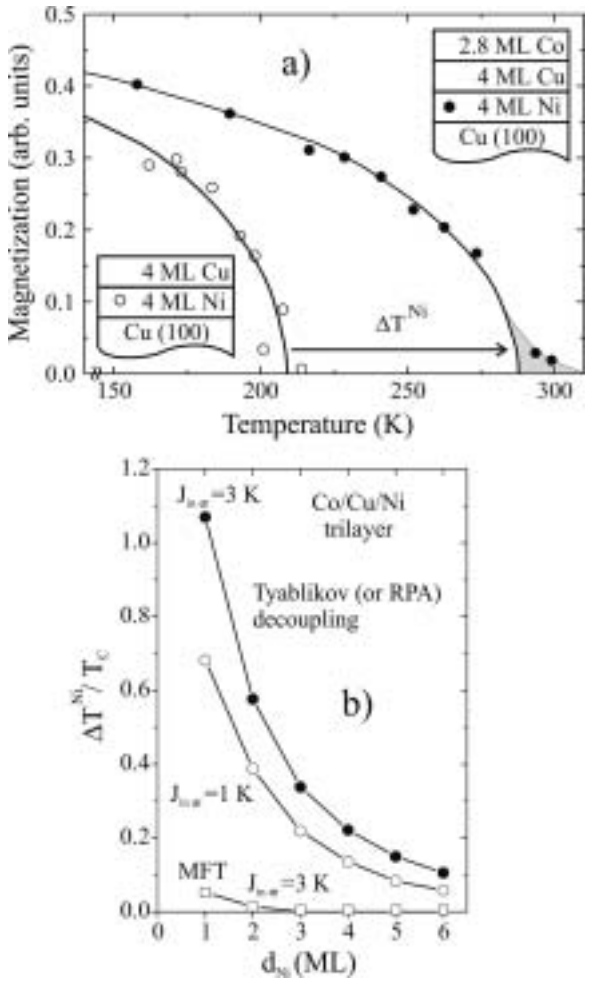

Fig. 1. (a) $M^{Ni}(T)$ measured at the Ni L_3 edge XMCD before and after evaporating a second ferromagnetic film (Co) on top. A small DC magnetic field was applied to avoid domain formation close to T_C, for details see [12]. (b) Shift of T_C^{Ni} calculated in mean field approximation and RPA [17]. It is obvious that the shift is the larger the stronger J_{inter} and the thinner the Ni layer is.

under the $(\mu^+ - \mu^-)$ spectrum. It is obvious that a spectroscopy delivers much more information: the line width of the resonance, the line shape, the asymmetry etc. For a full interpretation of experimental XMCD spectra it would be most advisable that the theory calculates the full X-ray absorption cross-section $\mu(E)$ as a function of energy. Examples are given in Sec. 5.

2. Enhanced Spin-Fluctuations in 2D Nanostructures

In Fig. 1 we show the temperature-dependent magnetization of an ultrathin Ni film (4 atomic layers) before and after the evaporation of a second ferromagnetic film (2.8 ML Co). The Co and Ni films are separated by a nonmagnetic spacer film of 4 ML Cu. XMCD is the technique of choice to measure the Ni and Co magnetizations separately. Here we show only the Ni magnetization, Co has a much higher magnetization and higher Curie temperature. At XAFS XI we have shown that by reducing the Co thickness one can even achieve that the Co film orders at a lower temperature than the Ni film [11]. The details of the current experiments are discussed in [12]. The exchange coupling of the Co and Ni film is described in an itinerant model as the interlayer exchange coupling (IEC), depending on the spin-dependent band structure for each layer. Experiments are usually analyzed in a local Heisenberg model where the coupling between two ferromagnets is defined as the difference in the free energy between parallel and antiparallel alignment $\Delta E \approx J_{inter}\vec{M}_1 \cdot \vec{M}_2$. Typical values for such a coupling (depending on d_{Cu}) correspond to 1 K $\triangleq$ 100 μeV $\triangleq$ 2.5 kG. XMCD and other techniques like ferromagnetic resonance have determined the coupling constant J_{inter} in a quantitative way [13]. It is also clear that the difference in the free energy between ferromagnetic and antiferromagnetic alignment depends on the temperature, details have been discussed elsewhere [14]. Here we focus exclusively on the effect of the Co exchange coupling on the Ni magnetization as shown in Fig. 1a). At first glance one might argue that Co produces an exchange field in the order of a few kG and that this exchange field leads to a so-called field induced magnetization ($M^{Co}(T)$ is not shown in Fig. 1a). A static field corresponding to $\langle S_z^{Co}\rangle$ would enhance $M^{Ni}(T)$ and T_C only by 2–5 K. Surprisingly, we observe in Fig. 1a) a shift $\Delta T^{Ni} \approx 80$ K. A shift of 80 K out of 210 K (≈40%) has never been observed in bulk materials [15]. It can be interpreted as follows: P. Jensen has calculated ΔT^{Ni} in a Heisenberg model to lowest order (mean field approximation). We see in Fig. 1b) that for $J_{inter} = 3$ K the shift is only a few percent. If he includes higher order approximation in the calculation (RPA), the higher spin correlations $\langle S^2\rangle$ result in a dramatic increase ΔT^{Ni}. In other words, for a 2D ferromagnet like 4 ML Ni higher order spin-fluctuations are very dramatic. Their effect is influenced very much by the Co exchange coupling and produces such a high shift in T_C. W. Nolting and coworkers have addressed the same experimental finding using an itinerant electron model with single Hubbard band. They find similar results. If they treat the itinerant model to lowest order (Stoner model) they fail to calculate the correct T_C and its shift. If they include higher order correlation they are able to explain the experiments fairly well [16].

In conclusion, for a complete description of the magnetization for nanostructures and two-dimensional films it is insufficient to treat only in a static manner spin-up and spin-down bands (Stoner model). Spin-fluctuation and higher order electron–electron correlations are very important and influence the magnetization close to T_C dramatically.

3. Layer Resolved Magnetic Profiles

Interfaces of 3d ferromagnets and 4d and 5d nonmagnetic metals are of technological importance. In the early days XMCD of 3d-4d and 3d-5d alloys were investigated by several groups. However, in principle one should speculate that an interface of these elements might not have the same electronic and magnetic band structure as in an alloy because the nearest neighbor coordination is well ordered at an interface and random in an alloy. Experiments do have the handicap that interfaces are never mathematically flat. The minimum are steps of one atomic layer. The theory might assume a perfect flat interface but the real crystallographic structure may not be treated correctly (layer relaxation, tetragonal distortion, etc). Only recently, with the new high power synchrotron facilities in the soft and the hard X-ray regime it has become possible to measure XMCD for single atomic layers more or less free of noise. One example is the layer resolved magnetic moment profile of Ni_n/Pt_m multilayers [18]. Induced magnetic moments at the Pt interface of 2 ML Pt only were recorded free of noise in the energy range of 11–13 keV at the ESRF beamline ID 12. By varying the number n of the Ni layers and m of Pt layers, the authors were able to construct layer resolved profiles of the Ni magnetic moment and the induced Pt moments. Pt carries a large magnetic moment only at the interface.

Already the second and third layer contribute very little to the Pt magnetization. The XMCD at the Ni L edges shows that the magnetic moment of the Ni atoms reduces at the interface, but remains magnetic. This is in contrast to earlier publications where it was believed that there are dead layers at such an interface. The Ebert group calculated the magnetic profile for these Pt/Ni multilayer. The results are in fair agreement. Differences between theory and experiment may be attributed to details of the local structure in the real specimen [18].

Another interesting case is the interface of Fe/W. An induced magnetization was also recorded at the W interface [19]. Even the smaller XMCD signal at the L_2 edge was intense. This enables us to apply the integral sum rules [3] and separate the orbital and spin moment and their relative alignment. The integral sum rules account only for the area under the L_3 and L_2 XMCD signal and they are derived assuming an atomic picture and λLS coupling. Both can be questioned for an element with $Z = 74$ and in a metallic state. Nevertheless, this commonly used procedure demonstrates the principal power and capability of XMCD analysis and interpretation. It follows straight forward from the sum rules that if the integral over the $L_3 + L_2$ XMCD (which determines the orbital moment) changes the sign as a function of energy, μ_S and μ_L are antiparallel aligned, if it does not change its sign they are parallel aligned. The experiment shows unambiguously that the integral does not change the sign, and consequently in Ref. [19] it is concluded $\mu_S || \mu_L$. This is in a way surprising because W is located at the beginning of the 5d series and following simple atomic Hund's rules one expects an antiparallel alignment of spin and orbital moment. Strictly speaking the Hund's rules are for single atom physics and small λLS coupling. However, it is surprising that these rules mostly hold also in solid state physics even up to heavy elements as uranium. Further experiments and theory are needed to get a better insight, but this example shows the full potential of a detailed analysis of orbital and spin magnetic moments in a large variety of nanostructures. For a detailed discussion see [20].

Although Ti and V, the early 3d metals, are nonmagnetic they show an induced magnetic moment if they get in contact with the ferromagnetic 3d elements. Recent progress in the gap-scan technique of the undulator beamline UE56/1-PGM at BESSY II did allow to measure the XMCD signal even of 1 ML V (or Ti) interface layer sandwiched between Fe films. These spectra are free of noise and also free of oxygen contamination so that a full V-XMCD signal from 510 eV up to 540 eV is recorded with a very detailed fine structure [20, 21]. In Fig. 2 we show spectra for the early and the late 3d elements. Also Cr was sandwiched between Fe to gain a net magnetization. It is obvious that the XMCD spectra (dashed lines) of Ti, V, and Cr show a detailed fine structure reflecting details of the spin-resolved DOS. We will come back to this in Sec. 5.

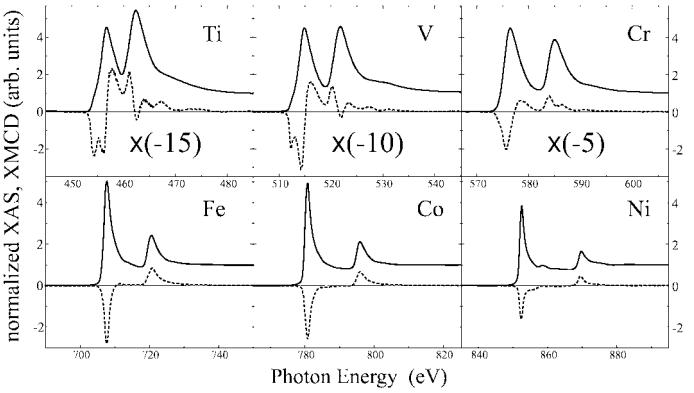

Fig. 2. Normalized XAS and XMDC spectra of the early 3d transition metals (TM's) in the upper panel versus the late 3d TM's, i.e. the ferromagnetic Fe, Co and Ni, in the lower panel. The XMCD spectra of the early TM's have been obtained from Fe/TM/Fe(110) trilayers. For clearer presentation of the systematics we have changed the sign of these XMCD spectra. (Please note the negative enlargement factors for Ti, V, and Cr).

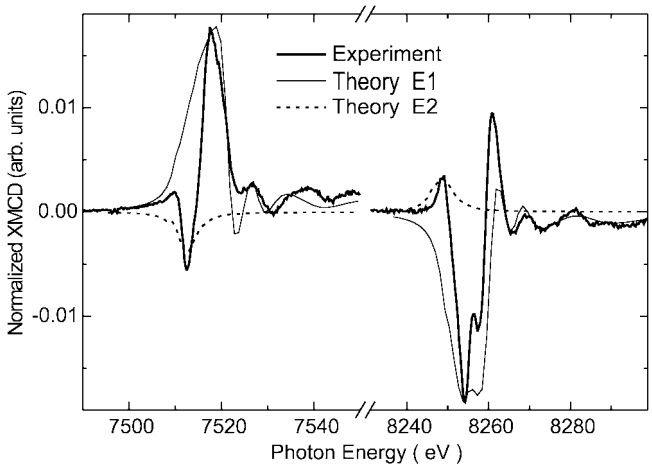

Fig. 3. Experimental and calculated XMCD signal for the L_3 and L_2 edges of Tb metal. Using FEFF8.2 the calculated cross section was separated into quadrupolar and dipolar contributions. The quadrupolar part (dashed) contributes only at the pre-edge with a single peak, the dipolar part (thin solid line) shows all the essential features including the EXAFS oscillations at the high energy side [24].

4. Disentanglement of E1 and E2 Contributions to XMCD

Usually, the near edge structure of the L_3 and L_2 absorption spectra – XANES and spin resolved XMCD – is discussed in terms of transitions from initial $p_{3/2}$ and $p_{1/2}$ states to final d states. It is clear that there are also transition probabilities to final *s* states which are usually assumed to be small. For heavy elements in reality it is even more complicated. Besides the dipole transitions E1 there exists also a finite probability for quadrupolar transitions E2. For example for the Rare Earth elements this would lead to final f states which mostly carry the magnetic information. This allows to determine in one experiment a shell-selective measurement of the magnetism in the 4f and in the 5d shell at the same time. In a real experiment both effects are superimposed and this may lead to a questionable interpretation if, for example, the area under the XMCD signal is taken as a measure of the magnetization. One way to disentangle this is to measure the different angular dependencies of E1 and E2 transitions. This was used in the early experiments by the french groups [22, 23]. In our days, using third generation synchrotron facilities and elliptical undulator beamlines as the ID 12 at the ESRF, it is possible to record experimental XMCD spectra of Rare Earth elements at the $L_{3,2}$ edges free of noise with a variety of spectral fine structures. An example is given in Fig. 3 taken from a Tb single crystal. The solid line shows oscillatory plus and minus intensities at the L_3 and L_2 edges as well as small oscillatory EXAFS wiggles. For such a spectrum it would be nice to separate in one experimental spectral recording the E2 from the E1 intensities. This is the great advantage of theory. Here one can calculate only the transition probability for E1, E2 only, and E1 + E2. Similar to the separation of single and multiple scattering in theoretical calculations, we are now able to switch on/off the various types of multipole transitions. This has been performed with the help of the UW

theory group and the most advanced FEFF version (FEFF8.2). Fig. 3 shows very nicely that the dipolar E1 simulation repeats the experimental spectra at the L_3 and L_2 edge including the small oscillatory feature at the high energy side. The theory explains also the double peak at the L_2 edge (main negative peak). It is caused by a spin-resolved fine structure in the final d states. The same is present at the positive peak of the L_3 edge but the splitting is smaller and it is neither resolved in theory nor in experiment [24]. The quadrupolar intensity appears at the L_3 edge, at lower energies as it is expected from a simple atomic picture: $2p \rightarrow 4f$ transitions have lower energy than $2p \rightarrow 5d$ transitions. This example demonstrates that the hand in hand work of advanced theory and experiments serves for a better understanding of the XMCD fine structure and consequently of fine details of the 4f and 5d magnetism.

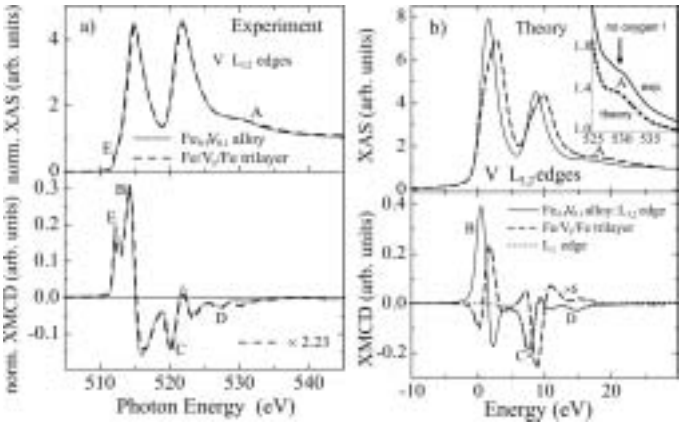

Fig. 4. Induced magnetism in vanadium at an Fe/V/Fe interface. (a) Experimental XAS and XMCD signals and (b) corresponding calculated $\mu(E)$ and $\mu^+(E) - \mu^-(E)$. The experiments show a detailed XMCD fine structure which is very much reproduced by the theoretical calculation (b – lower part). Note that in theory one is able to calculate only the L_2 signal (dotted line). The deviations in the XAS spectra between theory and experiment (branching ratio) is due to the fact that the theory did not take into account core hole correlation effects [25].

5. XMCD Beyond Sum Rules

The analysis of XMCD spectra at the L_3 and L_2 edges made an enormous progress by the so-called *sum rules*. In an atomic localized picture the integral sum rules relate the area under the L_3 XMCD and L_2 XMCD to the orbital and the spin moments. Numerous experimental groups have used these rules to determine separately μ_S and μ_L or even more sophisticated to investigate the anisotropy of the orbital moment $\Delta\mu_L$. This anisotropy of the non-spherical charge distribution is the main origin for the intrinsic magnetic anisotropy energy. (In an itinerant picture it corresponds to the difference in the band energy.) The community is well aware that these integral sum rules have certain limitations: Where does the L_3 edge stop and the L_2 edge start? Is there a dichroic response not originating from the $2p \rightarrow 3d$ transition but rather from some 4s polarization (diffuse magnetism)? How much does the core hole at the L_3 edge influence the L_2 edge (branching ratio)? As one can see in Fig. 3, there is a very detailed fine structure of the spin-dependent 5d band. Giving all credit to the pioneering success of the application of sum rules, we advocate very strongly to calculate and analyze the full spin-dependent spectral distribution. We know from other spectroscopy techniques that in addition to the integral intensity the line width and the line shape, i.e. the full spectral function of $\Delta\mu(E)$, include more specific information. One example is given for the induced vanadium magnetism at an Fe/V interface [25]. Already the integrated XANES spectrum of V $L_{3,2}$ edges at 515 eV – 525 eV shows interesting features. If one scans to higher photon energy up to 540 eV crossing the K edge of oxygen (532 eV) a small bump is seen in the experiment. At first glance one assumes that this stems from some oxygen contamination. Only the theory with the full band structure calculation could clarify that this is due to a van Hove singularity at the N point of the bcc Brillouin zone [25]. In the same work the dichroic spectrum was measured and calculated. Since the spin-orbit splitting between L_3 and L_2 decreases towards the early 3d elements, it is almost impossible in the experiment to separate the contributions of the two edges. Again, only the theory allows to calculate separately the XMCD L_2 edge only and compare it with experimental spectra. This path of analysis has been extended to other early 3d elements (Ti, Cr) [21]. We mention another approach to go beyond the sum rules: In [26] a multipole moment analysis is advertised to take care of the spectral changes. Expansion to first, second, third moment take care of the center of gravity, the width and asymmetry of the spectra. Such an approach is well known in the EXAFS commuity with cumulant expansion taking into account all details of the pair distribution function. Another step beyond simple application of sum rules is to take care of the dynamic screening of the core hole. In XAS the relative intensity of L_3 and L_2 signal change dramatically, e.g. the theory in Fig. 4 did not take into consideration core hole effects and therefore the experimental branching ratio differs very much from Fig. 4b). On the other hand the spin-resolved electronic structure as seen in XMCD shows rather detailed spectral features and seems to be much more sensitive to small changes in the local structure. Core hole effects have been addressed again recently in Refs. [27] and [28]. In conclusion, it seems that we have just opened the door to enter the field of XMCD spectroscopy and that many important details need to be discovered and clarified.

6. Conclusion and Future

The research in magnetism using circular and linear polarized synchrotron radiation in the soft and hard X-ray regime is very vital. With the advanced experimental possibilities new questions are addressed but also long standing problems to interpret magnetism have been reactivated. In the early days magnetism was usually discussed and interpreted in the language of thermodynamics calculating the free energy and its derivatives. Nowadays it is possible in theory as well as in experiment to discuss magnetism on an atomic scale. Magnetism is only a relativistic correction in electrodynamics. Depending on the observable neither s nor ℓ but only j is a good quantum number. These advanced theoretical treatments have become possible very recently and have an important impact on the interpretation and analysis of XMCD experiments. First attempts are made to calculate the full absorption cross section $\mu(E)$ also spin-dependendly and compare the results with experimental spectra. Experiments at the advanced light sources with much higher flux and brilliance yield spectra free of noise with detailed fine structure even for small induced magnetism in nonmagnetic materials. Undulator beamlines with a gap-scan technique provide a constant high degree of polarization over a large energy range which is important for recording $(\mu^+ - \mu^-)$ spectra. Having brilliant experimental spectra, it seems to us insufficient to analyze only the integral intensity. It will become much more advisable to analyze in detail the fine structure as it is usually done

in other spectroscopical techniques. Element specific magnetic microscopy and time-resolution down to femtoseconds open new experimental and theoretical possibilities.

Further work needs to be done to incorporate in the analysis the full spin and energy dependence of transition matrix elements in XAS and XMCD [29]. The well known core hole effects in the absorption spectra need to be included in the analysis. Finally, one needs to compare the magnetic quantities determined by XMD with other well established magnetization measurements. It is still an open question why magnetic anisotropy energy and/or the anisotropy of the orbital moments $\Delta\mu_L$ in recently published results are in most cases by more than an order of magnitude larger than taken from standard magnetic measurements.

Acknowledgments

This work has been performed in collaboration with C. Sorg, A. Scherz and H. Wende. We thank in particular C. Sorg for preparation of this manuscript. Ongoing discussions with the theory groups of K. H. Bennemann, H. Ebert, O. Eriksson, J. J. Rehr, D. L. Mills, W. Nolting, P. Weinberger, and R. Wu are acknowledged. The work is supported by BMBF (05KS1 KEB4) and DFG, Sfb 290.

Abstract

X-ray Optical Activity (XOA) is caused mainly by *E1E2* interference terms in systems with *odd* space Parity (P). Extra emphasis is put below on *nonreciprocal* XOA effects in Magneto-Electric (ME) solids in which both Parity and Time-reversal (Θ) symmetries are broken whereas the magnetic structure remains invariant in the product $P\Theta$. Two types of dichroism related to non-reciprocal XOA have been observed experimentally: (*i*) The X-ray Magnetochiral dichroism (XMχD) detected in the antiferromagnetic (AFM) phase of Cr_2O_3 is associated with the (unpolarized) Stokes component S_0; (*ii*) A *non-reciprocal* X-ray Magnetic Linear Dichroism (XMLD) was also observed in the low temperature AFM phase a $(V_{1-x}Cr_x)_2O_3$ single crystal and is associated with the Stokes components S_1 or S_2. Edge selective XOA sum rules were derived recently which give a unique access to a whole family of spherical ME operators mixing orbitals of different parities in what is assumed to be the ground state. It is proved that the *orbital anapole* moment $\Omega_0^{(1)}$ is primarily responsible for the XMχD signal measured both with a single crystal or a powdered sample of Cr_2O_3. It is suggested that the non-reciprocal XOA in both Cr_2O_3 and $(V_{1-x}Cr_x)_2$ O_3 is due to partially unquenched angular moments that had a different quantization axis from the spins.

1. Introduction

Unlike magneto-optical effects such as Faraday Rotation or Magnetic Circular Dichroism which refer to pure electric dipole ($E1E1$) or pure electric quadrupole ($E2E2$) transitions, Optical Activity (OA) is associated with transition probabilities mixing multipole moments of opposite parity (*e.g.* $E1M1$ or $E1E2$). The Curie principle states that OA can be observed only in *parity non-conserving systems*. OA related properties which are *even* with respect to the time-reversal operator Θ are commonly called "*natural*"; those which are *odd* with respect to Θ are referred to as "*non-reciprocal*". We have shown elsewhere [1] how to transpose for X-rays the theories of OA at optical wavelengths. Following Buckingham [2] and Barron [3], we found most convenient to introduce a complex *gyration tensor*: $\zeta_{\alpha\beta\gamma} = \zeta'_{\alpha\beta\gamma} - i\zeta''_{\alpha\beta\gamma}$. Since in deep core level spectroscopies, magnetic dipole transitions ($M1$) are very weak [4], it seems legitimate to neglect hereafter the $E1M1$ terms. Under such conditions, one is left with:

$$\zeta'_{\alpha\beta\gamma} = \mathrm{Im}\{E1_\alpha E2_{\beta\gamma}\} + \mathrm{Im}\{E1_\beta E2_{\alpha\gamma}\},$$
$$\zeta''_{\alpha\beta\gamma} = \mathrm{Re}\{E1_\alpha E2_{\beta\gamma}\} - \mathrm{Re}\{E1_\beta E2_{\alpha\gamma}\}. \quad (1)$$

The imaginary part (ζ'') is antisymmetric with respect to inter change of the α,β subscripts but also time-reversal *even*: it is therefore responsible for *natural* XOA. In contrast, the real part (ζ') is symmetrical but also time-reversal *odd* [3]: it is responsible for the *non-reciprocal* effects considered in this paper.

Every Stokes component S_j is associated with a well identified dichroism related to XOA [5, 6, 7, 8, 9, 10, 11, 12]:

- The X-ray magnetochiral dichroism:

  $XM_\chi D(S_0) \propto [\zeta'_{\beta\beta\gamma} + \zeta'_{\alpha\alpha\gamma}]$.
- The non-reciprocal X-ray magnetic linear dichroism:

  $XMLD(S_1) \propto [\zeta'_{\beta\beta\gamma} - \zeta'_{\alpha\alpha\gamma}]$.
- The non-reciprocal, *Jones* X-ray linear dichroism:

  $XMLD(S_2) \propto 2\zeta'_{\alpha\beta\gamma}$.
- The X-ray natural circular dichroism:

  $XNCD(S_3) \propto 2\zeta''_{\alpha\beta\gamma}$.

In the present paper, extra emphasis is put on the detection and the interpretation of non-reciprocal dichroisms measured in Magneto-Electric (ME) materials. ME solids appear as good candidates for detecting non-reciprocal OA effects because, as pointed out by Dzyaloshinskii [14], the ME tensor is *odd* with respect to both parity (P) and time-reversal (Θ) but it is left invariant in the product $P\Theta$. We will review in section 2 the experimental configuration used for such experiments. The cases of two antiferromagnetic crystals, *i.e.* chromium sesquioxide (Cr_2O_3) and a chromium doped vanadium sesquioxide $(V_{1-x}Cr_x)_2O_3$, were retained in order to illustrate the corresponding non-reciprocal dichroisms.

In section 3, we wish to draw attention onto the edge-selective XOA sum rules which were derived recently by Carra *et al.* [15]. There sum rules give access to a whole family of four spherical operators which mix orbitals of different parities in what is assumed to be the true ground state. In particular, it will be shown that XMχD spectra give a unique access to the projection of the *orbital anapole* moment $\boldsymbol{\Omega}_0^{(1)}$ along the direction of the wavevector $\boldsymbol{k}$. Finally, we will discuss briefly the physical implications of this result.

2. Non-reciprocal XOA: experimental evidence

2.1. *Experimental configuration*

The experiments reported below were carried out at the ESRF beamline ID 12 [16, 17]. The concept of the beamline is sketched in figure 1. Three helical undulators are available to cover the energy range 2–15 keV. They were optimized to deliver intense beams of circularly polarized X-ray photons with the capability to flip rapidly the polarization from left (L) to right (R). All spectra are systematically recorded in the total fluorescence yield mode using low noise PNN$^+$ photodiodes as detectors. The backscattering geometry makes it possible: (*i*) to set the optical

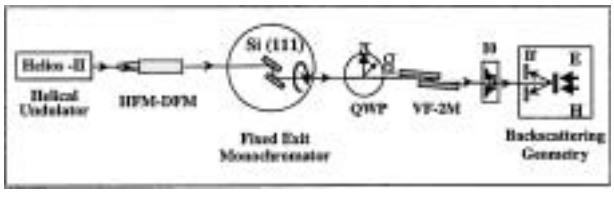

Fig. 1. ESRF beamline ID12 block diagram. Abbreviations: HFM-DFM = horizontally focusing and deflecting mirrors; QWP = quarter-wave plate; VF-2M = vertically focusing double mirror; I0 = photodiode intensity monitor.

axis of the crystal colinear with the wavevector $\boldsymbol{k}$ of the incident X-ray photons; (*ii*) to rotate the crystal around the direction of $\boldsymbol{k}$. The sample was inserted inside a cryomagnet so that both a magnetic field ($\boldsymbol{H}$) and an electric field ($\boldsymbol{E}$) parallel to $\boldsymbol{k}$ can be applied simultaneously for ME annealing. Using circularly polarized X-ray photons, two types of differential fluorescence signals (F) can be measured:

$$XNCD = F(I_0^L) - F(I_0^R)$$
$$XM\chi D = [F(I_0^L, H\uparrow) + F(I_0^R, H\uparrow)] - [F(I_0^L, H\downarrow) + F(I_0^R, H\downarrow)]. \quad (2)$$

The first one is the X-ray Natural Circular Dichroism, and the second, that is characteristic of an *unpolarized beam* is the non-reciprocal X-ray magnetochiral dichroism which we are looking for. Inserting a diamond quarter-wave plate (QWP) downstream with respect to the monochromator allows us to record two non-reciprocal linear dichroisms:

$$XMLD(S_1) = [F(I_0^{90^\circ}, H\uparrow) - F(I_0^{0^\circ}, H\uparrow)],$$
$$XMLD(S_2) = [F(I_0^{135^\circ}, H\uparrow) - F(I_0^{45^\circ}, H\uparrow)]. \quad (3)$$

The non-reciprocal character of these dichroisms implies that their sign should change whenever the direction of the magnetic field is inverted: this makes a fundamental difference with the time-reversal *even* X-ray magneto-optical linear dichroism first observed by Van der Laan *et al*. [18] in the soft X-ray range.

2.2. *Magnetochiral dichroism in eskolaite*

The generic example of ME solids is chromium sesquioxide (Cr_2O_3) also known in mineralogy as *eskolaite*. Below the Néel temperature ($T_N \approx 310$ K), the spin moments at the Cr sites order in either one of the two AFM domains shown in figure 2 and which

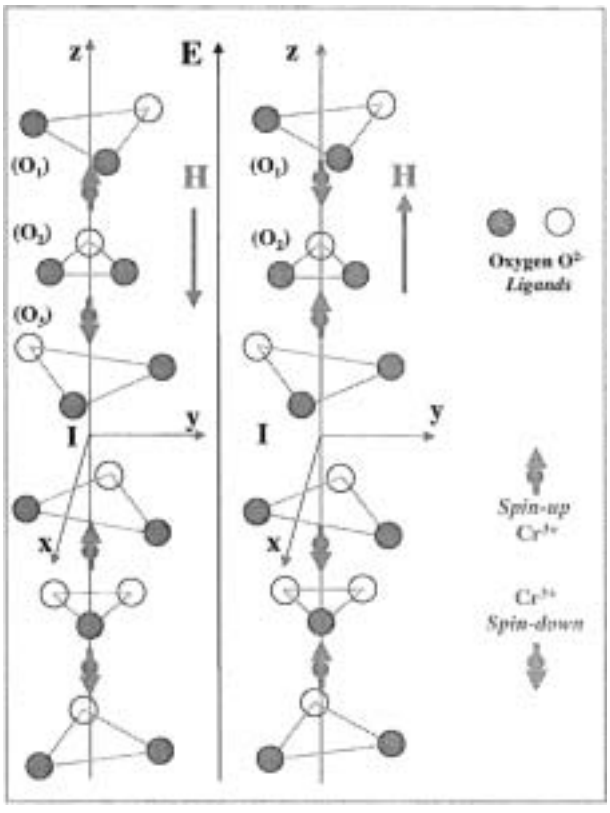

Fig. 2. Schematic representation of the two 180° antiferromagnetic domains of Cr_2O_3 grown by magnetoelectric annealing with antiparallel and parallel electric and magnetic fields.

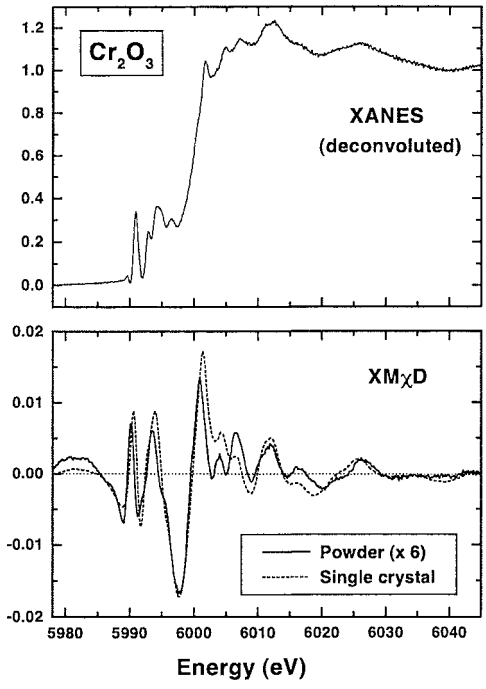

Fig. 3. Cr K-edge XMχD spectra of Cr_2O_3 recorded with either a single crystal ($\boldsymbol{c} \,||\, \boldsymbol{k}$) or with a powdered sample. The differential signal refers to the 180° domains of Fig. 2. The upper trace is the deconvoluted XANES spectrum.

transform into each other by time reversal symmetry. As far as one considers **only** the spin moments, the *space-time* group $\bar{3}'m'$ is well known to be ME [19] and one would easily check that, for each domain, the metal sites are left invariant in the product $P\Theta$ [14]. Recall, however, that no ME susceptibility nor any XMχD signal can be measured in equidomain states: ME *annealing* is required to create a remanent ME state with a net excess of one ME domain with respect to the other. This can be achieved by heating first the crystal in its paramagnetic state far above T_N: a modest electric field $\boldsymbol{E}$ (5 kV.cm^{-1}) plus a weak magnetic field $\boldsymbol{H}$ ($\pm$0.5 T) are then applied along the c axis before cooling the crystal slowly down below T_N [20]. Depending on whether $\boldsymbol{E}$ and $\boldsymbol{H}$ are parallel or antiparallel, the ME free energy is different and a single domain of well defined sign will grow [21].

The Cr K-edge XMχD spectra displayed in figure 3 were obtained by growing successively the two ME domains of figure 2 using either parallel or antiparallel $\boldsymbol{E}$, $\boldsymbol{H}$ fields in the annealing process. This first experiment [7] has been reproduced several times using different azimuthal orientations of the Cr_2O_3 (001) single crystal. We also proved that it was feasible to investigate with a focused beam the XMχD response to multiple domain inversions using only one single scan but our experimental configuration was not suitable to determine the size of the macroscopic ME domains. However, we perfectly succeeded in recording the magnetochiral dichroism using a powdered sample of chromium sesquioxide: as illustrated by figure 3, the XMχD spectra recorded with a single crystal or the powdered sample only differ by a 1 : 6 scaling factor.

2.3. *Non-reciprocal XMLD in* $(V_{1-x}Cr_x)_2O_3$

The magnetic structure of chromium doped vanadium sesquioxides $(V_{1-x}Cr_x)_2O_3$ in their low temperature antiferromagnetic *insulating* (AFI) phase is more controversial. The starting point of our work is a neutron diffraction study carried out on pure V_2O_3 (also known in mineralogy as the karelianite). Word *et al*. [22, 23]

confirmed the distorted, centrosymmetric $I2/a$ symmetry of the AFI phase and established that the vanadium atoms should carry a magnetic moment of *ca.* $1.2\,\mu_B$ tilted away from the trigonal **c** axis by 71° and perpendicular to the a axis. The observation of a forbidden reflection for $\ell = 6h + 3$ led them to conclude that the space-time group was not $2/m \otimes \Theta$ but rather a low symmetry group A2. They tentatively explained the symmetry reduction by a small magnetic contribution of the oxygen lattice. Interestingly, it was first considered by Moon, in an earlier paper [24], that *orbital moments* could result in a reduction of symmetry. Yethiraj [25] again admitted that a reduction of the magnetic symmetry could perfectly well be envisaged. The important point here is that the group A2 is inherently ME and should be compatible with the observation of non-reciprocal XMLD. A difficulty arises from the fact that the group A2 is not a subgroup of $2/m \otimes \Theta$ but Carra *et al.* [15] pointed out that the subgroup $2/m'$ would as well be compatible with the X-ray diffraction data: it can be shown that this group would have strictly the same generic ME tensor as the magnetic group A2 [5, 19].

The V K-edge non-reciprocal XMLD spectra [8] reproduced in figure 4 seem to support nicely the interpretation first proposed by Word *et al.* [22, 23]. For our experiments, we used a chromium doped crystal ($x = 0.028$) which is not prone to self-destruction at the phase transition ($T_N = 181$ K). It was realized recently that our crystal was miscut so that the c axis was tilted away from $\boldsymbol{k}$ by *ca.* 10°. Unfortunately, the orientations of the crystallographic axes **a** and **b** were unspecified in this first experiment so that we ignore whether we measured XMLD (S_1) or XMLD (S_2). Anyhow, let us note that the non-reciprocal XMLD signal measured in $(V_{1-x}Cr_x)_2O_3$ and the non-reciprocal XMχD signal in Cr_2O_3 are nearly of the same order of magnitude. One should not confuse the *non-reciprocal* dichroisms of figure 4 with a *reciprocal* XMLD signal of the van der Laan type. Recall that the reciprocal XMLD is expected to be very small at a K-edge: recently we have shown that, in the case of a ferrimagnetic YIG single crystal, it was only of the order of $2.5 \cdot 10^{-4}$ at the iron K-edge.

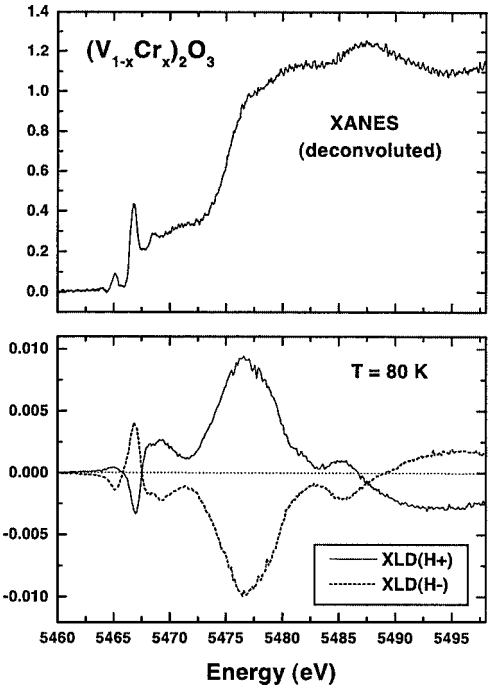

Fig. 4. V K-edge non-reciprocal XMLD spectra recorded with a single crystal of $(V_{1-x}Cr_x)_2O_3$ in the low temperature, antiferromagnetic, insulating phase. The differential signal refers to domains grown under the conditions of time-reversality. The upper trace is again the deconvoluted XANES spectrum.

Recently, Di Matteo and Jansen [26] reported that they failed to measure any ME susceptibility with the same crystal. We already argued elsewhere [5] that the use of a *static* field method was highly questionable to measure a ME susceptibility in a crystal exhibiting high conductivity losses: this might well explain the reported negative result. In contrast, apart from the ME annealing that can be achieved in several ways, XOA measurements are intrinsically insensitive to conductivity losses. Furthermore, it should be emphasized that ME susceptibility measurements and XOA do not probe the same properties of matter: non-reciprocal XOA probes only the *orbital* contribution to the total ME tensor, whereas all ME susceptibility measurements reported so far refer to *only* the spin part of the ME tensor. In the case of Cr_2O_3, our XMχD spectra tend precisely to show that the orbital contribution is much too small to be detected by macroscopic ME susceptibility measurements [5].

3. XOA Sum-Rules: first application

3.1. *Effective operators of XOA*

In 1992, Thole *et al.* [27] established a useful sum rule for X-ray magnetic circular dichroism (XMCD): it states that the integrated dichroic signal should be proportional to $\langle L_z \rangle$, *i.e.* to the ground state expectation value of the projection along the quantification axis of the angular momentum operator acting on the electronic shell accepting the excited photoelectron. In 1998, Natoli *et al.* [13] established a similar sum rule for XNCD:

$$\Sigma_{E1E2} = \int_{\Delta E} \frac{\sigma_{E1E2}(E)}{E^2}\,\mathrm{d}E \propto \langle \psi_g | \mathbf{N}^{(2)}(\ell, \ell') | \psi_g \rangle \tag{4}$$

where σ_{E1E2} denotes the X-ray absorption cross section due to the $E1E2$ interference terms in a finite energy range ΔE which should include, whenever this is relevant, the two partners (j_+, j_-) of a spin-orbit split edge. On the right handside, ℓ still refers to the final angular momentum of the electric dipole ($E1$) transition whereas ℓ' refers to the electric quadrupole transition ($E2$) and should satisfy the selection rule: $\ell' = \ell_c \pm 0, 2$, excluding $\ell' = \ell_c = 0$. Obviously, ℓ and ℓ' have opposite parity and the operator $\mathbf{N}^{(2)}(\ell, \ell')$ probes the mixing of atomic orbitals of the corresponding parity. The problem with eqn. (4) was that no clear physical meaning was given to the rank-2, spherical tensor $\mathbf{N}^{(2)}$.

Regarding eqn. (4), there is a serious limitation underlined by Di Matteo and Natoli [28]. Due to the core hole perturbation, $|\psi_g\rangle$ is merely a *pseudo* ground state. If we expand $|\psi_g\rangle$ in terms of *stationary* states $|\Psi_n\rangle$, the quantity which is obtained is actually:

$$\langle \psi_g | \mathbf{O}^{(q)} | \psi_g \rangle = \sum_{n,n'} \alpha_n^* \alpha_{n'} \langle \Psi_n | \mathbf{O}^{(b)} | \Psi_{n'} \rangle \tag{5}$$

where $\mathbf{O}^{(b)}$ is the pertinent parity mixing effective operator. As yet, there is no proof that the sum over all configurations will cancel the effects of the core hole and restore the property of a *true* ground state. Note that cross terms ($n \neq n'$) could contribute as well: typically, in the case of *XMCD* where $\mathbf{O}^{(1)} = L_z$, the matrix elements on the right handside of eqn. (5) are those of the Van Vleck paramagnetism.

In order to extend eq. (4) to all $E1E2$ dichroisms, it is most convenient to rewrite Σ_{E1E2} as:

$$\Sigma_{E1E2} = \sum_{b=1}^{3} \sum_{\beta=-b}^{b} \sum_{\theta=\pm 1} (-1)^{\beta} \mathbf{T}_{\beta}^{(b,\theta)} \boldsymbol{\Sigma}_{-\beta}^{(b,\theta)} \tag{6}$$

where $\boldsymbol{\Sigma}^{(b,\theta)}_{-\beta}$ are rank-b spherical tensors which characterize parity non conserving systems, whereas the spherical tensors $\mathbf{T}^{(b,\theta)}_{\beta} = [\hat{\epsilon}^*, [\hat{\epsilon}, \hat{k}]^{(2)}]^{(b)}_{\beta}$ characterize the polarization states of the X-ray photons and are split into their time-reversal even ($\theta = 1$) or time-reversal odd ($\theta = -1$) parts.

Carra *et al*. [15] established that all operators $\boldsymbol{\Sigma}^{(b,\theta)}$ can be built from the triad of mutually orthogonal vector operators:

1. $\boldsymbol{n} = \boldsymbol{r}/r$ which is a time-reversal *even*, polar vector typically associated with the electric dipole moment.
2. $\boldsymbol{L}$ which is the time-reversal *odd*, axial vector of the orbital angular momentum.
3. $\boldsymbol{\Omega} = [(\boldsymbol{n} \times \boldsymbol{L}) - (\boldsymbol{L} \times \boldsymbol{n})]/2$ which is a *toroidal* vector that is odd with respect to both P and Θ.

Clearly $\boldsymbol{\Omega}$ is to be identified with the *orbital anapole* moment as defined in textbooks [29]. Up to four spherical operators are required for a full description of XOA:

- The projection of the *orbital anapole* moment $\boldsymbol{\Omega}^{(1,-1)}_0$ along the direction of the wavevector $\boldsymbol{k}$ appears in the XMχD sum rule.
- The Θ-odd *pseudodeviator* $\boldsymbol{W}^{(2,-1)} = [\boldsymbol{L}, \boldsymbol{n}]^{(2,-1)}$ appears in the non-reciprocal XMLD sum-rules.
- The Θ-even *pseudodeviator* $\mathbf{N}^{(2,+1)} = [\boldsymbol{L}, \boldsymbol{\Omega}]^{(2,+1)}$ appears in the XNCD sum rule.
- The Θ-odd *septor* $\boldsymbol{\Gamma}^{(3,-1)} = [[\boldsymbol{L}, \boldsymbol{L}]^{(2)}, \boldsymbol{\Omega}^{(1)}]^{(3,-1)}$ will contribute as higher order terms to all non-reciprocal XOA sum rules.

3.2. *Orbital Anapole moment in eskolaite*

In the simplest case of magnetochiral dichroism XMχD (S_0), the sum rule reads:

$$\Sigma_{E1E2} = \frac{-2\pi^2\alpha}{\hbar c}(2\ell_c + 1)\sum_{\ell,\ell'} R^{(1)}_{\ell} R^{(2)}_{\ell'} \times \{\tfrac{2}{5} a^{(1,-1)}(\ell_c, \ell, \ell')\langle \Omega^{(1,-1)}_0(\ell, \ell')\rangle - \tfrac{16}{\sqrt{10}} b^{(3,-1)}(\ell_c, \ell, \ell')\langle \boldsymbol{\Gamma}^{(3,-1)}_0(\ell, \ell')\rangle\} \quad (7)$$

where $a^{(1,-1)}$ and $b^{(3,-1)}$ are basically numerical factors that are tabulated elsewhere [5, 15]. In eqn. (7), $R^{(1)}_{\ell}$ and $R^{(2)}_{\ell'}$ are the radial dipole and quadrupole integrals which need to be calculated numerically: this was done in the case of Cr_2O_3 using the FDMNES code (MSW option) of Y. Joly [30].

Recently, Di Matteo and Natoli [31] claimed that the largest contribution should come from the (octupolar) septor term $\boldsymbol{\Gamma}^{(3,-1)}_0$. This is however contradicted by our experiment carried on the powdered sample and illustrated with figure 3. Recall that the nucleation of ME domains of opposite timereversality in a powder depends critically on the orientation of each cristallite: one may use precisely this angular dependence in order to check whether the relevant spherical operator $\mathbf{O}^{(b)}$ will average out as a vector or as a higher order septor [5]. Typically, in a powder: $\langle \mathbf{O}^{(b)}_{\beta}\rangle_{powder} = \delta_{\beta,0}\langle \mathbf{O}^{(b)}_0\rangle_{crystal} I_{(b)}$ where $I_{(b)}$ is an integral taken over all orientations of a cristallite. This integral has already been calculated analytically by O'Dell [32] for a rank-2 tensor ($b = 2$): we simply extended the same calculation for $b = 1, 3$. This led us to predict that the XMχD signal in the powdered sample should be reduced by the factor $I_{(1)} \approx 0.18$ if the effective operator is $\boldsymbol{\Omega}^{(1,-1)}_0$, whereas it should become hardly measurable if the effective operator was $\boldsymbol{\Gamma}^{(3,-1)}_0$ since $I_{(3)} \leq 0.05$. This is nicely supporting our interpretation that the XMχD sum rule may give us – at least – a raw estimation of the expectation value of the orbital anapole moment in Cr_2O_3 : $\langle \boldsymbol{\Omega}^{(1,-1)}_0\rangle \approx 0.03$ a.u. This is a rather small value compared to known spin anapoles [5].

4. Discussion

It is a prerequisite to detect XOA that at least one of the four spherical effective operators discussed in the previous section should be an irreducible representation of the space-time group of the crystal. We have indicated elsewhere which dichroic effect could be measured for every ME group [5]. A problem arises precisely in the case of Cr_2O_3 since the universally cited magnetic group compatible with neutron diffraction, *i.e*. $\bar{3}'m'$, does not admit $\boldsymbol{\Omega}^{(1,-1)}_0$ nor $\boldsymbol{\Gamma}^{(3,-1)}_0$ as irreducible representations. The detection of a XMχD signal thus implies that the magnetic symmetry should be lower than in figure 2.

Di Matteo and Natoli [31] suggested that the presence of a weak magnetic field ($\boldsymbol{H} = \pm 0.5\,\mathrm{T}$) during the experiment could have induced some metamagnetic transition. This seems unlikely since recent experiments have confirmed the absence of any detectable spin-flop domain below the critical field of 5.8 T. On the other hand the ferromagnetic group $3m'$ resulting from a metamagnetic transition would still be incompatible with the detection of a magnetochiral dichroism [5].

It is our view that two alternative interpretations deserve attention:

- The reduction of symmetry could be due to some partially unquenched angular momentum that had a different quantization axis from the spins [33].
- The deep core hole could induce some mixing of the true ground state with low-lying excited states, as in the Van Vleck paramagnetism.

Let us stress that the two ME domains illustrated by figure 2 take only into consideration the spin configuration: the magnetic group $\bar{3}'m'$ implicitly assumes that there is no orbital magnetism. Recall that Shirane *et al*. [34] admitted that neutron diffraction data could not disprove models with canting angles less than 3 degrees: this implies that orbital moments as large as 0.13 μ_B may not be seen. The existence of orbital magnetism in Cr_2O_3 has however been suspected since it was reported by Foner [35] that the parallel magnetic susceptibility of Cr_2O_3 did not drop to zero below 4 K: this was interpreted by Siverstein and Jacob [36] as resulting from a large (orbital) Van Vleck Paramagnetism.

Unrestricted Hartree-Fock calculations reported recently by Dovesi *et al*. [37] revealed that covalency effects were particularly important in eskolaite. These calculations also produced clear evidence of a local spin polarization of the oxygens around the chromium sites. Given that spin-orbit coupling should lower the ligand field symmetry, it seems pertectly realistic to expect a component of an orbital magnetic moment perpendicular to the **c** axis thus inducing a small canting of the total magnetic moments. Dovesi *et al*. explicitly noted that the magnetic symmetry should be reduced below the Néel temperature: interestingly, the group $3m$ which they proposed admits the anapole as irreducible representation. Unfortunately, the ME tensor of this group would have no diagonal elements: this is in contradiction with the known ME (spin) properties of Cr_2O_3. This led us to suggest that the only magnetic group that would reconcile our XMχD spectra with the ME (spin) properties of Cr_2O_3 is $\bar{3}'$: it would combine the off-diagonal elements of the ME tensor of the group $3m$ with the diagonal elements of the ME tensor of the group $\bar{3}'m'$ [5].

Similar considerations could be transposed to the case of V_2O_3 which also exhibits a strong Van Vleck paramagnetism [38]. Particularly relevant is a model proposed by Tanaka [39] according to which each V atom has an *orbital* magnetic moment of $\approx 0.7\,\mu_B$ slightly tilted away from the antiferromagnetic spin lattice, with the practical consequences that the $2/m \otimes \Theta$ symmetry should be broken and that the low temperature phase should become *orbitally* Magneto-Electric [15].

Abstract

This paper reviews our recent study on the improvement of time-resolved energy-dispersive X-ray absorption fine structure (DXAFS) and its application to *in situ* dynamic characterization for structural changes in nano-structures and catalysts, also presenting new data. The issue addressed in this paper is relevant to deeper understanding of catalytic intermediate structures, elementary steps, and reaction mechanisms.

1. Introduction

Molecular-level to nano-scale chemical design of active structures on robust oxide surfaces and crystalline porous supports with the aid of *in-situ* analysis by modern physical techniques as well as chemistry of definite precursors is crucial to create new nano-structures and efficient catalysts [1–4]. It may also be prerequisite for fulfillment of the precise design to understand the dynamic change of active structures *in situ* during preparation and reaction processes of nano-structures and catalytic materials.

Local structures of non-crystalline dispersed metal species have been extensively studied by X-ray Absorption Fine Structure (XAFS) because it does not require long range order of the metal species [1, 5–9]. Perhaps the most important attribute for XAFS to be applied to characterization of supported catalysts is *in situ* investigation of the working catalyst because X-rays are not interfered by the reaction gases present in the catalytic systems. However, it takes about ten to several ten minutes to measure an Extended X-ray Absorption Fine Structure (EXAFS) spectrum for dispersed metal species by conventional XAFS technique. So the conventional technique cannot monitor time-dependent structures during dynamic chemical processes.

Recently time-resolved energy-dispersive XAFS (DXAFS) has been much improved and applied to studies on dynamic structural changes of metal sites during chemical processes and catalytic reactions [10–31]. The aim of this paper is to find the time scale and sequence of bond rearrangements in supported nano-structures and catalysts, such as bond formation-breaking and bond elongation-shortening, which may be relevant to the mechanism, efficiency, and stability for the catalysis, by time-resolved energy-dispersive XAFS (DXAFS). Two examples $[Ru_6C]/MgO$ (time resolution of 1 s) and $[Rh]_x/Al_2O_3$ (time resolution of 100 ms) are discussed.

2. Experimental

DXAFS is a technique to measure a whole range of X-ray absorption spectra using a bent crystal and a position sensitive detector (1024 ch. photodiode arrays) as shown in Fig. 1. While it is necessary in conventional XAFS technique to mechanically rotate a monochromator to monochromatize white X-rays stemming from a synchrotron storage ring (Fig. 1(a)), there is no mechanical motion for monochromatizing X-rays in the DXAFS technique as shown in Fig. 1(b) and (c). When a sample is placed at the focusing point, the sample can absorb X-rays of the whole energy range simultaneously, so EXAFS spectra for dispersed nano-structures and catalysts can be measured in a time period shorter than 1 s. By using the DXAFS technique (Bragg case) the structural changes in the temperature programmed reduction of Cu/ZSM-5 and the temperature programmed decarbonylation of $Mo(CO)_6/YZ$ by DXAFS have been analyzed [21–24, 31].

DXAFS measurements were carried out on BL-9C at KEK-PF with a Si(311) polychromator [24]. DXAFS setups using three-point bent and four-point bent Si crystals are shown in Fig. 1(b) and (c). The source-to-crystal distance, the crystal-to-focus distance, the radius of curvature of the Si crystal, and the Bragg angle at the center of the crystal are 30 m, 0.385 nm, 4.5 m and 9.9 degrees, respectively for the three-point bending system, and 30 m, 0.35 m, 2.1 m and 9.4 degrees, respectively for the four-point bending system. The two systems were used for $[Ru_6C]/MgO$ and $[Rh]_x/Al_2O_3$, respectively. At first the three-point bent crystal system was also applied to the $[Rh]_x/Al_2O_3$ catalyst, but the DXAFS quality was not good enough for analysis. Therefore a four-point supporting crystal bender was recently developed for a Si(311) bent-crystal polychromator (Bragg-type) to achieve elliptical optics for focusing the incident X-rays at the sample. The energy calibration at each sensing element of the PDA was performed by comparison with an XAFS spectrum of a Ru foil or Rh foil recorded using a Si(311) channel-cut monochromator. The quality of the DXAFS data in the Bragg case was high enough in the analysis though there may be asymmetric reflectivity at the Ru and Rh K-edges [32]. The *in-situ* DXAFS cell was made of stainless steel and had two slit windows with capton films to measure the incident and transmitted X-rays.

EXAFS data were analyzed by the UWXAFS package [33]. After background subtraction using AUTOBK [34], k^3-weighted EXAFS functions were Fourier transformed into *R*-space and fitted in *R*-space. Backscattering amplitudes and phase shifts were calculated by the FEFF8.0 code [35]. The energy resolution of spectrometers (5 eV for Ru and 4 eV for Rh) was taken into account to calculate the parameters by using the EXCHANGE flag of an input file in the FEFF8.0 code. To analyze DXAFS data, Debye-Waller factors calculated from conventional EXAFS data measured at several temperatures were used.

3. Results and Discussion

3.1. *Structural kinetics of [Ru_6C]/MgO*

We reported the specific catalysis of [Ru_6C] clusters on MgO for CO conversion to oxygenated compounds such as methanol, dimethyl ether and formaldehyde as main products [36, 37]. This is in contrast to the catalysis of supported Ru particles, which produce methane as the main product under identical reaction conditions. We also observed a structural change of the cluster framework; namely when the [Ru_6C]/MgO species with Ru-Ru bond at 0.265 nm was exposed to CO/H_2 reaction gas at 523 K, the cluster framework expanded to the framework with the Ru-Ru bond at 0.271 nm, adsorbing 11 CO molecules per cluster. At low CO pressure carbonylated [$Ru_6C(CO)_{11}$]/MgO was transformed back to the original shrunk [Ru_6C] framework, desorbing CO, under which reaction conditions the reaction rate for the oxygenate synthesis was much lower than that on the expanded framework. The information on how and when the cluster structure changes upon CO adsorption/desorption will provide knowledge and understanding, at the molecular-level detail, of the origin of key factors and structural dynamics for catalysis. The following is the first study on the kinetics of reversible structural change in cluster framework at surfaces [31].

[Ru_6C]/MgO catalyst was prepared by supporting [$Ru_6C(CO)_{16}Me]^-$ cluster on MgO, followed by evacuation at 623 K as shown in Fig. 2 [36, 37]. The Ru loading was 4.0 wt%. Figure 3 shows a series of DXAFS oscillations (a) and associated Fourier transformed functions (b) at the Ru K-edge during the carbonylation of [Ru_6C]/MgO under CO/H_2 at 523 K. Each spectrum was measured with a time-resolution of 1 s. The structural parameters, coordination numbers (*CN*s) and bond distances (*Rs*), determined by curve-fitting in R space were plotted against the CO/H_2 exposure time at 423, 473, and 523 K in Fig. 4. The *CN*s of Ru-C-(O) and Ru-(C)-O for the carbonyl ligands were set to be the same value in the curve fitting analysis. The detailed analysis will be described in a separate paper [31, 38].

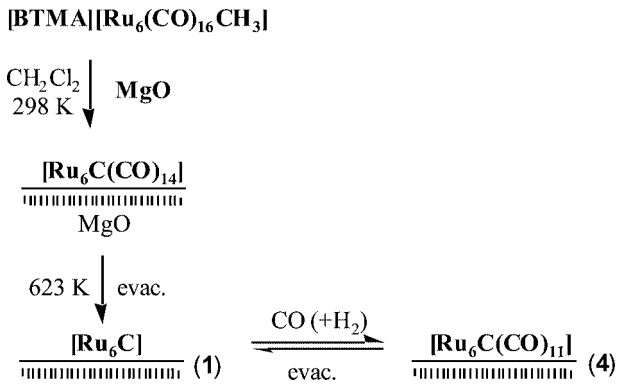

Fig. 2. Preparation steps for the $[Ru_6C]$/MgO catalyst and the reversible transformations between $[Ru_6C]$ (**1**) and $[Ru_6C(CO)_{11}]$ (**2**) on MgO.

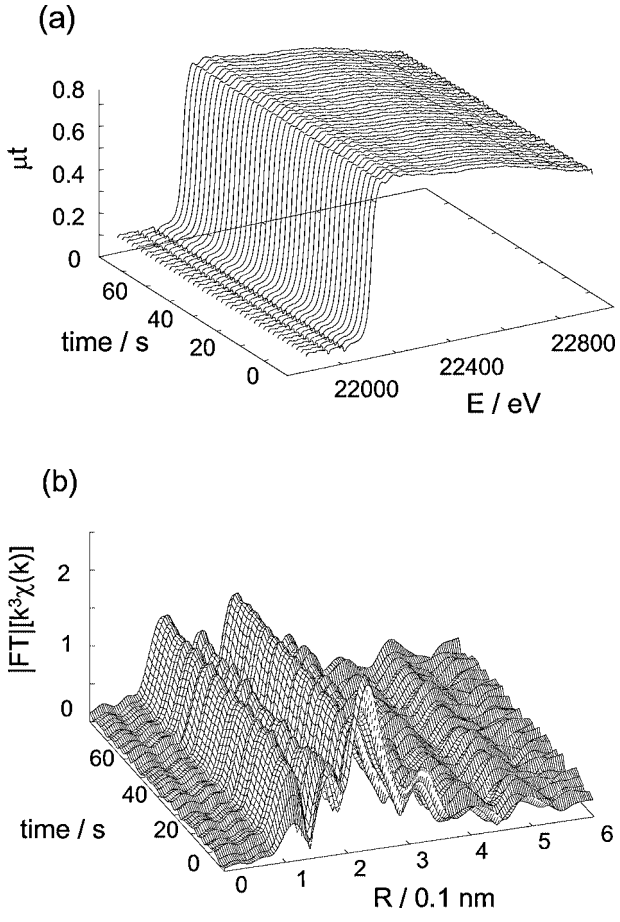

Fig. 3. (a) A series of DXAFS oscillations at Ru K-edge and (b) a series of their associated Fourier transformed functions during the carbonylation of $[Ru_6C]$/MgO under CO/H_2 at 523 K.

CN of Ru-CO increased from 0 to 0.7 for the first 2.1 s at 423 K, where *R* of Ru-Ru changed little. *CN* of Ru-CO increased to about half of the value at saturation after 4.2 s, but *R* of Ru-Ru did hardly change. After 4.2 s *R* rapidly increased to 0.269 nm and the bond expansion was completed in 10.4 s at 423 K. The rates of the carbonylation and the bond expansion were promoted by an increase in temperature. There was break at 4.2 s in the slope of the increase in *CN*, followed by a gentle slope over 35 s. It is obvious that the increase in *R* has a time lag from the CO adsorption. Both CN and R values increased further over 30 s. Thus it is reasonable that we postulate the existence of two intermediate structures $[Ru_6C(CO)_6]$ with Ru-Ru

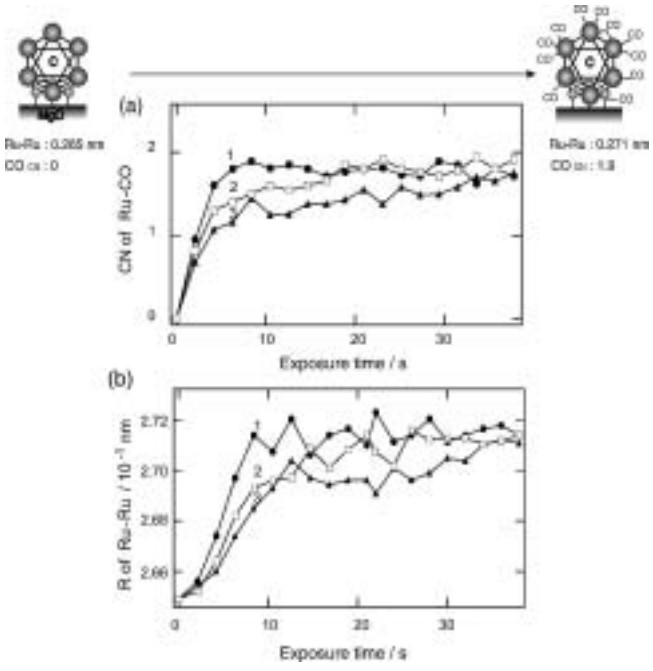

Fig. 4. The coordination numbers (*CN*s) of Ru-CO (a) and the bond distances (Rs) of Ru-Ru (b) as a function of the CO-exposure time in the carbonylation processes at 423 K (filled triangle), 473 K (open square), 523 K (filled circle).

distances of 0.265 nm and 0.269 nm during the CO adsorption on $[Ru_6C]$/MgO [31, 38]. The number of carbonyls per cluster was also estimated by CO adsorption experiments and FTIR spectra [38]. In the first step, six CO molecules adsorb on a $[Ru_6C]$ cluster and in the second step, following the CO adsorption, the cluster framework expands from 0.265 to 0.269 nm. After the formation of the second intermediate $[Ru_6C(CO)_6]$ with a Ru-Ru distance of 0.269 nm, CO molecules further adsorb on the cluster, and eventually the final cluster structure $[Ru_6C(CO)_{11}]$ with 11 CO ligands and Ru-Ru of 0.271 nm is formed. The rates of the structural transformations increased by increasing temperature, indicating thermally activated processes, by which the activation energies were calculated.

Figure 5 shows a series of DXAFS oscillations (a) and associated Fourier transformed functions (b) at the Ru K-edge during the decarbonylation of the carbonylated $[Ru_6C(CO)_{11}]$/MgO under vacuum at 573 K. Each spectrum was measured with a time-resolution of 2 s. The structural parameters determined by curve-fitting in *R* space were plotted against the evacuation time at 623 K and 573 K in Fig. 6. The error bars for *R* for Ru-Ru and *CN* for Ru-CO were ± 0.001 nm and ± 0.2–0.3, respectively. The decarbonylation process was slower than the carbonylation process. At 573 K, *R* changed slightly from 0.271 to 0.269 nm in 4 min, while *CN* of Ru-CO decreased to about half of the original value. *R* remained constant during 13 min, whereas *CN* decreased to zero after 11 min. After the complete CO desorption *R* of Ru-Ru decreased from 0.269 nm to 0.265 nm at 16 min. The stepwise feature of the decarbonylation was also observed at 623 K in Fig. 6. It is reasonable to postulate the existence of two intermediate structures $[Ru_6C(CO)_6]$ and $[Ru_6C]$ with Ru-Ru of 0.269 nm during the CO desorption from $[Ru_6C(CO)_{11}]$/MgO [31, 38]. The number of carbonyls per cluster in the slow decarbonylation process was confirmed by FTIR [38]. Consequently, in the first step the $[Ru_6C(CO)_{11}]$ cluster is partially decarbonylated and simultaneously the framework slightly shrinks. In the second step the CO completely desorbs, whereas the Ru-Ru bond length does

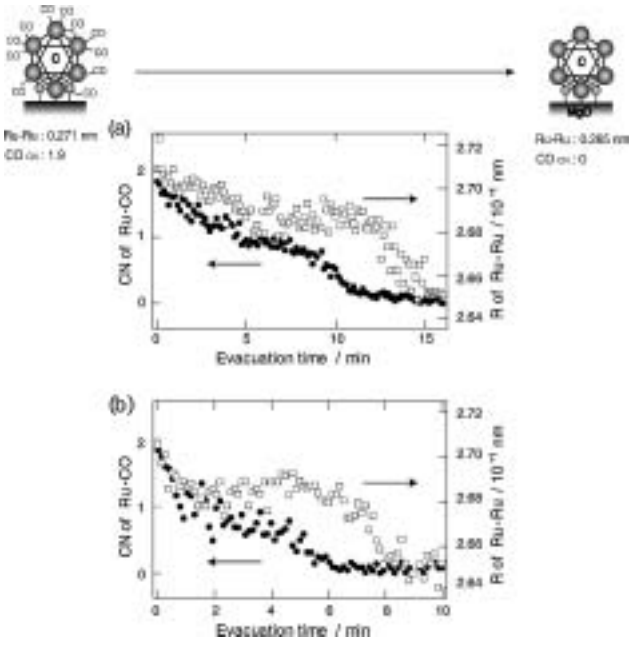

Fig. 6. The coordination numbers (CNs) of Ru-CO (filled circle) and the bond distances (Rs) of Ru-Ru (open square) during the decarbonylation processes at 573 K (a) and 623 K (b).

not change. After completion of the CO desorption, the cluster framework shrinks from 0.269 to 0.265 nm.

The structural changes in the carbonylation and decarbonylation processes are illustrated in Fig. 7, where the energy profile involving the activation energies for each step are also shown. The activation energy for the step from $[Ru_6C]$ (**1**)

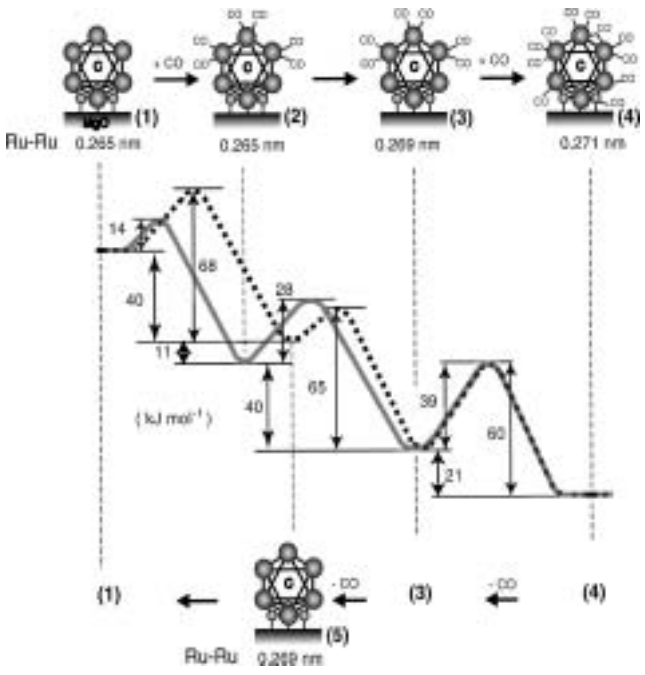

Fig. 7. The structural changes in the carbonylation and decarbonylation processes and the energy profile for the structural changes involving the activation energies.

(Ru-Ru : 0.265 nm) to $[Ru_6C(CO)_6]$ (**2**) (0.265 nm) was determined to be 14 kJ mol^{-1} by using the rates of the increase in *CN* of Ru-CO, while the activation energy for the step from $[Ru_6C(CO)_6]$ (**2**) (0.265 nm) to $[Ru_6C(CO)_6]$ (**3**) (0.269 nm) was determined to be 28 kJ mol^{-1} by using the rates of the increase in *R* of the Ru-Ru bond. The activation energy for the step from $[Ru_6C(CO)_6]$ (**3**) (0.269 nm) to $[Ru_6C(CO)_{11}]$ (**4**) (0.271 nm) was obtained by using the rates of the increases in *CN* and the *R*, independently. The values determined from *CN* and *R* were 41 and 38 kJ mol^{-1}, respectively, which agreed well with each other. The activation energies for the decarbonylation processes were also determined by the DXAFS analysis. The activation energy for the step from $[Ru_6C(CO)_{11}]$ (**4**) (0.271 nm) to $[Ru_6C(CO)_6]$ (**3**) (0.269 nm) was determined to be 59 and 62 kJ mol^{-1} from the rates of the decreases in *CN* of Ru-CO and *R* of Ru-Ru bond, respectively. The values agree with each other, indicating the validity of the values. The activation energy for the step from $[Ru_6C(CO)_6]$ (**3**) (0.269 nm) to $[Ru_6C]$ (**5**) (0.269 nm) was determined to be 65 kJ mol^{-1} from *CN*. The activation energy for the step from $[Ru_6C]$ (**5**) (0.269 nm) to $[Ru_6C]$ (**1**) (0.265 nm) was determined to be 68 kJ mol^{-1} from *R*. This sort of information on the kinetics of structural change in the cluster framework at the surface as the catalytically active site was obtained by the time-resolved DXAFS technique for the first time, which may open a new area of kinetics of active structures at catalyst surfaces [31, 38].

3.2. *Structural kinetics of* $[Rh]_x/Al_2O_3$

We have succeeded in observing the CO-induced disintegration process of Rh clusters on Al_2O_3 surface by DXAFS every 100 ms. The details of the time-resolved DXAFS study will be reported in a separate paper [39], but the results are summarized here. Previous static studies on a similar surface phenomena have been performed by IR [40–42], XAFS [43, 44], and STM [44, 45], which revealed the structural modification of highly dispersed Rh nanoparticles/Al_2O_3 catalysts leading to the formation of isolated $Rh(CO)_2$ species by CO adsorption.

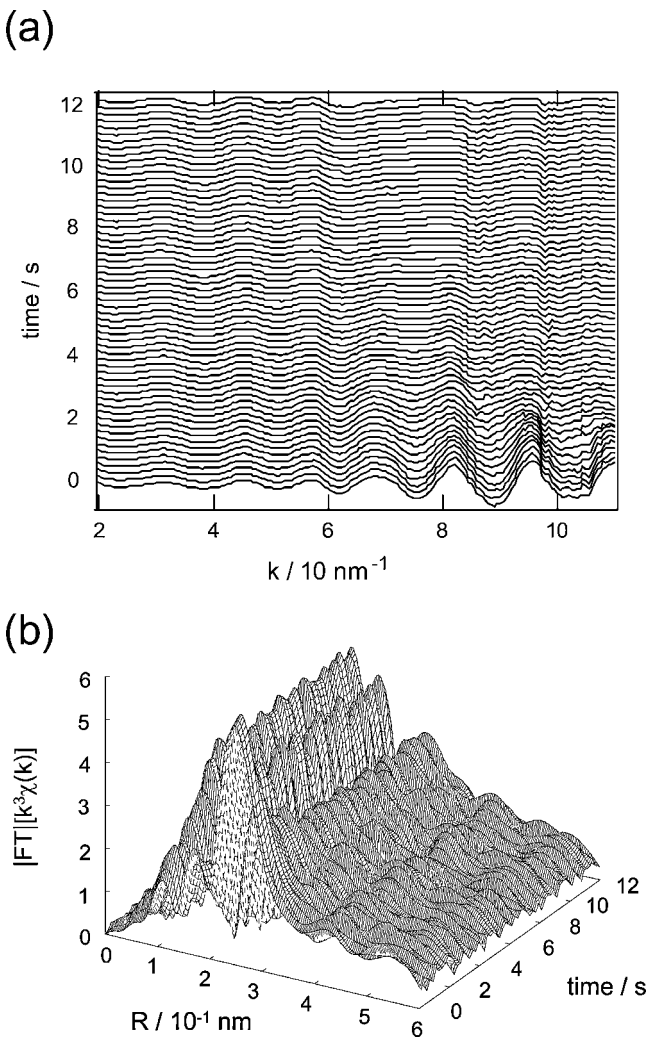

Fig. 8. A series of k^3-weighted DXAFS oscillations (a) and a series of their associated Fourier transformed functions (b) for Rh/Al_2O_3 at the Rh K-edge during the CO adsorption process at 298 K measured by DXAFS every 100 ms.

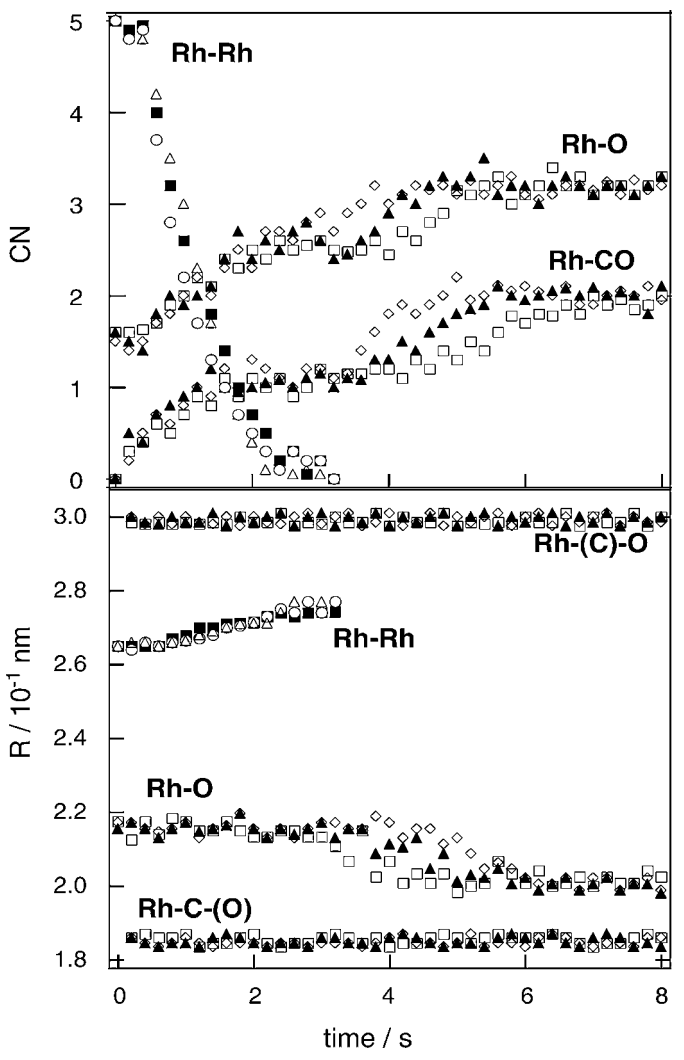

Fig. 9. The values of coordination numbers (*CN*) and bond distances (*R*) determined by the curve fitting as a function of CO exposure time at 298, 333, and 353 K. 298 K: Rh-Rh (filled sqaure); Rh-CO (open square); Rh-O (open square). 333 K: Rh-Rh (open triangle); Rh-CO (filled triange); Rh-O (filled triangle). 353 K: Rh-Rh (open circle); Rh-CO (open diamond); Rh-O (open diamond).

There were two isosbestic points at 23.234 keV and 23.239 keV in the serial XANES spectra at the Rh K-edge during the CO adsorption process of the Rh/Al_2O_3 catalyst under 26.7 kPa of CO at 298 K, indicating the existence of two intermediates in the process [39]. The k^3-weighted EXAFS oscillations at the Rh K-edge during the CO adsorption process and associated Fourier transformed functions are shown in Fig. 8. The amplitude of EXAFS oscillations did not change significantly at 0–600 ms, but a remarkable decrease in the amplitude in the higher k range was observed from 600 ms till 3000 ms (Fig. 8(a)). This corresponds to the first isosbestic point in the XNAES. A change in the EXAFS oscillations after 3 s corresponds to the second isosbestic point, which indicates that another structural change occurs as a sequential process during the period of 3–6 s (Fig. 8(a)).

At $t = 0$ two distinct peaks in the FT at 0.174 and 0.248 nm (phase-shift uncorrected) due to Rh-O and Rh-Rh, respectively, were observed as shown in Fig. 8(b). By the CO admission a FT peak due to Rh-C-(O) bond appeared at 0.123 nm (phase-shift uncorrected) within the first 200 ms, while the FT peaks for Rh-O and Rh-Rh remained unchanged over 600 ms. A drastic change in the FT occurred at 800–3000 ms, where the Rh-Rh peak completely dumped. The *CN* and *R* values determined by the curve fitting in R space were plotted as a function of CO exposure time at 298, 333, and 353 K in Fig. 9. There were no changes in the Rh-Rh and Rh-O bonds at 0–600 ms, but *CN* for Rh-CO increased from 0 to 0.7 at 600 ms. After 600 ms, the *CN* of Rh-Rh bond decreased monotonously during the period of 800-3000 ms, accompanied with elongation of *R* of Rh-Rh and an increase of *CN* for Rh-O from 1.6 to 2.5 at 3000 ms. The *CN* values for Rh-O and Rh-CO were almost constant at 2000–3000 ms, indicating the existence of a semistable structural state for CO-adsorbed Rh clusters on Al_2O_3. After 3000 ms the *CN*s increased from 2.5 to 3.2 and from 1.2 to 1.9, respectively as shown in Fig. 9, where *R* of Rh-O also decreased from 0.213 to 0.200 nm. The rate of changes at this step increased with increasing temperature. The details of structural parameters will be reported in a separate paper [39]. The change in the *CN* values for Rh-CO determined by DXAFS analysis was in excellent accordance with the result of volumetric measurements [39].

Thus the time-resolved DXAFS analysis evidences the existence of three elementary steps for the surface disintegration of Rh clusters (**6**) involving two intermediate states ((**7**) and (**8**)) as depicted in Fig. 10 [39]. At $t = 0$ Rh atoms in the cluster interact with the surface oxygen atoms of Al_2O_3 at a distance of 0.213 nm. *CN* and *R* of Rh-Rh were 5.0 and 0.265 nm, respectively, and they were in good agreement with those (4.9 and 0.264 nm) determined

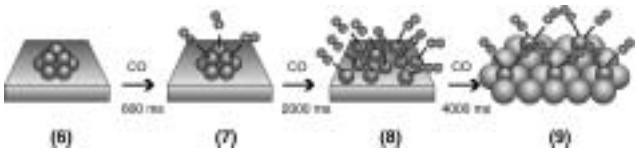

Fig. 10. An illustrative mechanism and time scales of three elementary steps at 298 K for the disintegration of Rh clusters on Al_2O_3 during CO adsorption by time-resolved DXAFS.

by conventional XAFS. These structural parameters assume that the Rh cluster (**6**) consists of 7 atoms in the first layer and 3 atoms in the second layer as shown in Fig. 10, which shows a *CN* of 5.4 for the Rh-Rh bond. The *CN* value of 1.6 for Rh-O indicates that each Rh atom in the lower layer interacts with two O atoms of the Al_2O_3 surface. At the first step of the dynamic disintegration processes (0–600 ms) CO rapidly adsorbs on the Rh cluster to show the *CN* of 0.7 for Rh-CO, which indicates that one CO molecule adsorbs on each Rh atom of the second layer of the cluster (**7**). At this stage no Rh-Rh bond breaking occurs. At the second step after 600 ms the Rh-Rh bonds become weaker by further CO adsorption and the Rh clusters are completely disintegrated at 3000 ms, where the ratio of adsorbed CO to Rh is one. The [Rh-CO] (**8**) can migrate across the Al_2O_3 surface to react with OH groups. The fragmentation of the Rh cluster permits the adsorption of further CO molecules on the Rh atoms at the third step (3000–6000 ms) to form [$Rh(CO)_2$] (**9**) which interacts with three surface O atoms as shown in Fig. 10. The Rh atoms more strongly interact with the surface because of a decrease in the Rh-O distance from 0.213 to 0.200 nm (Fig. 9). These processes proceed consecutively as evidenced by the existence of the isosbestic points and by the time profile of *CN*. The [Rh-CO] species and the [$Rh(CO)_2$] species were also confirmed by *in-situ* FT-IR, which exhibits a peak at 2060 cm^{-1} for terminal CO on Rh atom and two peaks around 2095 and 2023 cm^{-1} for Rh discarbonyl species [39]. After the 1.5 s CO exposure, the peak intensity at 2060 cm^{-1} increased at first, followed by the development of peaks at 2095 and 2023 cm^{-1} (4.5 s). Only these two bands were observed at 10.5 s. The formation of Rh dicarbonyl species (**9**) is in accordance with the previous reports [1–3].

The rates of the first and second steps in Fig. 10 were independent of temperature under the present conditions. On the contrary, the rate of the third step depended on temperature. The activation energies were calculated to be 15 ± 2, 17 ± 2, and 19 ± 2 kJ mol^{-1}, respectively for the changes in the CN of Rh–CO, the *CN* of Rh–O, and the *R* of Rh–O, which are in good agreement with each other. By CO adsorption the Rh-Rh bond distance increased from 0.26 nm for the incipient Rh clusters (**6**) to 0.27 nm for the $[Rh\text{-}CO]_{10}$ species, while the Rh cluster framework was disintegrated during the Rh-Rh elongation. Thus the [Rh-CO] species (**8**) are dispatched from the cluster and move on the surface without any significant energy barrier. The slowest step in the cluster disintegration with an energy barrier of 17 kJ mol^{-1} is the formation of [$Rh(CO)_2$] monomers (**9**) which occur concertedly with the bond rearrangement (change in *CN* and *R* of Rh-O) at the interface.

4. Conclusion

We have shown the time scale and bond sequence in the dynamic structural changes of Ru-carbido clusters on MgO and Rh clusters on γ-Al_2O_3, which both proceed through two intermediate states detected by means of *in-situ* time-resolved DXAFS every 1 s or 100 ms. The present time-resolved structural analysis provides crucial structural aspects to grasp the mechanism for dynamic surface processes and catalysis and contributes to a new area of structural dynamics of metal clusters and nanoparticles dispersed at surfaces.

Further improvements in the synchrotron source and detection systems will make it possible to measure the change of active structures with much shorter life time in catalytic reaction processes by time-resolved DXAFS. The trends of XAFS relevant to future progress in the study of nano-structures and heterogeneous catalysts may be μs-ns time-resolved XAFS observation, and besides space-resolved XAFS, more precise 3D-structure characterization, characterization of each metal site with different chemical states, more routinely reliable structural analysis, and more accurate theoretical analysis.

Abstract

Time-resolved X-ray absorption spectroscopy (TR-XAS) possesses excellent capabilities to reveal *quantitative phase composition and average valence* together with the evolution of the *local structure* of a system under dynamic reaction conditions. The work discussed here focused on time-resolved *in situ* XAS investigations aiming, first, at understanding structural evolution under dynamic conditions and, second, at revealing properties of the system studied not available from investigations under stationary conditions. In order to demonstrate the potential of TR-XAS in heterogeneous catalysis, TR-XAS investigations combined with mass spectrometry of the structural evolution of Keggin type heteropolyoxomolybdates (HPOM) during thermal treatment in propene and in propene and oxygen in the temperature range from 300 K to 773 K are presented. It is concluded, that the undistorted Keggin ion in the as-prepared HPOM has to be regarded as a precursor of the active catalyst, while the formation of lacunary Keggin ions is a prerequisite for catalytic activity.

1. Introduction

X-ray absorption spectroscopy (XAS) is a powerful technique that can provide element specific short-range structural information in heterogeneous catalysis. Moreover, XAS studies in catalysis can be performed in situ under reaction conditions with pressures and temperatures larger than 1 bar and 293 K, respectively. Several recent publications have reviewed parts of the literature related to time-resolved XAS (TR-XAS) [1–5]. The majority of studies that used time-resolved XAS in heterogeneous catalysis, focused on both structure-reactivity relationships from investigating the catalyst under reaction conditions and sevolution of the catalyst structure under preparation conditions [6–13, 14]. Time-resolved energy-dispersive XAS (TR-DXAS) has been used to elucidate reaction intermediates [15–20] and for a kinetic analysis of the reactions proceeding in bulk catalysts [21, 22] and on supported catalysts [23–26] TR-XAS investigations employing the Quick-EXAFS mode were performed of both bulk metal and metal oxide catalysts, [27, 28] sulfidation catalysts [29–32], and supported catalysts [33–37].

The work discussed in this paper focused on *in situ* XAS investigations aiming, first, at understanding structural evolution under dynamic conditions and, second, at revealing properties of the system studied not available from investigations under stationary conditions. In order to demonstrate the capabilities of TR-XAS investigations in heterogeneous catalysis, combined *in situ* time-resolved XAS/mass spectrometry studies on the evolution of the structure of various heteropolyoxomolybdates (i.e. $H_3[PMo_{12}O_{40}]$*$13H_2O$ denoted as HPOM, $Cs_2H[PMo_{12}O40]$ denoted as Cs_2-HPOM, $Cs_3[PMo_{12}O_{40}]$ denoted as Cs3-HPOM, and $Cs_2H_2[PVMo_{11}O_{40}]$ denoted as Cs_2-V-HPOM) during thermal treatment in 10% propene in helium (reducing conditions), and 10% propene and 10% oxygen in helium (catalytic partial oxidation conditions) are presented. In addition, some specific details about the TR-XAS experimental set-up and the data analysis procedure employed is provided. The latter is intended to illustrate the characteristic requirements of time-resolved XAS investigations compared to conventional *in situ* XAS studies.

Heteropolyoxomolybdates (HPOM) composed of Keggin ions (Figure 1) constitute highly active heterogeneous catalysts for partial oxidation of alkenes and alkanes (e.g. methacrolein to methacrylic acid) [38, 39]). Hence, the structure and the catalytic properties of the material have been extensively studied in the past. It has been suggested that the active phase of the HPOM under reaction conditions may correspond to the intact and undistorted Keggin structure of the HPOM [40, 41, 42, 43]. Other authors have observed, that the Keggin ions may not be particularly stable during thermal treatment and under catalytic conditions, resulting in partial reduction of the HPOM under reaction conditions, [44, 45] a considerable inhomogeneity of HPOM, [46, 47, 48, 49, 50, 51] and migration of molybdenum addenda ions [51, 52, 53, 54, 55, 56] or vanadium addenda substituents [51, 53, 57, 58, 59, 60, 61] from the Keggin anion onto interstitial sites in the HPOM structure. Apparently, reliable structure-reactivity relationships for HPOM needed for a rational improvement of the catalytic properties of the material are lacking. Open questions remain such as (*i*) what is the thermal and chemical stability of intact or partially decomposed Keggin ions and (*ii*) is the onset of the structural instability of the Keggin ion correlated to the catalytic activity of the material?

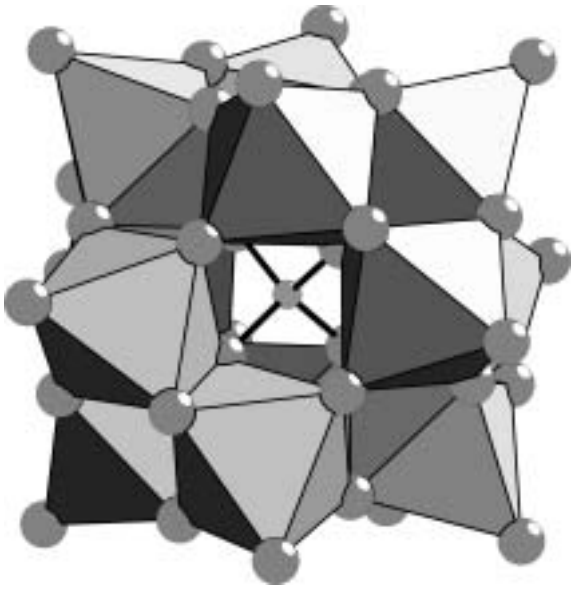

Fig. 1. Schematic structural representation of the Keggin anion in heteropolyoxomolybdates.

2. Experimental

2.1. *Sample preparation*

The heteropolyoxomolybdates $H_3[PMo_{12}O_{40}]^*13H_2O$, $Cs_2H[PMo_{12}O_{40}]$, and $Cs_3[PMo_{12}O_{40}]$ were prepared according to the method described by Tsigdinos *et al*. [62] Phase purity was verified by XRD.

2.2. *Instrumentation for TR-XAS in Catalysis*

The majority of XAS beamlines operating in the hard X-ray regime (>2.5 keV) are dedicated to transmission and fluorescence EXAFS using a double crystal monochromator. In order to obtain a reliable data quality in the step-scanning mode, a total measuring time of at least several minutes is required. Using the QEXAFS (Quick-EXAFS) [63, 64] technique, the measuring time is reduced to several tens of seconds. Evidently, QEXAFS offers a superior versatility as experiments can be performed in different detection modes (transmission, fluorescence, electron yield, etc.) on a large variety of systems (solid, liquid, or diluted samples, enhanced surface sensitivity, etc.). Conversely, with the energy-dispersive XAFS set-up (DXAS [65]), an entire absorption spectrum is collected at once, without requiring any movement of the spectrometer components. However, the energy range available for EXAFS analysis is restricted by the monochromator angle used and DXAS studies are restricted to the transmission mode. The *in situ* transmission XAS experiments reported here were performed at the Mo K edge (19.999 keV) at beamline X1 at the *Hamburg Synchrotron Radiation Laboratory*, HASYLAB. Because the objective of the investigations presented was a detailed analysis of the structural evolution of the heterogeneous catalysts employed, a conventional Si (311) double monochromator set-up was chosen.

2.3. *In situ cell for TR-XAS studies in Catalysis*

A variety of flow-through cells or batch reactors can be used for *in situ* X-ray absorption studies in the energy range from 2.5 keV to 30 keV. The *in situ* XAS experiments described here were conducted in a flow-reactor [35] on 5 mm self-supporting pellets at atmospheric pressure in flowing reactants (~30 ml/min, temperature range from 300 K to 773 K at 5 K/min). The heteropolyoxomolybates were mixed with boron nitride (7 mg HPA, 30 mg BN) and pressed with a force of 1 ton into a 5 mm in diameter pellet resulting in an edge jump at the Mo K-edge of $\Delta\mu_x \sim 1.5$. The twofold advantage of the set-up employed is the very small volume and the fact that the reactor can be used with both the DXAS set-up and the QEXAFS set-up. Hence, by using the same experimental cell, time-resolved DXAS data under rapidly changing conditions can be obtained (time-resolution better than 1 s) as well as high quality EXAFS data in the conventional scanning mode or the QEXAFS mode (time-resolution of ~1 min). Temperature and reactant mass flow can be controlled with an *Eurotherm* PID temperature controller and *Bronkhorst* mass flow controllers, respectively. The product composition at the *in situ* cell gas outlet is continuously monitored using a mass spectrometer in a mass scan mode (QMS200 from *Pfeiffer*) which is crucial for *in situ* studies in heterogeneous catalysis when bulk structural changes are to be correlated to catalytic performance.

2.4. *Analysis of TR-XAS data in catalysis*

X-ray absorption fine structure (XAFS) analysis was performed using the software package WinXAS v2.3 [67]. Background subtraction and normalization were carried out by fitting linear polynomials to the pre-edge and the post-edge region of an absorption spectrum, respectively. A quantitative phase analysis of mixtures is particularly desirable for studies in heterogeneous catalysis where one frequently has to deal with more than one phase present under reaction conditions. Principle component analysis (PCA) permits a quantitative determination of the number of primary components in a set of experimental XANES spectra [68, 69]. Recently, this approach has been successfully extended to the analysis of EXAFS data measured for various phase mixtures [70, 71].

The extended X-ray absorption fine structure (EXAFS) $\chi(k)$ was extracted by using cubic splines to obtain a smooth atomic background, $\mu_0(k)$. The radial distribution function FT($\chi(k)$) was calculated by Fourier transforming the k^3-weighted experimental $\chi(k)$ function, multiplied by a Bessel window, into the R space. EXAFS data analysis was performed using theoretical backscattering phases and amplitudes calculated with the *ab-initio* multiple-scattering code FEFF7 [72]. Single scattering and multiple scattering paths in the Keggin ion model structure were calculated up to 6.0 Å with a lower limit of 2.0% in amplitude with respect to the strongest backscattering path. EXAFS refinements were performed in R space to magnitude and imaginary part of a Fourier transformed k^3-weighted experimental $\chi(k)$ using the standard EXAFS formula (k range from 3.4 to 15.1 $Å^{-1}$, R range 0.7 to 4.1 Å) [73]. Structural parameters that are determined by a least-squares EXAFS refinement of a Keggin model structure to the experimental spectra are (*i*) one E_0 shift, (*ii*) Debye-Waller factors for single-scattering paths, (*iii*) distances of single-scattering paths, (*iv*) one third cumulant for the Mo–O distances in the first coordination shell and one third cumulant for all remaining scattering paths. Coordination numbers (CN) and S_0^2 were kept invariant in the refinement.

3. Results and Discussion

3.1. *Structural evolution during thermal treatment in propene*

An experimental Mo K edge $\chi(k)$ of Cs_2-HPOM at 300 K is shown in Figure 2. The sufficient signal to noise ratio up to

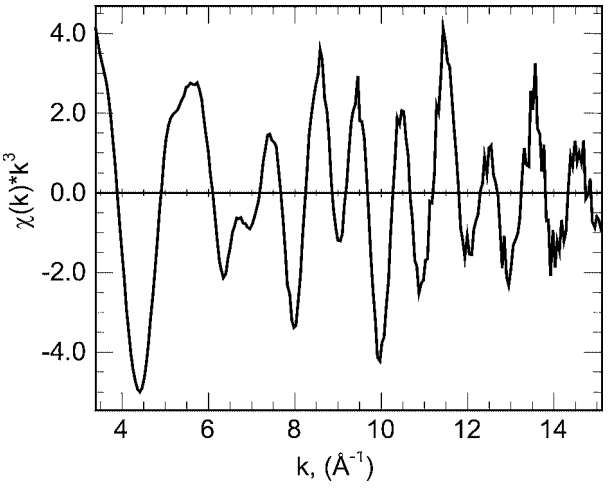

Fig. 2. Experimental Mo K edge $\chi(k)$ of $Cs_2H[PMo_{12}O_{40}]$ measured at 300 K.

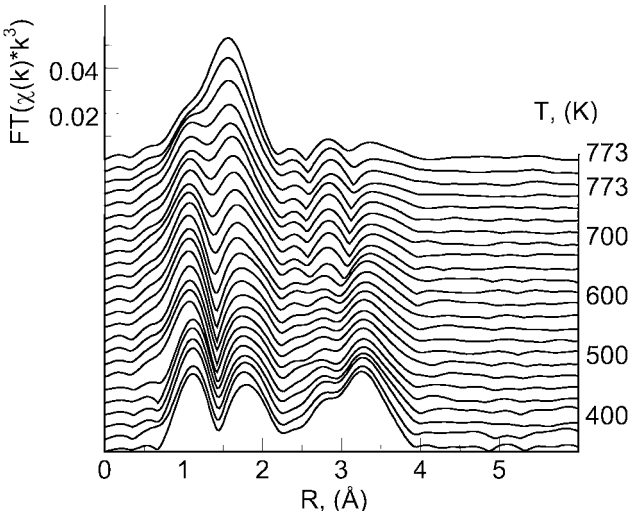

Fig. 3. Evolution of Fourier transformed Mo K edge $\chi(k)$ measured during treatment of $H_3[PMo_{12}O_{40}]$ in 10% propene in helium in the temperature range from 300 K to 770 K.

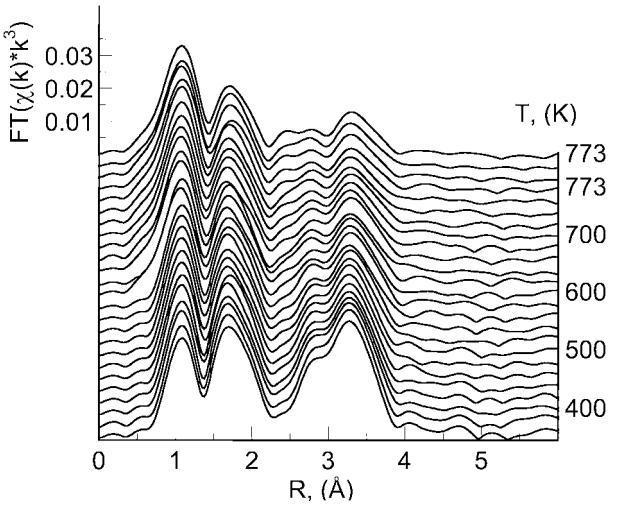

Fig. 4. Evolution of Fourier transformed Mo K edge $\chi(k)$ measured during treatment of $Cs_2H[PMo_{12}O_{40}]$ in 10% propene and 10% oxygen in helium in the temperature range from 300 K to 770 K.

$\sim$15 Å^{-1} enables a reliable structural analysis of changes in the local structure of the Keggin ion under reaction conditions. The evolution of the Fourier transformed Mo K edge $\chi(k)$ during thermal treatment of HPOM in 10% propene in the temperature range from 300 K to 773 K is depicted in Figure 3. Significant changes in the local structure of the Keggin anion in both materials can be seen at temperatures above $\sim$600 K. The Mo K edge spectrum measured at 773 K can be assigned to that of the cubic HPOM observed by *in situ* XRD. Conversely, no significant changes in the local structure were detected during thermal treatment of Cs_3-HPOM in propene or hydrogen. *In situ* XRD experiments performed during the thermal treatment of HPOM in propene revealed the formation of a HPOM consisting of a cubic arrangement of Keggin anions with a certain amount of the molybdenum ions migrated onto sites between the Keggin anions [74].

In order to elucidate the evolution of the short-range order structure of the heteropolyoxomolybdates studied under reducing and partial oxidation reaction conditions, a detailed XAFS analysis of the Mo K edge $\chi(k)$ measured was performed. From Figure 6, a good agreement between the experimental

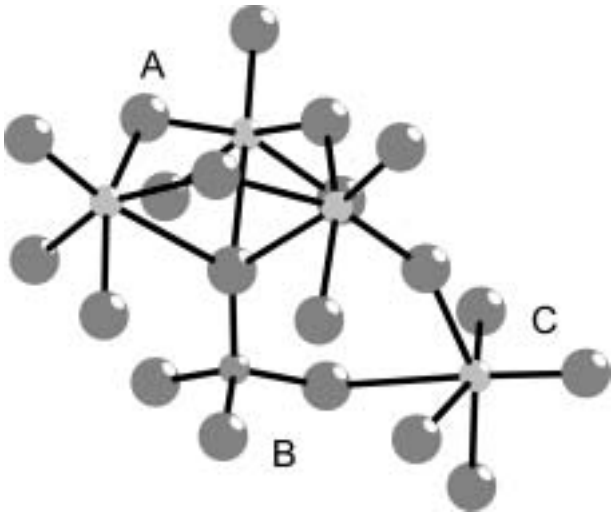

Fig. 5. Experimental (Exp.) and theoretical (Fit) Mo K edge $\chi(k)$ of $H_3[PMo_{12}O_{40}]$ *$13H_2O$ (HPOM) and $Mo_zH_{3-x}[PMo_{12-z}O_{40-x/2}]$ (Mo-HPOM) (measured *in situ* during treatment of HPA in 10% propene at 773 K). Selected individual single-scattering paths in cubic "Mo-HPOM" are shown.

Fourier transformed $\chi(k)$ of HPOM and a XAFS refinement using theoretical phases and amplitudes calculated for the Keggin ion in the structure of $K_2H[PMo_{12}O_{40}]^*H_2O$ (*P*n-3m, [ICSD 209]) can be seen. Very similar results of the corresponding XAFS refinements were obtained for Cs_2-HPOM, Cs_2-V-HPOM, and Cs_3-HPOM. Figure 5 shows a schematic representation of a part

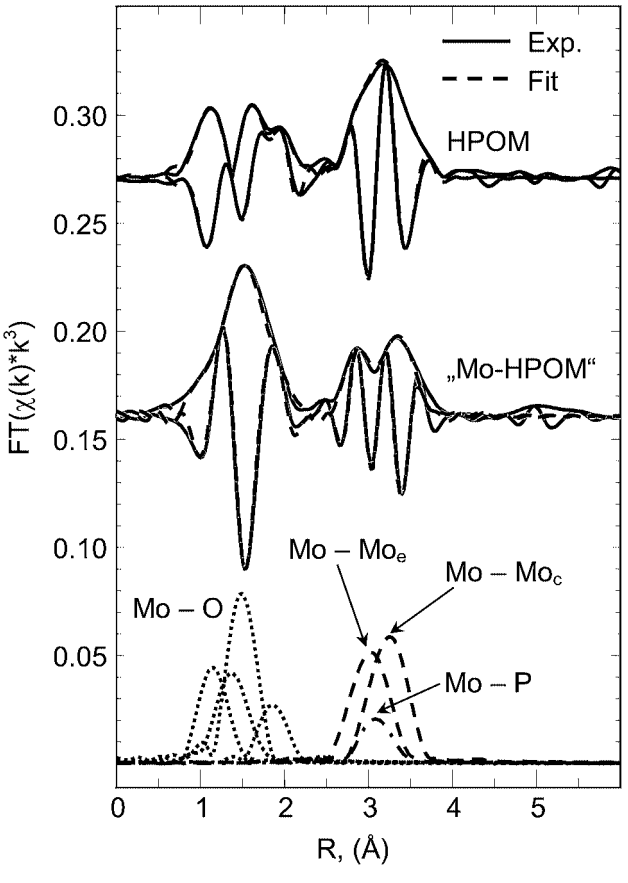

Fig. 6. Schematic structural representation of a section of the Keggin anion. Shown is a "triad" consisting of three edge-sharing MoO_6 units connected to the central PO_4 tetrahedron and connected via corner-sharing to one MoO_6 unit of one of the neighboring "triades".

of the Keggin structure. The Keggin ion consists of four "triades", each built up by three edge-sharing MoO_6 units (A in Figure 5). The three MoO_6 units share one common oxygen atom that is connected to the central heteroatom in the Keggin ion (B in Figure 5). The four triads in the Keggin anion are linked together by common corners of the corresponding MoO_6 units (C in Figure 5). The individual shells that can be clearly distinguished in the FT($\chi(k)$) of the heteropolyoxomolybdates correspond to the Mo–O distances within the MoO_6 units (from 1.69 Å to 2.43 Å), the Mo–Mo distances within the triads (3.41 Å, edge-sharing), and the Mo–Mo distances between the triads (3.71 Å, corner-sharing). Additionally, Figure 6 displays the experimental Fourier transformed $\chi(k)$ of the cubic HPOM obtained from the treatment of HPOM in propene (Figure 3) and a XAFS refinement using the same phases and amplitudes as described above. A good agreement between the experimental spectrum of the cubic HPOM and the theoretical XAFS calculations was achieved using the Mo–O and Mo–Mo distances and the respective coordination numbers in the Keggin ion as start parameters. The Mo–O, Mo–P, and Mo–Mo distances in the Keggin anion of HPOM and the cubic HPOM obtained from the XAFS analysis indicate, that treatment of HPOM, Cs_2-HPOM, and Cs_2-V-HPOM in propene results in slightly modified Keggin anions with elongated Mo–O and Mo–Mo distances.

In Figure 7 the evolution of selected Mo–O and Mo–Mo distances in the Keggin anion of Cs_2-HPOM, Cs_2-V-HPOM, and Cs_3-HPOM during treatment in 10% propene in the temperature range from 300 K to 773 K is depicted. At temperatures above ~573 K an increase in the Mo–O and Mo–Mo distances in Cs_2-HPOM and Cs_2-V-HPOM can be noticed, being the strongest for the Mo-Mo distance between edge-sharing octahedra in the Keggin anion (within the "triades"). Eventually, at 773 K the treatment results in the formation of the characteristic local structure of the Keggin ion of the cubic HPOM structure (Figure 5). Interestingly, the presence of vanadium as an addenda substituent in the Keggin ion shows no significant effect on the structural evolution of Cs_2-V-HPOM compared to that of Cs_2-HPOM.

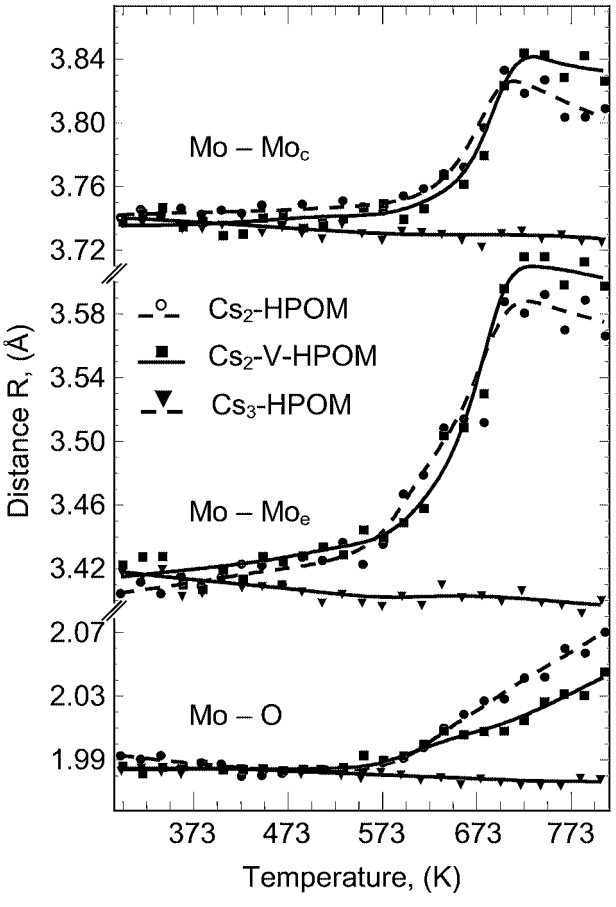

Fig. 7. Evolution of selected Mo–O and Mo–Mo distances in the Keggin structure of $Cs_2H[PMo_{12}O_{40}]$, $Cs_2H_2[PVMo_{11}O_{40}]$, and $Cs_3[PMo_{12}O_{40}]$ during treatment in 10% propene in helium in the temperature range from 300 K to 773 K.

The changes in the Fourier transformed Mo K edge $\chi(k)$ of HPOM (Figure 3) indicate significant alterations of the local structure under reducing conditions. The FT($\chi(k)$) of the cubic HPOM and Cs_2-HPOM with Mo on interstitial sites indicate a remarkable degree of order in the partially reduced and decomposed Keggin ions. Hence, it must be concluded that most Keggin ions undergo a structural transition into a stable modification of the Keggin ions. The local structure of the HPOM probed by XAFS corresponds to the local arrangement of edge and corner-sharing MoO_6 units in the Keggin anion (Figure 6). Both the structure of the original HPOM and the structure of the cubic HPOM obtained after treatment in a reducing atmosphere can be simulated by theoretical XAFS calculations based on the structure of the Keggin anion (Figure 5). For the former the Mo–O and Mo–Mo distances obtained from the XAFS refinement agree well with those obtained from single crystal structure analysis, whereas for the latter a significant lengthening of the Mo–O and Mo–Mo distances in the Keggin anion is obtained.

From Figure 7 it can be seen, that the onset of the structural changes in the Keggin anion of Cs_2-HPOM is at about 573 K. In comparison, no significant structural changes were observed in Cs_3-HPOM over the temperature range studied (Figure 7). The same holds for the evolution of the average Mo valence of the Keggin anion, where no changes were observed during treatment of Cs_3-HPOM in propene or hydrogen. The average Mo valence was obtained from comparing the Mo K edge position of the heteropolyoxomolybdates to that of various molybdenum oxide reference compounds [75]. Conversely, a partial reduction of the molybdenum in Cs_2-HPOM was detected at temperatures above 573 K which coincides with the local structural changes observed at this temperature. The average Mo valence of ~5.4 of the resulting cubic HPOM at 773 K is in good agreement with thermogravimetric measurements of the treatment of HPOM in propene that showed a loss of about four oxygen atoms per Keggin ion in the temperature range from 573 K to 773 K (Mo average valence of 5.33) [76].

3.2. *Structural evolution during activation in propene and oxygen*

The evolution of Fourier transformed Mo K edge $\chi(k)$ during thermal treatment of Cs_2-HPOM in 10% propene and 10% oxygen in helium in the temperature range from 300 K to 773 K shows minor changes to the FT($\chi(k)$), mostly attributable to the increasing reaction temperature (Figure 4). Figure 8 illustrates the corresponding evolution of selected Mo–O and Mo–Mo distances in the Keggin anion of Cs_2-HPOM and Cs_2-V-HPOM. At temperatures above ~573 K an increase in the Mo–O and Mo–Mo distances in Cs_2-HPOM and Cs_2-V-HPOM can be noticed. The onset of the structural changes in the Keggin ion in Cs_2-HPOM and Cs_2-V-HPOM are correlated to the onset of catalytic activity of the materials as can be seen from the increasing

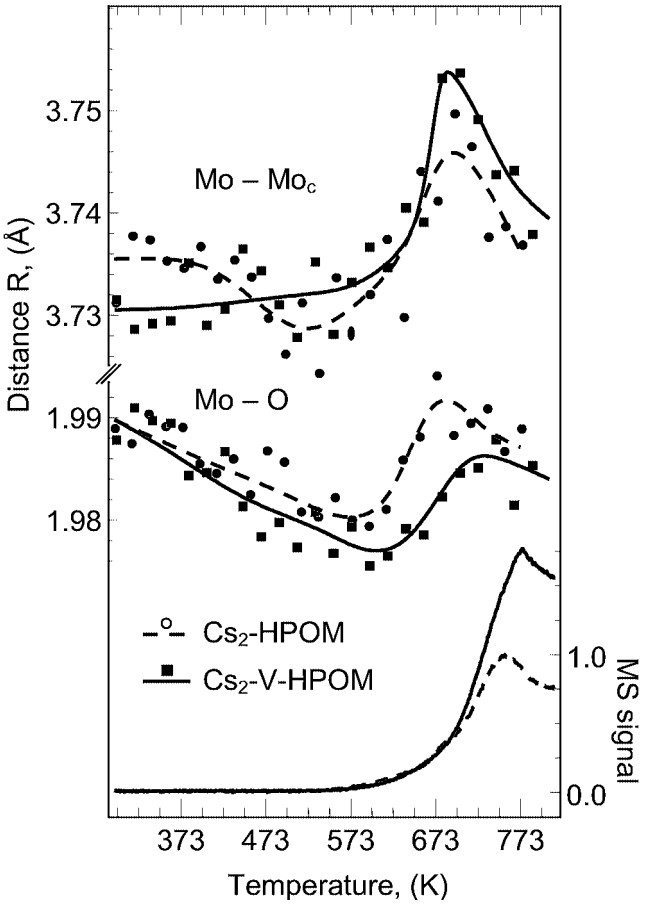

Fig. 8. Evolution of selected Mo–O and Mo–Mo distances in the Keggin structure of $Cs_2H[PMo_{12}O_{40}]$ and $Cs_2H_2[PVMo_{11}O_{40}]$ during treatment in 10% propene and 10% oxygen in helium in the temperature range from 300 K to 773 K together with the acrolein concentration in the gas phase measured by MS.

concentration of the partial oxidation product acrolein in the gas phase. It can be seen from Figure 7 and Figure 8 that the onset temperature and the relative amplitude of the lengthening of the Mo–O and Mo–Mo distances in the Keggin anion of Cs_2-HPOM and Cs_2-V-HPOM under catalytic reaction conditions coincide with the formation of the cubic HPOM during the treatment of Cs_2-HPOM and Cs_2-V-HPOM in propene (Figure 7).

During activation of HPOM in propene and oxygen, the evolution of the local structure of Cs_2-HPOM in the temperature range from 300 K to ~700 K indicates, that the structural characteristics of the Keggin anion are mostly preserved (Figure 4). This is in agreement with the structural evolution of Cs_2-HPOM during thermal treatment in propene. The local structural changes observed in the Keggin ion of Cs_2-HPOM during treatment in propene and oxygen, that coincide with the onset of catalytic activity, are in good agreement with those observed during treatment in propene. Both onset temperature and changes in the Mo–O and Mo–Mo distances during treatment in propene and oxygen indicate that similar to the treatment of Cs_2-HPOM in propene, in both Cs_2-V-HPOM and Cs_2-HPOM a partial decomposition of the Keggin ion (i.e. migration of Mo cations and modified short-range coordination) takes place during activation in propene and oxygen at temperatures above ~573 K.

3.3. *Structure-activity relationships in heteropolyoxomolybdates*

Elucidating relationships between the structure of a heterogeneous catalyst and its reactivity requires a detailed knowledge about the structure of the catalyst under reaction conditions ("in situ"). The *in situ* TR-XAS results presented indicate, that for heteropolyoxomolybdates under reaction conditions, 'structure' does not refer to the undisturbed Keggin structure of the initial material but rather to the electronically and geometrically distorted structure of lacunary partially reduced Keggion ions. It seems, that a certain instability of the structure of the heteropolyoxomolybdates is inevitable in order to obtain an active catalyst under reaction conditions (inactive Cs_3-HPOM compared to active Cs_2-HPOM). Moreover, the correlation between the structural changes described and the onset of catalytic activity indicates, that the original Keggin structure is the precursor for the structure of the partially reduced active catalyst. Time-resolved in situ XAS under dynamic reaction conditions (i.e. increasing reaction temperature) has proven very valuable to elucidate the subtle structural changes that occur in Keggin ions during activation in propene. The slightly altered structure of the HPOM under reaction conditions would have been difficult to unambiguously identify from measurements under stationary conditions. Therefore, the evolution of the local structure of HPOM under reaction conditions as monitored by *in situ* XAS revealed new insights into the correlation of the structure of this heterogeneous catalyst and its catalytic behavior, complementary to structural changes in HPOM as previously reported in the literature (for instance from XRD, Raman, or IR measurements).

4. Concluding remarks

The examples presented clearly demonstrate the potential of TR-XAS investigations to extend the suitability of XAS for *in situ* studies in heterogeneous catalysis to investigations under dynamic conditions. XAS experiments under stationary conditions may reveal the structure of a working catalyst, however, correlations between the structure of the catalyst and its catalytic properties can more readily be elucidated from monitoring the structural response of the catalyst to changing reaction conditions (i.e. temperature, gas phase, etc.). Although the experiments shown demonstrate the structural details that can be obtained from TR-XAS studies, the structural information obtained becomes much more reliable when corroborated by results from complementary techniques (in the case presented for instance *in situ* XRD, TG/DTA, IR, etc.). When used complementary with other techniques, the capability of TR-XAS to reveal *quantitative phase composition and average valence* together with the evolution of the local structure of a system under dynamic (reaction) conditions, combined with a time-resolution of 100 ms is a very powerful tool for structural and kinetic studies in heterogeneous catalysis.

Acknowledgement

We are grateful to R. E. Jentoft and F. Girgsdies for participating in the XAS measurements, to HASYLAB for providing beamtime for this work, and to Prof. R. Schlögl for continuous support.

Abstract

Energy dispersive EXAFS (EDE), using a Laue monochromator on ID24 of the ESRF, and multiple ion monitoring mass spectrometry have been used to monitor the structure and function of alumina-supported rhodium and palladium catalysts within a microreactor. Metallic 5%-Rh/Al_2O_3 was preformed *in situ* by hydrogen reduction, and shown to react rapidly with NO at room temperature yielding an oxidised phase. In order for this material to catalyse the reduction of NO by H_2 (to N_2), it was shown that the metallic phase must be reformed. The "light-off" temperature at which the metallic phase was formed and catalysis commenced varied with NO : H_2 stoichiometry, this temperature lowering in more reducing conditions. N_2O formation was concomitant with the conversion from the oxidised to the metallic phase.

The EDE configuration allowed the simultaneous monitoring of structure at both the rhodium and palladium K-edges. Incorporation of a 20% palladium mole fraction into 5%-Rh-Pd/Al_2O_3 protected rhodium from oxidation and also reduced the light-off temperature, and this is reflected in low coordination number values for the composite Pd to Rh/Pd shell. This favours palladium being preferentially on the surface of the nanoparticles. At higher temperatures there are changes in coordination numbers than imply a redistribution of metal sites under catalytic conditions. Future plans to include infrared spectroscopy as a third simultaneous technique will be outlined.

1. Introduction

Many platinum group metal heterogeneous catalysts consist of a dispersion of small metal particles chemisorbed onto a low-ordered surface of an often disordered support, such as a metal oxide. It is thus not surprising unravelling these complexities to create an atomic-level understanding of catalytic processes has proven to be tantalisingly difficult. Elegant surface science approaches to this problem have included imaging of reaction fronts at the atomic scale by scanning tunnelling microscopy (STM) on single-crystal metal surfaces [1]. This is certainly an excellent approach to modelling catalysts with very large metal particle sizes, but the possibility of more complicated chemistry when metal particles are interacting with their supports is also evident. Again, surface science approaches can be employed based upon single crystal oxides [2]. So, for example, platinum group metals may be introduced onto the surface of a single-crystal rutile surface by metal vapour deposition (MVD) [3] and metalorganometallic chemical vapour deposition (MOCVD) [4]. In such cases, deriving a surface of sufficient order and stability to achieve a diffraction analysis from the overlayer has proven difficult. However, STM has been employed to probe the arrangement of $Rh(CO)_2$ units on a rutile (110) surface and to monitor the aggregation of these mononuclear centres into metal particles [5]. The nature of the oxide surface plane of rutile has been found to have a significant effect upon the initially observed rhodium site after MOCVD of $[RhCl(CO)_2]_2$ also on subsequent particle growth patterns [6].

This support-surface dependence on the properties of adsorbed metal particles makes it therefore important to be able to identify the nature of these particles on catalysts themselves, since, they provide a variety of local surface morphologies. X-ray absorption spectroscopy (XAS) has proven to be a very effective technique for such studies [7, 8, 9, 10]. An important feature of XAS has been the capability of probing structure under ambient, reactive gases and this allowed the technique to settle a long-standing dichotomy on the structure of the heterogeneous catalyst Rh/Al_2O_3 that had resulted from the divergence of surface environment in TEM and IR spectroscopy studies that used CO as a probe molecule. Here analysis of the extended X-ray absorption fine structure (EXAFS) revealed the corrosive nature of the chemisorption of CO on small rhodium particles, affording mononuclear $Rh^I(CO)_2$ sites [11].

Such spectra were recorded by scanning XAS as structural studies, and thus require that the nature of the sample is invariant during the acquisition period. In practice this means that any reaction that might be studied *in situ* should proceed over a time period that is considerably longer than the acquisition period. In order to monitor changing systems, there are four approaches that may be adopted [12]:

i) quenching of the reaction,
ii) a rapid-scanning, quick EXAFS approach (QEXAFS),
iii) a parallel measurement, energy dispersive or dynamic EXAFS approach (EDE or DEXAFS),
iv) a time-drive spectral reconstruction method.

Each of these is appropriate to different circumstances. Quenching is essential when rapid acquisition cannot provide viable data. It suffers from the possibility of sample reaction during the cooling period, unless the cooling is sufficiently rapid, but recently a rapid freeze quench method (2 ms) has been applied to metalloenzyme studies [13]. The QEXAFS approach has been developed to a very high degree using a piezo mechanism [14], providing repetition rates of EXAFS data of $\sim$10 Hz. Since this is a scanning technique, again the reactions studied should be of the order of 1–2 Hz to ensure that the recorded spectra are representative of the same species throughout the energy range. The last method involving a single X-ray energy was used to provide a kinetic study of a zinc metalloenzyme site [13], and, as in FTIR spectroscopy, probably, with microchannel flow reactors as an alternative, provides the best means of studying extremely rapid reactions ($<$1 μs) by XAS.

2. Energy Dispersive EXAFS (EDE) experimental techniques

In this paper we describe our application of the energy dispersive method to *in situ* catalytic studies. The potential advantages

*email: je@soton.ac.uk; john.evans@diamond.ac.uk; M.A.Newton@soton.ac.uk

of this technique have been established for 20 years [15, 16]. Since then there have been some seminal applications, such as monitoring reactions under stopped flow conditions [17], and heterogeneous catalysts [18]. However, the uptake of the method has been restricted due to stringent requirements on beam stability, focus characteristics and X-ray detector [12]. The incorporation of feedback systems into the electron beam has proven to achieve a significant improvement in beam stability, and the focal characteristics have also been improved by use of 4-point bender mechanisms [19, 20]. Differing solutions to detectors were adopted, with photodiode arrays [21] and a masked CCD camera [22], respectively, adopted on Station 9.3 at the SRS and ID24 at the ESRF. In the experiments described in this paper that were performed of Beamline ID24, each exposure time is of the order of 1–3 ms. Normally data from ∼10 strips of the CCD are collected and accumulated. The readout time is ∼300 ms, and this limits the repetition rate of these experiments to multiples ∼3 Hz, depending upon the number of acquisitions collected for each sample (typically 1–10). This matches the gas pulse width attained with this sampling arrangement. The monochromator used was an asymmetric cut Si(111) crystal used in a Laue geometry to avoid the loss of energy resolution intrinsic to attempting to record spectra at the Rh and Pd K-edges using a Bragg monochromator, due to the broad reflectivity curves at these energies [19].

The catalysis cell is based upon quartz microreactors in containing a bed of powdered sample catalyst. Pressed discs were eschewed to avoid their known problems of confined cavities, surface reconstruction and restricted diffusion [23]. The experimental arrangement as set up on ID24 is shown in Fig. 1. This allows for the microreactor, an I_0 sample and a calibration foil to be incorporated. The use of this cell for *in situ* studies of metal particle formation was on the reduction of $Pt(acac)_2$ on the mesoporous silica H_1-SiO_2 [22] on Station 9.3 of the SRS. The interesting capability of EDE to monitor two elements simultaneously was then demonstrated as the steps in the formation of Pt-Ge/H_1-SiO_2 were investigated using the Pt L_{III} and Ge K-edges [24]. The co-monitoring of the gas phase composition by mass spectrometry and metal structure by EDE was performed on the reaction of $RhCl(CO)_2/Al_2O_3$ with NO using the Rh K edge on ID24 [25]. This showed that different steps in the reaction sequence could be monitored kinetically using the two different monitoring techniques. In situ monitoring of solid state reactions (*e.g.* reduction of MoO_3 [26]) and catalysis (*e.g.* CO oxidation by Pd/C [27] and oxychlorination catalysis by Cu/Al_2O_3 [28]) have also been reported from experiments performed with alternative, pressed disc reactors. Our studies have focussed upon reactions related to the three-way automotive catalysts [29], which contain Rh, Pd and Pt supported on oxides [30].

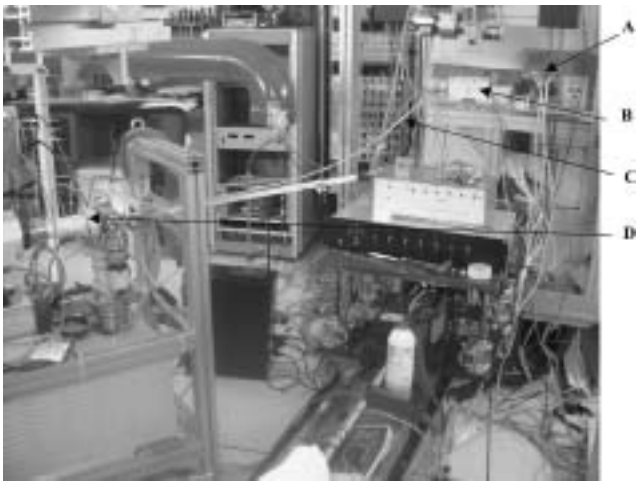

Fig. 1. Equipment used for *in situ* microreactor studies of ID24 at the ESRF. This shows the mass flow controllers (A), the reactor cell in its furnace (B), the capillary lead (C) and the mass spectrometer (D).

3. In Situ EDE characterisation of Rh/Al_2O_3 catalysts for the reduction of NO by H_2

Once loaded into the reactor, the 5% Rh/Al_2O_3 samples (prepared after deposition from aqueous rhodium trichloride, drying, calcinations and reduction by hydrogen) displayed Rh K-edge EXAFS curves unlike those of a fcc structure, indicating that oxidation had transpired in storage and loading (Fig. 2a). Exposure to 4% H_2/He evidently effects reduction to metallic rhodium (Fig. 2b), which may be readily re-oxidised on exposure to 4% O_2/He (Fig. 2c).

Such *in situ* reduced samples of Rh/Al_2O_3 are very rapidly oxidised on exposure to 4% NO/He at 313 K [31], with a similar oxidised rhodium material being formed. This exothermic oxidation is accompanied by the liberation of N_2, and N_2O, both of which require there to have been dissociative chemisorption of the nitric oxide. The NO oxidised rhodium species is rather resistant to reduction by hydrogen. When heated under 4% H_2/He, desorption of molecular NO occurs above room temperature. Reduction of the rhodium to a metallic form, as evidenced by the rise Rh-Rh coordination number, occurs once the temperature reached ∼400 K, at which point the evolution of NO is complete. This reduction is accompanied by evolution of N_2O, and at slightly higher temperatures N_2 is evolved. The temperature required for reduction is considerably higher than that for O_2 treated catalysts, which are readily reduced at room temperature, suggesting that the NO coordination may be stabilising the oxidised rhodium

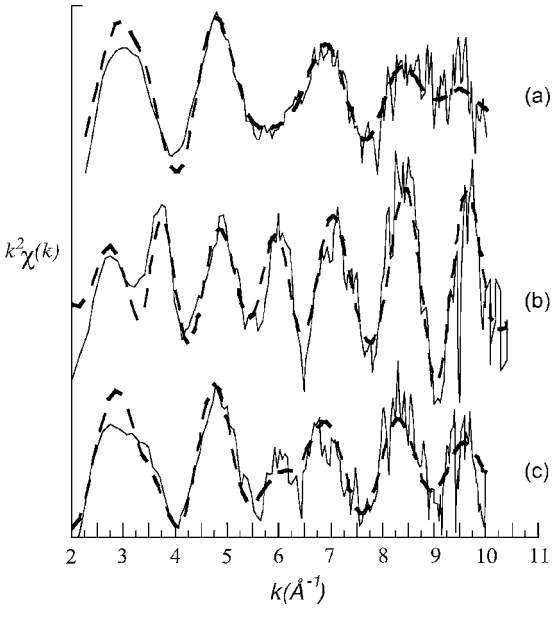

Fig. 2. k^2 weighted EDE derived from (a) a fresh 4 wt% air-exposed Rh/Al_2O_3 under a flow of He; (b) a 5 wt% Rh/Al_2O_3 after subsequent *in situ* reduction to 373 K in 10 ml min^{-1} 4% H_2/He; (c) from the 5 wt% Rh/Al_2O_3 used in (b) after subsequent exposure to 10 mlmin^{-1} 4% O_2/He at 373 K. Solid lines = experiment; dashed line = theory.

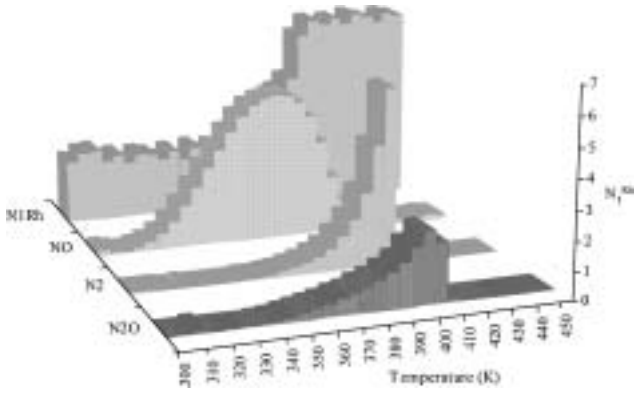

Fig. 3. Variation in the Rh-Rh co-ordination number (grey) and relative mass spectrum intensities for NO (dotted), N_2 (hatched) and N_2O (lined) of a 5 wt% Rh sample previously oxidised by 4% NO/He and then exposed to 4% H_2/He with a 10 K/min temperature ramp.

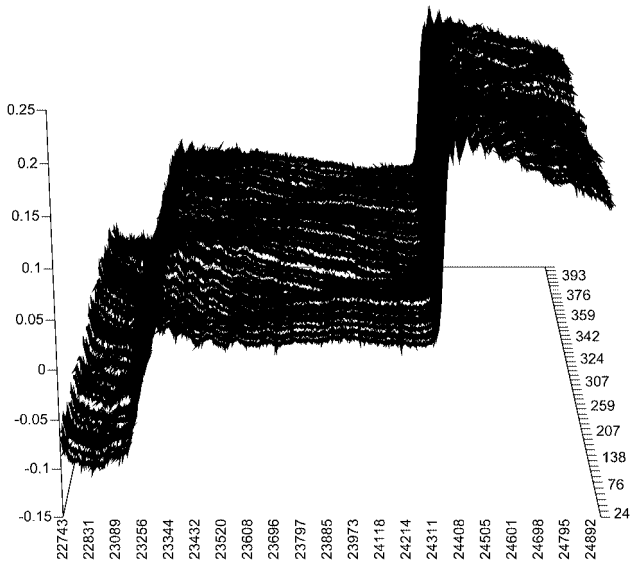

Fig. 4. Plots of the Rh and Pd K-edge XAS of (3% Rh-2% Pd)/Al_2O_3 prepared by co-impregation. Under a 10 ml/min flow of 5% H_2/NO (3 : 2) in He.

species. This provides a background to probing structural changes that occur accompanying the catalytic reduction of NO by H_2 [32]. This demonstrates that metallic rhodium is essential for effecting efficient reduction of NO to N_2. This requires at least a 50% fraction of H_2 in the NO/H_2 proportions. The light-off temperature, at which the efficiency of the catalytic process rises rapidly with temperature decreases with higher H_2/NO ratios, and this is mirrored by the rise in Rh-Rh coordination number to a value of ∼8, which corresponds to a mean particle size of 70–150 atoms [33]. Under the most oxidising (leanest) conditions, the Rh-Rh coordination number remains at ∼2 and only a small proportion of NO is converted to N_2O. See fig. 3.

The EDE/MS experiments with sampling rates of 0.3–3 Hz allow the catalytic process to be investigated over a wide range of experimental conditions with a fine toothcomb. They demonstrate an intimate relationship between the catalytic activity and selectivity and the nature of the dominant phase of the supported rhodium. At the catalytic temperatures studied (>400 K), it is clear that the potential rate of dissociative chemisorption of NO and oxidative fragmentation of the rhodium particles is fast (≪1 s), and so sufficient hydrogen is required to remove the N and O (as N_2 and H_2O respectively) to avoid this.

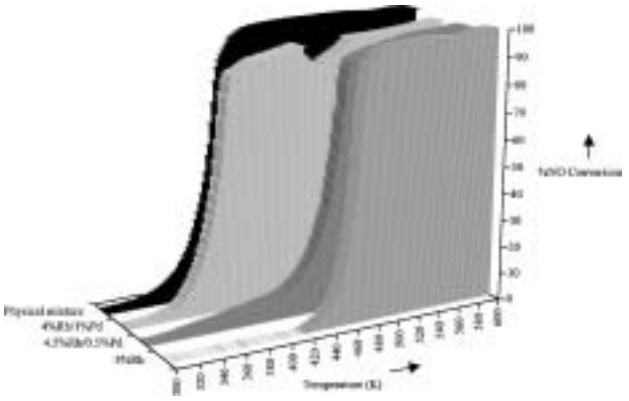

Fig. 5. Plot of NO conversion for a series of 5% (Rh-Pd)/Al_2O_3 catalysts under 5% H_2/NO (3 : 2) in He.

4. In Situ EDE characterisation of Rh-Pd/Al_2O_3 catalysts for the reduction of NO by H_2

The degree of bending of the monochromator affords an energy span over ∼2500 eV, quite sufficient to monitor both the Rh and the Pd K-edges simultaneously and provide a digital resolution of 2 eV [12]. Both of these are key elements in formulations of automotive exhaust catalysts [29, 30]. So a series of catalysts were prepared based upon a 5 wt% (Rh, Pd)/Al_2O_3 synthesised in differing ways: co-impregnation of Pd and Rh (CI), sequential impregnation of Rh and then Pd (SI) and also a physical mixture of 5% Rh/Al_2O_3 and 5% Pd/Al_2O_3.

The raw, calibrated double-edge X-ray absorption spectra of a 3% Rh-2% Pd/Al_2O_3 sample are shown in Figure 4, the sample being under a flow of H_2-NO (3 : 2)/He and undergoing a temperature ramp. It may be seen that there are some variations in the background, probably due to optical instabilities, but these do not prevent the data from being treated with standard background subtraction [34] and spherical wave analysis analysis methods [35]. The NO conversion for a series of four catalysts is presented in Figure 5. Incorporation of 10% Pd into the Rh-Pd phase has relatively little effect, apart from an increase in activity at lower temperatures. As the proportion is increased to 20%, the "light-off" temperature, at which convertion starts to rise rapidly is markedly reduced, and this behaviour is similar to that observed for a physical mixture of 5%Rh/Al_2O_3 and 5%Pd/Al_2O_3 (1 : 1). Figure 6 shows the refined Rh-Rh/Pd coordination number (first shell) from the EDE data. As discussed above, the increase in Rh-Rh coordination number for the Rh/Al_2O_3 sample parallels the onset of catalytic activity showing the importance of creating metallic clusters for the onset of catalysis (forming N_2 with high selectivity). It was also observed previously that this could not be achieved under oxidising conditions (excess of NO over H_2). It is interesting therefore that once a proportion of 20% Pd is achieved that the rhodium centres maintain there metallic environment over the entire temperature range studies, suggesting that palladium is stabilising the rhodium from oxidation. By comparing the results from the Pd edge, it appears that small alloy particles are present. From a catalytic point of view, however, this stabilisation is accompanied by a loss in selectivity for N_2 formation, with the proportion of N_2O substantially increased, as is observed for Pd/Al_2O_3 alone. Nevertheless, these results do provide considerable insight into the strong dependence of catalyst structure on the ambient conditions.

At the Rh edge, not surprisingly the behaviour of the physical mixture of the two alumina supported catalysts is essentially as found for Rh/Al_2O_3 on its own.

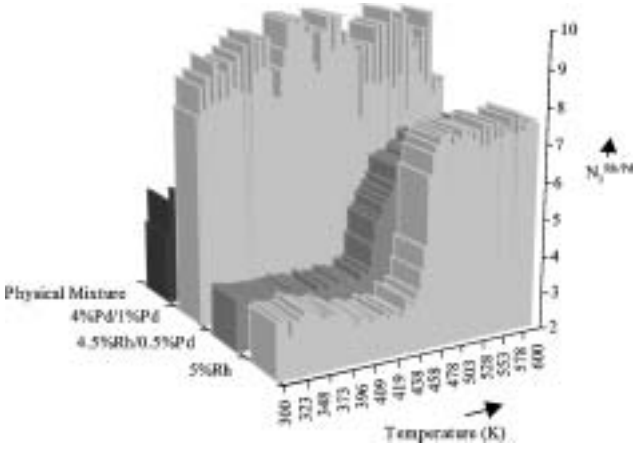

Fig. 6. Plot of the first shell Rh-Pd coordination number from analysis of the Rh K-edge EXAFS data during NO reduction for a series of 5% (Rh-Pd)/Al_2O_3 catalysts under 5% H_2/NO (3:2) in He.

5. Future possibilities

These experiments do not represent any limit on the time resolution that is currently attainable under practical conditions. Stopped flow experiments, with mixing times of ∼1 ms or below, now closely match the normally attainable rate of acquisition for single scans [36, 37]. In order to improve the time resolution of these catalysis experiments and to gain more information about the surface species, two developments are in progress: incorporating a modulated gas composition flow programme and to combine diffuse reflectance Fourier transform infra red spectroscopy (DRIFTS) as a third simultaneous technique.

Detector developments are also important for enhancing acquisition and repetition rates, and considerable progress has been made with the silicon microstrip detector, XSTRIP [38], which offers a repetition rate of 10 s of microseconds. Then very rapid system perturbations may be introduced to try to identify in transients in catalysis.

Acknowledgements

We wish to thank the staff of the ESRF for enabling these experiments and providing access. The technical skills of John James, Melanie Hill, Sebastian Pasternak, and Ralph Wiegel, are gratefully acknowledged, as is the beamline stewardship of Dr Sakura Pascarelli (ID 24). This work was funded under the "Catalysis and Chemical Processes initiative of the EPSRC" and through Long Term Projects for allocation of beamtime by the ESRF. We would like to thank the ESPRC (MAN) and ICI (SGF) for postdoctoral funding and EPSRC for a project studentship (BJ). The technical skills of John James, Melanie Hill, Sebastian Pasternak, and Ralph Wiegel are Gratefully acknowledged.

In-situ Al K-edge Spectroscopy on Zeolites: Instrumentation, Data-interpretation and Catalytic Consequences

Jeroen A. van Bokhoven[1]

Institute for Chemical and Bioengineering, Swiss Federal Institute of Technology (ETH), 8093 Zurich, Switzerland

Received June 26, 2003; accepted November 4, 2003

Abstract

Zeolites are used for a wide variety of reactions, such as cracking and isomerization of alkanes, and for the production of fine-chemicals. Although these catalytic systems are extensively studied, very often structure – activity relations are lacking. Relevant techniques that determine the catalyst structure under catalytic conditions are limited. In many reactions, the aluminum atom is associated with catalytic activity, making an experimental tool that detects the aluminum coordination in a controlled atmosphere extremely valuable. Conventional methods often fail in providing such data.

Developments in instrumentation and data-interpretation enable measurements in controlled gas-atmosphere at elevated temperature at the Al K edge. A thorough theoretical interpretation of the XANES spectra using FEFF8 enables assignment of different aluminum coordinations in the samples. The measurements on zeolitic samples have shown that the aluminum coordination is a subtle function of the precise measurement conditions, which has consequences for interpretation of catalytic data. Moreover, measurements at extreme high temperature show the appearance of unique spectral features that can be attributed to a unique aluminum coordination previously not observed using *ex-situ* techniques.

1. Introduction

Alumina-silicates and zeolites are active in a wide variety of Brønsted and Lewis acid catalyzed reactions. Commercial applications are found in the petrochemical and refining industry [1]. Moreover, they are active in the production of fine-chemicals and intermediates [2] and new applications continue being reported. A unique feature of zeolites is, besides their high activity, the selectivity imposed by the limited sizes of the micropores in the crystals.

Zeolites are built of alumina and silica tetrahedra, forming a three-dimensional crystalline network with pores and cages with sizes in the range of 2–14 Å (vide infra), which equals the size of small molecules [3]. The structure of a zeolite determines its activity and the aluminum atom is responsible for Brønsted and Lewis acid-catalyzed reactions. For this reason, many studies are concerned with the determination of the aluminum coordination in zeolites [4, 5, 6]. The crystal structures of zeolites are well known, however, an active structure is obtained after one or more activation steps that generally consist of steaming and acid or base leaching. Dealumination and stabilization of the framework occurs, thereby partly destroying the crystalline framework and forming framework and non-framework species. An additional complication during the determination of structure/activity relationships is that the catalytic conditions differ from those used in a typical characterization method like ^{27}Al MAS NMR. In principle, X-ray absorption fine-structure spectroscopy at the Al K edge enables these measurements.

This article describes the developments that enable *in-situ* XAS spectroscopy on samples with adsorption edges of energies between $1 < E < 3$ keV. Instrumentation has been developed and implemented at station 3.4 of the SRS Daresbury (UK). Theoretical interpretation of experimental spectra using the FEFF8 code was performed, and fingerprinting of the Al K edge spectra enables the determination of different aluminum coordinations from the spectra. The range of conditions that can be achieved in the developed instrumentation has opened up the possibilities of studying a wide range of edges in the low energy range ($E > 1$ keV) in *in-situ* conditions up to 1000 K in vacuum and 675 K at 1.5 bars pressure. Application to zeolitic systems has provided vital information on the structure of these catalysts in catalytic relevant conditions and during treatment of the material.

2. Experimental

2.1. *Samples*

Zeolitic samples were obtained from Linde and checked for crystallinity with ^{27}Al MAS NMR, X-ray diffraction, and nitrogen physisorption.

NaY (LZ-Y54) was converted into NH_4Y via threefold ion exchange with 1 M NH_4NO_3. Steamed zeolite Y, H-USY, was obtained by calcination of LZ-Y84 at 725 K for 4 h using a ramp of 1 K/min. ^{27}Al MAS NMR showed 100% tetrahedrally coordinated aluminum in NH_4Y zeolite.

2.2. *XAS measurements*

Al K edge XAS measurements have been performed at the SRS, Daresbury (UK), Station 3.4. The synchrotron was operating at 2.0 GeV with an average current of 120 mA. A double crystal scanning monochromator mounted with YB_{66} crystals was used. Measurements were performed in the ILEXAFS set-up [7, 8] that enables treatment of the sample during measurement. The intensity of the incoming photon beam (I_0) is measured by the total electron yield signal of a fine copper or gold mesh. The X-ray energy is calibrated using an aluminum foil, setting the energy at the first maximum of the first derivative to 1560 eV.

2.3. *FEFF8 calculations*

Interpretation of the XANES spectra is performed using the *ab-initio* self-consistent field full multiple scattering code, Feff8 [9, 10]. The output of a calculation includes the X-ray absorption spectrum and the density of states. It is known that multiple scattering within a radius of 15 Å affects the shape of the spectra [11, 12]. A cluster ($HAlSi_{28}O_{78}$) of about 20 Å in diameter was taken from the crystallographic structure of zeolite Y. The aluminum atom is positioned in the center of the cluster. The structure of a three-coordinate aluminum is unknown. Therefore, the structure of three-coordinate aluminum is mimicked by distorting the tetrahedrally coordinated aluminum into threefold coordination [13].

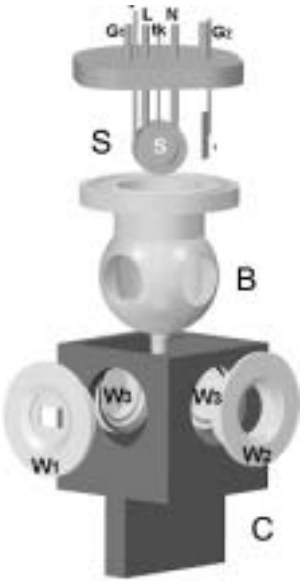

Fig. 1. In-situ cell for measurement of edges of energies $1 < E < 3$ keV; maximum achievable temperature is 1000 K, maximum pressure is 1.5 bar. S is the sample-holder; B is the reaction chamber; and Wx are the window holders.

3. Instrumentation

Figure 1 shows the cell for *in-situ* low-energy X-ray absorption fine-structure (ILEXAFS) spectroscopy [7]. The sample holder (S) is connected to a flange that fits vacuum tight onto a hollow sphere (A). The flange has several gas and electric feedthroughs that enable gas-flow through the sphere and the transport of electric signals: electron yield signal, heating wire, and thermocouple. Two openings in the sphere at an angle of 90 degrees enable the initial X-ray radiation to irradiate the sample and the produced fluorescence radiation to exit the sphere. The sphere fits into a cube (B) onto which window-holders (Wx) are attached that seal the hollow sphere vacuum tight. The entrance window is a supported 7 µm thick beryllium window of 8 × 12 mm. The exit window is spherical with a diameter of 22 mm and thickness of 13 µm. This window holder is integrated in a gas proportional counter fluorescence detector, ensuring a large solid angle for the fluorescence radiation. The *in-situ* cell is mounted in a large vacuum vessel (not shown) onto a (x, y, z) manipulator at beamline 3.4 of the SRS Darebsury (UK). The vacuum vessel has several connectors for feedthrough of gasses and electric signals, in addition to view ports. Specially shielded electrical feedthroughs are used for the measured signals. In the vacuum vessel, a fine metal mesh can be positioned in the initial X-ray beam for measuring the I_{zero} signal.

4. Data-analysis

XAS spectra of compounds with a well-known structure are simulated with the full multiple scattering code FEFF8. Figure 2 shows the large agreement between experimental (left) and theoretical spectra (right) of tetrahedrally and octahedrally coordinated aluminum. All characteristic experimental features are reproduced by theory. The spectrum of a tetrahedrally coordinated aluminum atom is that of a zeolite NH_4Y. The spectrum of an octahedrally coordinated aluminum is that of an aluminum in corund, a crystalline alumina (α-Al_2O_3). Based on these spectra and a large number of spectra from the literature, typical features for different aluminum coordinations

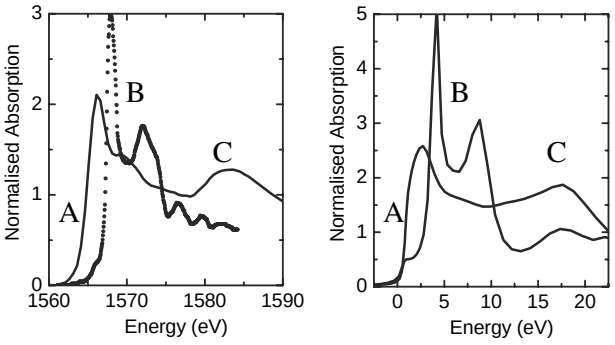

Fig. 2. There is a large agreement between the experimental (left) and theoretical spectra (right). The dotted line represents the data points of the octahedrally coordinated aluminum. FEFF8 reproduces the characteristic features for tetrahedrally and octahedrally coordinated aluminum: A. different energy of the edge; B. characteristic shape of the whiteline, and C. characteristic multiple scattering peaks.

are distinguished as summarized in detail in ref [14]. In the figure, typical characteristic features are emphasized.

From full multiple scattering calculations and symmetry considerations using Extended Huckel theory, the orbital origin of the spectral features has been determined [11, 12]. The spectral region up to about 15 eV above the absorption edge is determined by long-range scattering up to a radius of 15 Å, which originates from hybridization of d-orbitals with the p DOS. The little pre-edge feature that is typically visible in spectra of an octahedrally coordinated aluminum is a non-localized p orbital that contains s and d character. Hybridization of p and d orbitals is allowed when the geometry deviates from an ideal octahedron. Multiple scattering in the first coordination shell of a tetrahedrally coordinated aluminum causes a broad peak at about 20 eV above the adsorption edge. The exact energy position is sensitive to the aluminum oxygen bond length. Other coordinations have comparable peaks at different energies.

The edge position in a spectrum of a tetrahedrally coordinated aluminum is about 2 eV lower than for an octahedrally coordinated aluminum, because of the allowed p,d hybridization in the tetrahedral coordination. Based on symmetry arguments, the core-hole in an octahedral coordination is more shielded, because of the allowed mixing of the aluminum p orbitals with the oxygen p orbitals near the valence band maximum.

5. Zeolite structure in *in-situ* conditions

Figure 3a shows the cages that are typical of the structure of Y zeolite. Figure 3b shows the atomic network in this zeolite, with the tetrahedrally coordinated silicon or aluminum atoms. Due to the lower charge on an aluminum atom compared to silicon, there is a negative charge on the framework for each aluminum atom. Extra-framework cations in the pores or cages of the structure compensated this charge. When protons compensate the charge, a bridging hydroxyl causes Brønsted acidity (figure 3c).

Figure 4 shows the influence of water on the aluminum coordinations in acidic zeolites. Figure 4a shows the room temperature spectrum of H-Y, which is obtained after heating NH_4-Y in the in-situ cell to 675 K in vacuum. The spectrum shows the typical characteristics of tetrahedrally coordinated aluminum. Spectral changes occur under a flow of helium containing 40 mbar water. The differences can be attributed to the presence of a small amount of octahedrally coordinated aluminum [15], covering 8% of the total aluminum content. These measurement conditions

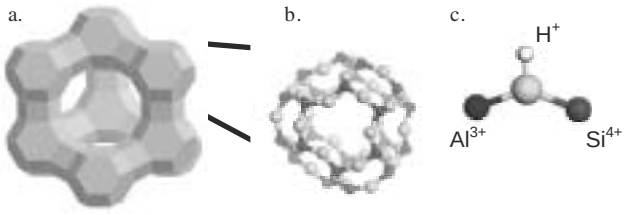

Fig. 3. Schematic view of the pore wall in zeolite Y showing the 12 Å opening; b. atomic connection of the tetrahedrally coordinated Si and Al atoms bridged by oxygen atoms; and c. schematic view of the bridging Brønsted acid hydroxyl group in zeolites.

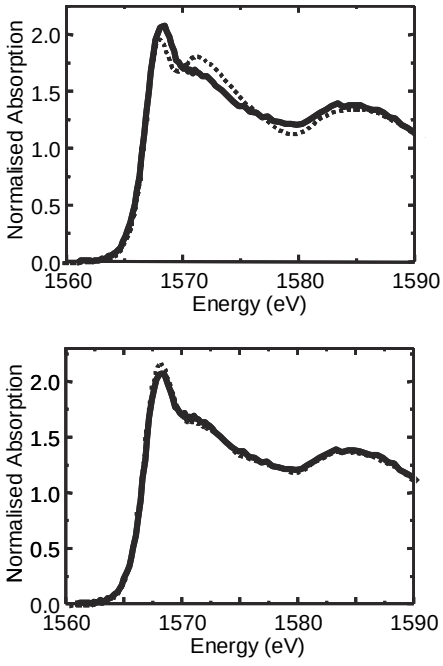

Fig. 4. The spectrum of H-Y zeolite under different measurement conditions: (top) solid line: dry conditions at room temperature; dotted line: wet conditions at room temperature; (bottom) solid line: dry conditions at room temperature; dotted line: wet conditions at 395 K.

resemble those of a typical ^{27}Al MAS NMR experiment, which also showed the presence of about 10% octahedral aluminum [16]. In the spectrum of the same sample measured at a temperature of 395 K (Figure 4 bottom), the characteristics of the octahedral coordination are no longer visible and the octahedral aluminum has converted into tetrahedral. These measurements indicate that the zeolitic aluminum coordination is a subtle function of the temperature and water content present in the pores of the zeolite. Spectra of zeolites Beta (not shown) and H-Mordenite that are taken under identical conditions showed an identical behavior. This indicates that in acidic zeolites a transformation of framework tetrahedral aluminum into octahedral and back occurs easily.

The effect of steaming on the aluminum coordination and its sensitivity to the presence of water and temperature is shown in Figure 5. It shows the spectrum of ultra-stable Y, which is a commercial sample of a steamed zeolite Y measured at room temperature in the presence and absence of water. The large intensity in the range of 5–15 eV above the absorption edge is indicative of the presence of a large amount of octahedrally coordinated aluminum in the sample that is measured in wet environment. When measuring the sample in vacuum, part of the octahedrally coordinated aluminum is transformed into tetrahedral, visible in Figure 5 by a loss of intensity at 5–15 eV

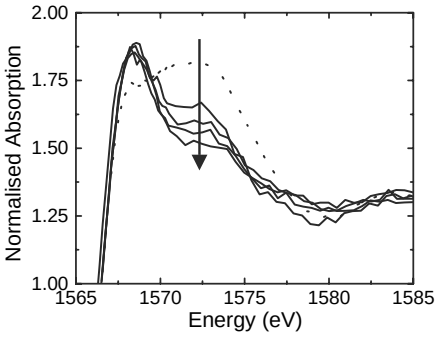

Fig. 5. Al K edge XAS spectra of steamed Y zeolite. The dotted line represents the room temperature spectrum under a flow of wet helium. The solid lines represent spectra taken in vacuum. The temperature increase from room temperature, via 375 K, 475 K, to 675 K.

above the absorption edge and an increase in intensity of the tetrahedral whiteline. Up to 600 K, a transformation of octahedral aluminum into tetrahedral occurs. This differs from the non-steamed sample that showed no octahedrally coordinated aluminum at temperatures higher than 395 K. This indicates that during steaming a different silica-alumina phase is formed in which the octahedrally coordinated aluminum is stabilized.

The spectra of H-USY measured at temperatures higher than 675 K (Figure 6) show a small pre-edge feature at 1565 eV, which is still present after cooling the sample down to room temperature (not shown). Such pre-edge features have been observed for the acidic zeolites that have been measured: Mordenite, Beta and Y. Increasing the temperature enhances the intensity of the pre-edge feature. Full multiple scattering calculations with the FEFF8 code on several large clusters with various aluminum coordinations indicate that a pre-edge feature is indicative of the presence of a non-bonding p orbital. Figure 7 shows the p DOS of a three-coordinated aluminum in a zeolitic structure. A different local geometry of the threefold coordinated aluminum shows small variations in the pre-edge intensity. Also the DOS of a square planar and a square pyramidal coordinated aluminum atom shows a pre-edge feature. However, based on chemical arguments [13], these coordinations are highly unlikely in a zeolitic structure. It is more likely that a partial dehydroxylation of the bridging hydroxyl group occurs, creating a threefold coordinated aluminum. Previously, it was shown that the presence

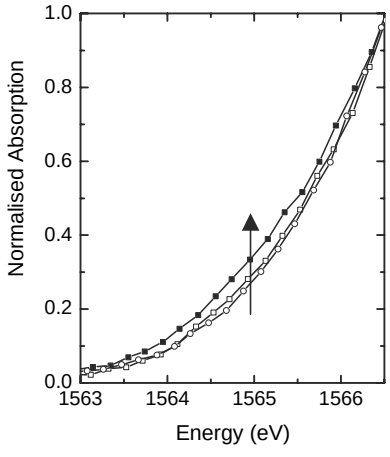

Fig. 6. Pre-edge region of H-USY measured in vacuum at room temperature (◯), 675 K (□), and 975 K (■). At $T > 675$ K, a small pre-edge feature appears. This pre-edge feature is stable after cooling the sample to room temperature, however, disappears after the adsorption of water.

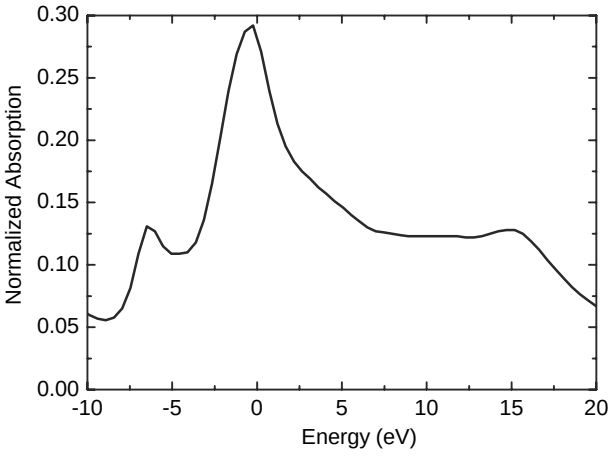

Fig. 7. p DOS of a three-coordinated aluminum, showing a pre-edge feature, which arises from a non-bonding p-orbital. Three-coordinate aluminum is embedded in a large cluster of about 20 Å radius cut from the crystalline structure of Y zeolite. The exact position of the Fermi level determines the intensity of the pre-edge in the X-ray absorption spectrum.

of traces of water annihilates the pre-edge feature, and thus the three-coordinate aluminum. In the meantime, octahedrally coordinated aluminum is created.

6. Aluminum coordinations in zeolites

ILEXAFS measurements on zeolites at the Al K edge provide detailed information about the aluminum coordination chemistry in zeolites. Part of the framework tetrahedral aluminum shows Lewis acid character by coordinating to the Lewis base water. The aluminum coordination thereby changes to octahedral. This process is reversible as function of temperature. It is likely that this process is accompanied by hydrolysis of part of the aluminum oxygen bonds [17]. The ability of framework tetrahedral aluminum to transform into an octahedral has been associated with activity in Lewis acid catalyzed reactions [18, 19, 20]. The Al K edge XAS measurements during controlled conditions provide unique detail on the stability of octahedrally coordinated aluminum in zeolites. Activation of a zeolite by steaming shows a significant amount of octahedrally coordinated aluminum that is transformed into tetrahedral by heating to temperatures above 600 K. It is likely that a non-framework silica alumina phase is formed that stabilizes the octahedrally coordinated aluminum. The formation of a unique aluminum coordination occurs at temperatures higher than 675 K. The exact structure remains to be resolved, however, its coordination is likely threefold. At such high temperatures, dehydroxylation of the framework occurs, which lowers the aluminum coordination to threefold. Low-coordinated aluminum sites are energetically unfavorable and therefore strongly attract water molecules or any other Lewis basic molecule. This process is accompanied by the formation of octahedrally coordinated aluminum, suggesting that these processes are linked. Low-coordinated aluminum, like the threefold coordination observed here, is often associated with Lewis catalytic activity, however, the precise mechanism remains unclear. The Al K edge XAS measurements indicate that traces of water are sufficient to coordinate to the threefold coordinated aluminum. Only the harsh conditions during heat treatment above 675 K may restore the three-coordinate aluminum. During typical reaction conditions in a Lewis catalyzed reaction, traces of water are often present, thus a direct catalytic role of the three-coordinate aluminum is not expected. The role of the three-coordinate aluminum on catalytic activity for this type of reactions may however be indirect via the formation of octahedrally coordinated aluminum. This remains topic of further research.

7. Conclusions

Developments in the fields of instrumentation, data-analysis and theoretical interpretation enable the performance and interpretation of *in-situ* measurements on zeolite catalysts at the Al K edge. The ILEXAFS set-up can be used for measuring X-ray absorption edges in the range of $1 < E < 3$ keV. This covers the K edges of sodium until chlorine and the L edges of the second row of the d block elements. The temperature range that can be achieved is $77 < T < 1000$ K. The fragile windows can withstand a total pressure difference of 1.5 bar at a maximum temperature of 675 K. Structural information on zeolites that is relevant for catalysis has been obtained in ILEXAFS and unique structural changes in zeolitic catalysts are observed under well-defined measurement conditions.

Acknowledgments

Many people have been involved in this work. I would like to explicitly thank the following people for their contributions to this work: Professor D. C. Koningsberger (Utrecht University), A. M. J. van der Eerden (Utrecht University), Dr J. T. Miller (BP), Dr A. D. Smith (SRS Daresbury), and Professor D. E. Ramaker (George Washington University). The SRS in Daresbury (UK) is acknowledged for providing the beamtime under allocation numbers 38108 and 37410.

Abstract

During the past decade, applications of synchrotron radiation (SR) methods to environmental science have grown significantly, resulting in a new interdisciplinary field known as *molecular environmental science*, which focuses on the molecular-level speciation of environmental pollutants and the fundamental chemical and biological processes determining their behavior in complex systems. Here we review some recent applications of XAFS spectroscopy and related SR methods, including micro-XANES and X-ray Standing Wave (XSW) spectroscopy, micro-XRD, X-ray fluorescence micro-tomography, and photoemission spectroscopy to heavy metals and actinides in model systems and more complex environmental samples. Examples include XAFS studies of heavy metals and actinides at environmental interfaces, combined XAFS and XSW studies of heavy metal interactions with microbial biofilm-coated metal oxide surfaces, and combined XANES and photoemission studies of microbial interactions with metal sulfide surfaces.

1. Introduction

Since X-ray absorption fine structure (XAFS) spectroscopy was introduced over 30 years ago as an element-specific local structural probe [1, 2], it has become the technique of choice for determining the local coordination environment of specific elements in solids (both amorphous and crystalline) and liquids at low concentrations, where X-ray and neutron diffraction methods are relatively insensitive. Because of this attribute and the ability to examine samples under *in situ* conditions with minimal preparation, XAFS spectroscopy has become the most important method for determining the speciation of environmental pollutants such as zinc, lead, and arsenic, which are often present in complex, multi-phase, natural samples at concentrations ranging from greater than a weight percent to less than a ppm in a variety of chemical forms, including those in which such elements are sorbed at solid/aqueous solution interfaces [3, 4]. Applications of XAFS and micro-XAFS spectroscopy and other SR methods (micro-synchrotron X-ray fluorescence (μ-SXRF), X-ray standing wave (XSW) spectroscopy, photoemission spectroscopy (PES), and micro-X-ray diffraction (μ-XRD), X-ray fluorescence micro-tomography, scanning transmission X-ray microscopy (STXM), transmission X-ray microscopy (TXM)) to complex environmental samples has led to the development of a new field referred to as *molecular environmental science* (MES) [5–7]. MES is concerned with determining the speciation of environmental pollutants and with understanding the chemical and biological processes that affect their speciation, transformation, sequestration, transport, toxicity, and potential bioavailability. The term *speciation*, as used here, refers to (1) the identity of the element (or elements), (2) its (their) oxidation state, (3) its (their) physical state (*i.e.*, phase association; presence in a liquid, gas, or solid phase (amorphous or crystalline), colloidal particle, animal or plant cell, or biofilm; presence as a surface coating or thin film on a solid, as a sorption complex (monomeric or polymeric) on a solid, colloidal particle, or an organic substance; etc.), (4) its stoichiometry, and (5) its detailed molecular structure. Knowledge of the molecular-level speciation of pollutants is essential for predicting their environmental properties, *i.e.*, their stability, mobility, toxicity, and potential bioavailability to humans and other organisms [5, 8], as well as for designing effective remediation strategies (*e.g.*, [9, 10]).

Because of the complexity of environmental samples, which often contain dissolved and solid phases, including amorphous materials (natural organic matter), as well as biological components (plant matter, fungi, microorganisms), it is essential to conduct SR-based studies of simplified model systems in parallel with studies of natural samples in order to gain a more fundamental understanding of the chemical and biological processes that control the behavior and toxicity of environmental pollutants. This need has led to numerous studies of adsorption processes at environmental interfaces, including interfaces between minerals and microbial biofilm coatings, as well as plant-root/water and microbe/water interfaces [4]. To date, XAFS studies of environmental samples have focused mainly on inorganic pollutants, particularly heavy metals such as Cr, Ni, Zn, Cd, Hg, and Pb, metalloids such as As and Se, and actinides such as U, Pu, and Np. Such elements have relatively high K- or L-edge energies, thus can be studied at low concentrations (currently $\leq$50 ppm with insertion device beam lines on 3rd-generation SR sources) even in strongly absorbing matrices, assuming that spectral interferences are minimal

*e-mail: gordon@pangea.stanford.edu

or can be resolved using solid-state detectors or wavelength dispersive spectrometers. Nonetheless, XAFS studies of organic pollutants and natural organic matter (NOM) are becoming more common using UHV soft X-ray XAFS methods (*e.g.*, [11–13]). Soft X-ray μ-XANES studies by Myneni, in particular, are beginning to reveal the types and distribution of the dominant carbon-containing functional groups in NOM [12]. In addition, soft X-ray XANES spectroscopy methods have been used to characterize sulfur in S-containing coals by Huffman, Huggins, and co-workers [14], Bancroft and co-workers [15], and Fendorf *et al.* [16].

In this paper, we present examples of recent MES research that has utilized XAFS spectroscopy and related methods, such as PES and XSW spectroscopy, to address fundamental issues involving chemical processes at environmental interfaces and in biota. We also present several examples of more applied XAFS and μ-XAFS studies that address the question of speciation of heavy metal, metalloid, and actinide ions in environmental samples. A more comprehensive review of recent SR-based studies of environmental samples can be found in [4].

We begin with a brief discussion of some of the major issues that must be considered in molecular-level studies of complex environmental samples and in simplified model systems designed to mimic natural systems in order to highlight the utility of XAFS spectroscopy and other SR-based methods in such studies.

2. Major Issues in Molecular Environmental Science Addressable by SR Methods

2.1. *Environmental materials are complex, requiring parallel studies of real and model systems and the use of complementary characterization methods*

This issue can be addressed using bulk XAFS, μ-XAFS, and μ-SXRF methods in an element-specific fashion, which is a major advantage over phase-specific methods when the pollutant element of interest is at low concentrations, as is often the case, or is associated with amorphous materials. A given element in different phases often has a XANES or EXAFS spectral signature that makes it possible to identify the phase in which a particular element is located, even when the phase is at a concentration far below that needed for identification by X-ray diffraction ($\approx$1 percent by volume). Linear combination fitting of XANES (*e.g.*, [17, 18]) or EXAFS spectra (*e.g.*, [19, 20]) can be used in cases where the spectra of an element in different phases are unique. μ-XRD is becoming an important complement to XAFS and μ-SXRF to definitively identify crystalline phases and determine the spatial distribution and association of specific pollutant elements with different solids (*e.g.*, [21]). The use of bulk XAFS methods is still essential in such studies, however, because it provides a more statistically significant sample volume in which to identify and quantify the different chemical species of a particular element than μ-XAFS methods. Non-SR-based methods can also provide important information on the speciation of pollutants in environmental samples. For example, the use of analytical transmission electron microscopy can provide important information, complementary to XAFS spectroscopy, on the identification of nanoparticles containing the element of interest (*e.g.*, [22]). In addition, indirect macroscopic methods such as sequential chemical extractions, combined with XAFS spectroscopy, are often essential for distinguishing among different phases with different solubilities that have similar EXAFS signatures for a given element (*e.g.*, [20, 23]).

2.2. *Water and atmospheric or soil gases are ubiquitous in environmental systems*

Because of the presence of water and hydrous phases (*e.g.*, hydrous metal oxides, microbial organisms, plant roots) in environmental samples and the fact that introducing such samples into UHV systems for SEM, TEM, or XPS studies can result in their desiccation, and thus potential changes in speciation, it is desirable to study environmental samples with a minimum of sample preparation under conditions that closely mimic those in a particular environmental setting. Hard X-ray XAFS spectroscopy can be used under such conditions, thus can provide unique information about the speciation of heavy metal and metalloid pollutants under appropriate conditions. It is also possible to carry out soft X-ray XAFS spectroscopy studies of elements like oxygen [24] and carbon [12] in the presence of water using differentially pumped vacuum chambers and photon in-photon out methods.

2.3. *The nature of the solid/water interface and of sorbed species must be known*

Most chemical reactions important in controlling the speciation, transformation, and distribution of pollutant species in the environment occur at interfaces, particularly those involving solids and aqueous solutions [6, 25]. Surface complexation models of various levels of sophistication have been developed [26, 27], based on the Gouy-Chapman-Stern-Graham model of the solid/water interface [28]. Such models allow prediction of the partitioning of solute species from aqueous solutions to solid surfaces under different solution conditions and may be parameterized through fitting macroscopic uptake data. This approach, although very useful, cannot provide a molecular-scale description of the electrical double layer (EDL) or of sorbed species at the solid surface. Instead, direct molecular-level probes are needed to map out the spatial distribution of solute species in the EDL and to identify the types of surface complexes they form as a function of solution conditions. XAFS spectroscopy (see [29] for review), in combination with X-ray reflectivity (*e.g.*, [30]) and X-ray standing wave measurements (*e.g.*, [31, 32]), is capable of providing this type of information.

2.4. *Nanoscale environmental materials play a major role in interfacial chemical reactions*

There is growing recognition that nanoparticles of earth and environmental materials play major roles in environmental processes [33]. This is true because such nanoparticles collectively have immense surface areas and therefore are often a significant, if not dominant, fraction of the reactive surface area available for complexing dissolved species. There is also growing evidence that the structure and properties of nanoparticles change as particle size decreases [34–36]. For example, TiO_2 nanoparticles exhibit differences in photocatalytic reduction of redox-sensitive metals like Cu(II) and Hg(II) in the presence and absence of surface adsorbers like alanine, thiolactic acid, and ascorbic acid relative to bulk TiO_2 [37–40]. These differences are attributed to different surface structures of nanoparticulate *vs*. bulk TiO_2. Using EXAFS spectroscopy, Chen *et al.* [37, 38] found shorter Ti-O bonds and increasing disorder around Ti with decreasing size of TiO_2 nanoparticles. The unique surface chemistry exhibited by nanoparticulate TiO_2 was attributed to

the increasing number of coordinatively unsaturated surface Ti sites with decreasing nanoparticle size. In a similar EXAFS study of nanoparticulate α-Fe_2O_3, surface Fe sites were found to be undercoordinated relative to Fe in the bulk structure and are restructured to octahedral sites when the nanoparticles are reacted with enediol ligands [41].

Nanoparticles play an important role in the transport of heavy metal and organic contaminants in the environment. For example, Kersting *et al.* [42] concluded that colloid-facilitated transport of Pu is responsible for its subsurface movement from the Nevada Test Site in the United States to a site 1.3 km south over a relatively short time period (≈40 years), based on the unique $^{240}Pu/^{239}Pu$ isotope ratios of the samples. EXAFS spectroscopy and μ-SXRF are now shedding light on how Pu and other actinide ions sorb on colloidal mineral particles and undergo redox transformations in some cases [43, 44].

2.5. *Inorganic and organic ligands and coatings can have a major impact on the sorption behavior of metal ions*

There are a number of common natural inorganic ligands (*e.g.*, SO_4^{2-}, PO_4^{3-}, CO_3^{2-}, Cl^-) and organic ligands (*e.g.*, oxalate, citrate, humic materials) that can enhance or inhibit the sorption of metal ions from aqueous solutions onto mineral surfaces. For example, sulfate enhances the sorption of Pb(II) on goethite surfaces over the pH range 5 to 7 due to the reduction of the positive surface charge of goethite at these pH values and the formation of a stable ternary Pb(II)/SO_4^{2-}/goethite surface complex [45]. In contrast, chloride ligands inhibit the sorption of Hg(II) on goethite at similar pH values because of the formation of a stable Hg(II)-chloride aqueous complex [46]. Organic ligands can have similar effects. For example, citrate [47] and malonic acid [48] can enhance the sorption of U(VI) and Pb(II), respectively, onto goethite through the formation of ternary surface complexes, as revealed by EXAFS and FTIR spectroscopy. Combined *in situ* XAFS and ATR-FTIR spectroscopy studies are beginning to reveal some of the molecular-level details of ternary surface complexes involving metal ions, organic (or inorganic) molecules, and mineral surfaces (*e.g.*, [49–51]).

2.6. *Biota can have a major effect on the speciation and sequestration of contaminant and pollutant species*

Many microorganisms and plants can sequester toxic chemical species and transform them into less toxic forms. EXAFS spectroscopy studies of microorganism-metal interactions are beginning to reveal the types of cell-wall functional groups to which metal ions bind [52–61]. For example, in an EXAFS study of the sorption products of Cd(II) and U(VI) on *Bacillus subtilis*, Kelly *et al.* [58] found that U(VI) binds to phosphoryl groups and that Cd(II) binds to carboxyl groups at low pH.

The transformations and sequestration of metal ions in hyperaccumulating plants has also been studied in several systems using XAFS and μ-XAFS spectroscopy (*e.g.*, [62–66]) and X-ray fluorescence μ-tomography [66]. For example, several groups have found that aqueous Cr(VI) is accumulated in and rapidly reduced to Cr(III) in aquatic ferns [62, 63]. In one of the first X-ray fluorescence μ-tomography studies (coupled with XAFS), Hansel *et al.* [66] showed that Pb and As are associated with iron plaque (in the form of ferrihydrite, goethite, and siderite) on plant roots of *Phalaris arundinacea*, a common aquatic plant from a mine waste impacted wetland in the Coeur d'Alene Basin of northern Idaho, U.S.A. Mn and Zn occur as isolated nodules of mixed-metal carbonate (rhodochrosite/hydrozincite) on the root surface. In most cases, the molecular-scale mechanisms of metal transformations or hyperaccumulation by bacteria or plants are unknown.

3. XAFS Studies of Metal Ion Adsorption at Solid/Aqueous Solution Interfaces

Most chemical reactions involving environmental materials take place at interfaces, most importantly solid/aqueous solution interfaces [6, 25]. Although not inherently surface (or interface) sensitive, when the element of interest occurs dominantly at a surface (or interface), XAFS spectroscopy is often capable of providing unique information about the structure and composition of an adsorbate, as well as its mode of attachment to a solid surface (*i.e.*, inner-sphere vs. outer-sphere, mononuclear vs. multinuclear, and (if inner-sphere) monodentate vs. bidentate or tridentate). Because of this capability, XAFS studies have now been carried out on over 200 metal ion/mineral sorption systems (see [4] for a recent review). Here we review the results of two such studies, one on Zn(II) sorption on alumina [67] and one on Au(III) sorption on Fe(III)- and Al-oxyhydroxides [68, 69].

The products of sorption reactions of Zn(II) with high surface area alumina (Linde-A) were characterized by XAFS spectroscopy as a function of Zn sorption density ($\Gamma = 0.2$ to $3.3\,\mu mole/m^2$) at pH values of 7.0 to 8.2 by Trainor *et al.* [67] (see Fig. 1). Over equilibration times of 15–111 hrs and at low Zn sorption densities ($\Gamma = 0.2$ to $1.1\,\mu mole/m^2$), we found that Zn(II) forms dominantly inner-sphere bidentate surface complexes with AlO_6 polyhedra. At higher sorption densities

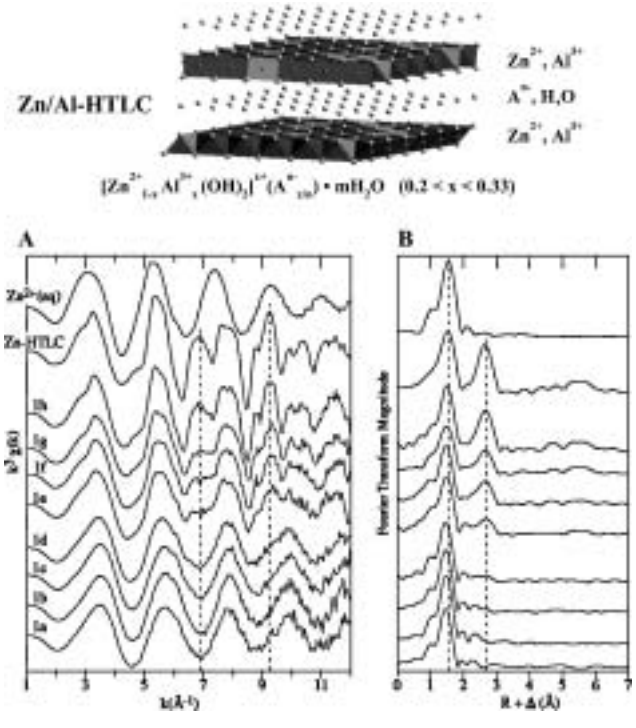

Fig. 1. Zn K-edge EXAFS spectra (k^3 weighted) (A) and corresponding Fourier transforms (B) of Zn sorbed onto high surface area alumina at the following surface coverages (Γ = μmoles m^{-2}): 0.2 (1a), 0.3 (1b), 0.8 (1c), 1.1 (1d), 1.7 (1e), 1.6 (1f), 1.5 (1g), and 3.3 (1h), compared with Zn-hydrotalcite (Zn-HTLC) and Zn^{2+} in a 10 mM $Zn(NO_3)_2$ aqueous solution (Zn^{2+}(aq)) (after [67]). The structure and composition of Zn/Al-hydrotalcite (Zn/Al-HTLC) are shown.

($\Gamma = 1.5$ to $3.5\,\mu mole/m^2$), we found evidence for the formation of a mixed-metal Zn(II)-Al(III)-hydroxide co-precipitate with a hydrotalcite-type local structure. These conclusions are based on an analysis of first- and second-neighbor interatomic distances derived from EXAFS spectra collected under ambient conditions on wet samples. At low Γ the sorption mechanism involves a transformation from six-coordinated Zn-hexaaquo solution complexes (with an average Zn-O distance of 2.07 Å) to four-coordinated surface complexes (with an average Zn-O distance of 1.97 Å) as described by reaction (1):

$$\equiv Al(OH_a)(OH_b) + Zn(H_2O)_6{}^{2+} \rightarrow \equiv Al(OH_{a'})(OH_{b'})Zn(OH_{c'})(OH_{d'}) + 2H_2O + zH^+ \quad (1)$$

where $\equiv Al(OH_a)(OH_b)$ represents edge-sharing sites of $Al(O,OH,OH_2)_6$ octahedra to which $Zn(O,OH,OH_2)_4$ bonds in a bidentate fashion. The proton release consistent with this reaction ($z = a\text{-}a' + b\text{-}b' + 4\text{-}c'\text{-}d'$), and with Pauling bond valence analysis falls in the range of 0 to 2 $H^+/Zn(II)$ when hydrolysis of the adsorbed Zn(II) complex is neglected. This interpretation suggests that proton release is likely a strong function of the coordination chemistry of the surface hydroxyl groups. At higher Γ (1.5 to $3.5\,\mu mole/m^2$), a high amplitude, second-shell feature in the Fourier transform of the EXAFS spectra (Fig. 1B) indicates the formation of a three-dimensional mixed-metal co-precipitate, with a hydrotalcite-like local structure. Al(III) is provided by dissolution of the alumina substrate. Nitrate anions presumably satisfy the positive layer charge of the Al(III)-Zn(II)-hydroxide layers in which the Zn/Al ratio falls in the range of 1 : 1 to 2 : 1. Our results for the higher Γ-value sorption samples suggest that Zn-hydrotalcite-like phases (Zn-HTLC) may be a significant sink for Zn(II) in natural or catalytic systems containing appreciable dissolved aluminum. In section 6, we show evidence for the presence of Zn-HTLC phases in Zn-contaminated soils from northern France.

Another recent example of XAFS applied to sorption reactions at solid/aqueous interfaces involves the study of gold sorption products on powdered ferrihydrite, goethite, and boehmite samples [68, 69]. The samples were prepared by reacting Au(III)-chloride solutions ($[Au] = 3.10^{-3}$–4.10^{-5} M; $[Cl] = 0.02$–0.60 M) with these sorbents at pH values of 4 to 9 and Au sorption densities ranging from 0.046 to $1.53\,\mu mol/m^2$. The speciation of gold was determined using Au-L_{III} XAFS spectroscopy. Several effects observed in the Au L_{III}-edge XAFS spectra, including X-ray beam-induced photo-reduction, multi-electronic excitations, disorder effects, and multiple scattering, would complicate interpretation of the spectra if not accounted for. A combination of methods (spectral deconvolution, principal component analysis, spectral inversion, and wavelet analysis (see [70]) (see Fig. 2) was used to identify and quantify these effects, to characterize the nature of mixed ligands around gold, and to distinguish between multiple-scattering features and features due to next-nearest neighbors in the XAFS spectra.

Analysis of the Au-L_{III} XAFS spectra showed that Au(III) is present as square-planar $Au(III)(O,Cl)_4$ complexes in the aqueous solutions and on the surfaces of the Al/Fe-(oxy)hydroxide sorption samples with dominantly O ligands at pH > 6 and mixed O/Cl ligands at lower pH values [69]. The EXAFS-derived Au-O and Au-Cl distances are 2.00(2) and 2.28(2) Å, respectively, and the magnitudes of the Debye-Waller factors and third cumulants from anharmonic analyses indicate very little thermal or positional disorder around Au(III) in the sorption samples. Iron second neighbors are present around Au in the Au(III)/ferrihydrite and Au(III)/goethite sorption samples, with Au-Fe distances of 3.1(1) and 3.3(1) Å. In boehmite, two sets of Au-Al distances were detected at 3.0(1) and 3.2(1) Å. A reverse Monte Carlo study of the XAFS data suggests the presence of a continuum of edge-shared AuO_4-FeO_6 distances, which cannot be described correctly by a classical model in which only a mean distance is derived. These results indicate that $Au(III)(O,Cl)_4$ units are bonded as inner-sphere, bidentate binuclear and monodentate (corner-shared) complexes with $Fe(O,OH)_6$ and $Al(O,OH)_6$ octahedra on the Fe(III)-(oxy)hydroxide and boehmite surfaces, respectively. No Au second neighbors were detected in any of the sorption samples, except for natural goethite, indicating that gold atoms don't form clusters on the synthetic sorbents under the conditions investigated.

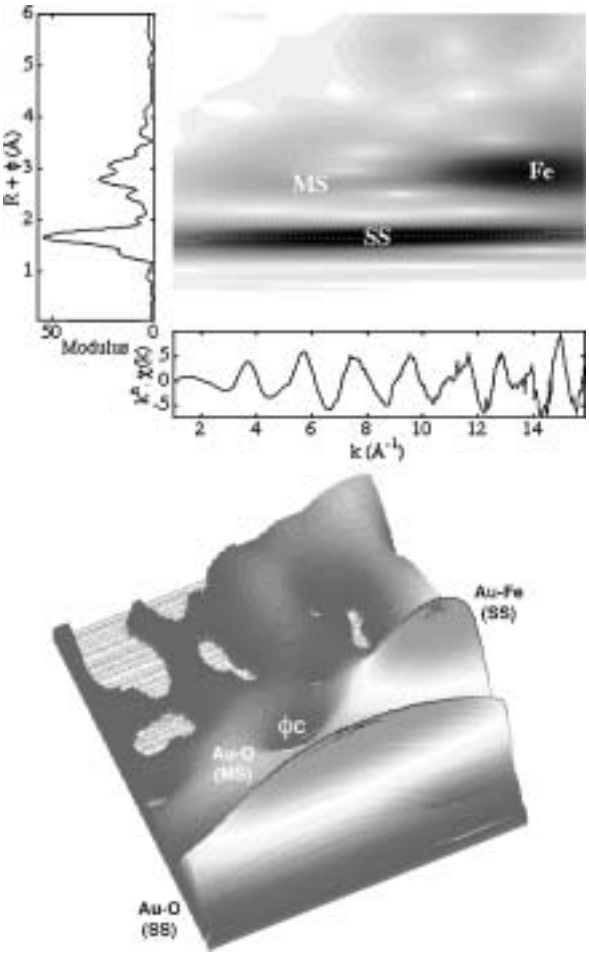

Fig. 2. (a) top: Wavelet Transform (WT) plot for Au(III) sorbed at the goethite/water interface (pH 7.9), with the momentum vector (k) plotted along the abscissa and the direct space distance ($R + \phi$) plotted along the ordinate. (b) bottom: reconstructed surface of the WT, using false gray levels for the WT magnitude. Three types of contributions around Au(III) consist of (1) harmonic Au-O pair correlations, (2) single and multiple-scattering Au-O features, and (3) Au-Fe next nearest neighbor contributions (important to k values of 15.5 Å). The modeled edge for the first neighbors (dotted line) is essentially horizontal, indicating a harmonic Au-O shell of neighbors (from [69]).

4. Effects of Microbial Biofilm Coatings on Metal Ion Adsorption at Metal Oxide/Aqueous Solution Interfaces

Long-period X-ray standing wave (XSW) techniques provide a direct approach for studying the partitioning of metal ions between a single crystal surface and a microbial biofilm coating

[52, 53, 61]. In a long-period XSW experiment, the crystal is used as a reflecting mirror substrate. The interference of the (grazing) incident and specular reflected beams generates a standing wave in the direction normal to the surface. The position and spacing of the standing wave antinodes are determined by the angle of X-ray incidence. As the standing wave intensity field above the mirror substrate is varied by adjusting the X-ray incident angle, a characteristic fluorescent yield (FY) profile is generated from metal ions residing at and above the reflecting surface (*e.g.*, [32]). The FY profiles generated can be analyzed to provide quantitative information on the distribution function of each metal species above the solid-solution interface, thus yield unique information on the relative affinity of each metal species for reactive sites present within the biofilm *vs.* the underlying solid surface.

In a detailed XSW-FY study of heavy metal interactions with biofilm-coated mineral surfaces, Templeton *et al.* [53] measured the Pb L_{III}-edge FY from *Burkholderia cepacia*-coated α-Al_2O_3 (0001) and (1-102) and α-Fe_2O_3(0001) surfaces that had been exposed for 2 hr. to aqueous solutions containing various Pb concentrations (ranging from 1 μM to 60 μM) at pH 6 and an ionic strength of 0.005 M. At a Pb concentration of 1 μM, the FY intensity for the α-Al_2O_3 (1-102) and α-Fe_2O_3 (0001) surfaces peaks at the critical angles of the two substrates (≈160 mdeg and 185 mdeg, respectively, at 14 keV), indicating that Pb(II) is located primarily at the corundum or hematite surfaces at this concentration (Fig. 3). With increasing Pb concentration, the FY peaks show a doublet, with a peak in intensity at the critical angle as well as increasing intensity at ≈60 mdeg for the α-Al_2O_3 (1-102)-coated surface and at about 85 mdeg for the α-Fe_2O_3 (0001) surface. The growing intensity at the lower incidence angles indicates that Pb(II) is also binding to sites in the *B. cepacia* biofilm coating, which increases with increasing Pb concentration. At all Pb concentrations studied, the FY-data indicate that Pb(II) binds primarily to functional groups in the biofilm on the α-Al_2O_3 (0001) sample (Fig. 3).

The results of this study show that Pb(II) binds initially to reactive sites on the α-Al_2O_3 (1-102) and α-Fe_2O_3 (0001) surfaces even with a biofilm coating that covers essentially the entire mineral surface, as shown by SEM and confocal microscopy studies. The order of reactivity of these biofilm-coated surfaces for Pb(II) [α-Fe_2O_3 (0001) > α-Al_2O_3 (1-102) ≫ α-Al_2O_3 (0001)] is the same as that observed in uptake and EXAFS studies of Pb(II) sorption on biofilm-free alumina and hematite surfaces [71–74]. This XSW study also shows that the *B. cepacia* biofilm does not block all reactive sites on the alumina and hematite surfaces and that sites on the α-Al_2O_3 (1-102) and α-Fe_2O_3 (0001) surfaces "outcompete" functional groups in the biofilm (including the exopolysaccharide exhudate) at low Pb concentrations. Although these findings should not be generalized to the interaction of aqueous metal ions with all NOM- or biofilm-coated mineral surfaces, they do raise questions about the generalization that NOM or biofilm coatings change the adsorption characteristics of mineral surfaces (*cf.*, [75–77]), and they are also inconsistent with the suggestion that NOM blocks reactive sites on mineral surfaces (*cf.*, [78]).

When the XSW approach is coupled with grazing-incidence (GI) XAFS and μ-XAFS spectroscopy, it is also possible to determine the speciation of each metal(loid) at separate locations within the sample (*i.e.*, at the mineral surface and within the biofilm matrix). This can be accomplished by taking GI-XAFS data at an incident angle corresponding to the critical angle of the substrate, which is sensitive primarily to the metal(loid) sorbed

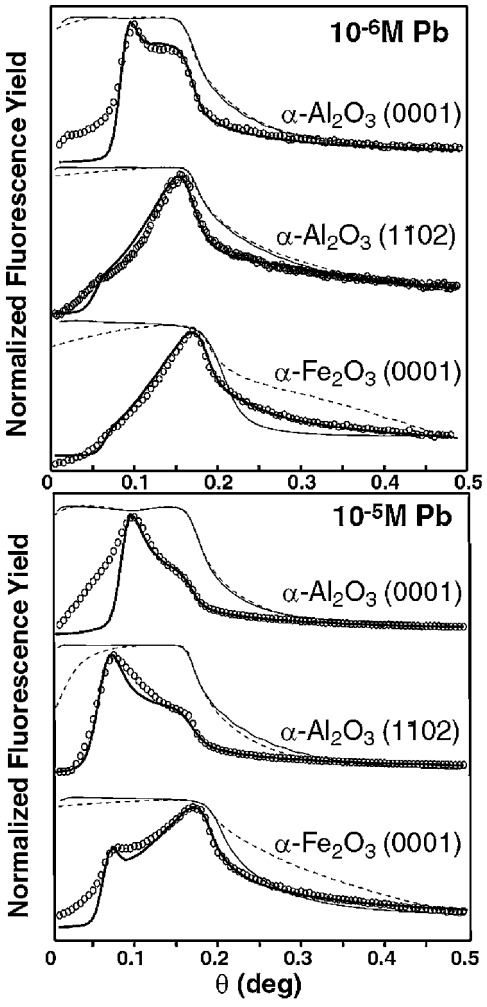

Fig. 3. Measured (dashed) and modeled (light line) reflectivity (log I_0/I_1) profiles and Pb La FY profiles (circles) with model fits (heavy line) for the α-Al_2O_3 (0001), α-Al_2O_3 (1-102), and α-Fe_2O_3 (0001) surfaces at 10^{-6} M and 10^{-5} M [Pb]. Data were taken on SSRL beam station 6-2 (from [53] with permission).

at the mineral surface, and, in separate measurements, at an incident angle corresponding to the lower angle FY peak, which is sensitive primarily to the metal(loid) sorbed in the biofilm. The results of these types of experiments for the Pb(II)-*B. cepacia*-alumina and Pb(II)-*B. cepacia*-hematite systems indicate major differences in the local coordination environment of Pb(II) at these two interfaces [79–82]. This type of spatially resolved speciation information has also been extended to redox processes within biofilms. A combined XSW and GI-XANES study of the reaction of selenate and selenite with *B. cepacia*-coated α-Al_2O_3 (1-102) surfaces has provided unique information about the partitioning behavior of Se(VI), Se(IV), and Se(0) between the biofilms and alumina surfaces. In particular, the angle-dependent Se K-edge XANES measurements show that microbially-induced reduction of selenate leads to a strong vertical segregation of selenium species at the interface, where Se(IV) preferentially binds to the alumina surface whereas Se(VI) and Se(0) accumulate within the overlying biofilms [82].

5. Pyrite Oxidation – A Major Cause of Acid Mine Drainage

The oxidation of pyrite is one of the major causes of acid mine drainage [83], yet the mechanism of this oxidation reaction is not completely understood at a molecular level. A number of studies

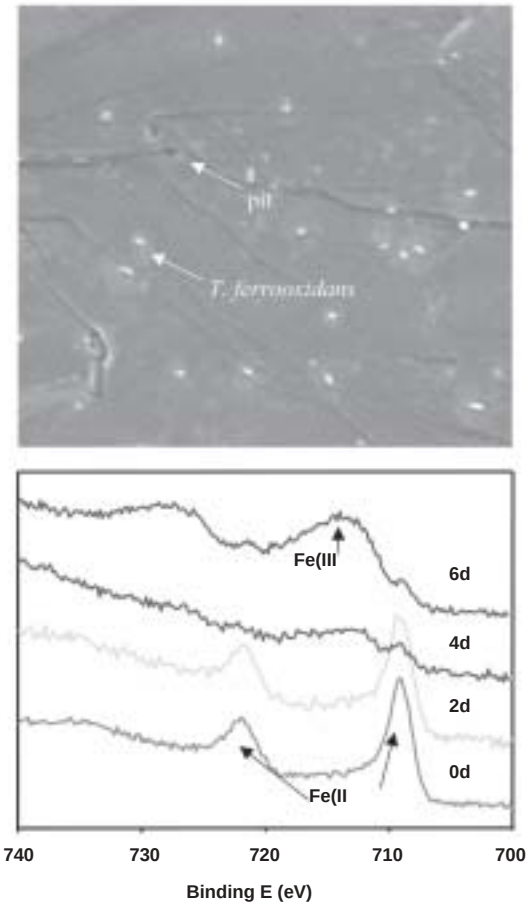

Fig. 4. Top: SEM image of pyrite fracture surface in air showing *Thiobacillus ferroxidans*, after six days of exposure to the bacteria. Halos of oxidized Fe species (identified by Fe 2p photoemission spectra) are visible around the bacteria on a pyrite fracture surface. Bottom: Fe 2p photoemission spectra of Fe of pyrite fracture surfaces after 0 days, 2 days, 4 days, and 6 days of exposure to *T. ferroxidans* (from [84]).

have suggested that various acidophililc, chemolithoautotrophic bacteria (*e.g.*, *Thiobacillus* sp.) catalyze part of this multi-step reaction, resulting in oxidation rates that are one to five orders of magnitude faster than abiotic oxidation rates [83]. We have recently investigated this reaction on natural pyrites before and after exposure to various inorganic oxidants (O_2, As(V), Cr(VI), water, peroxide solutions) and *Thiobacillus ferrooxidans* using ultra-high vacuum SR methods, including O K-edge, S K-edge, and Fe L-edge XANES spectroscopy and S 2p and Fe 2p photoemission spectroscopy [84–86]. Figure 4 shows an SEM image of the pyrite surface after 6 days exposure to *T. ferrooxidans* in air [84]. Small light-colored haloes are visible around each bacterium, suggesting the build-up of some type of reaction product. Fe 2p photoemission spectra (Fig. 4) clearly show that oxidation of iron from Fe(II) to Fe(III) has occurred during this exposure. In abiotic systems following exposure to molecular oxygen, air, water, or peroxide solutions, defective pyrite surfaces (*i.e.*, those with monosulfide groups) show oxidation of both sulfur and iron, resulting in the formation of ferric sulfate coatings, as revealed by O K-edge, Fe L-edge, and S K-edge XANES spectra taken in total electron yield [85] (see Fe L-edge and O K-edge XANES spectra in Fig. 5). However, the build-up of oxidation products at the pyrite surface only proceeds when the oxidant is sufficiently concentrated to facilitate rapid surface oxidation.

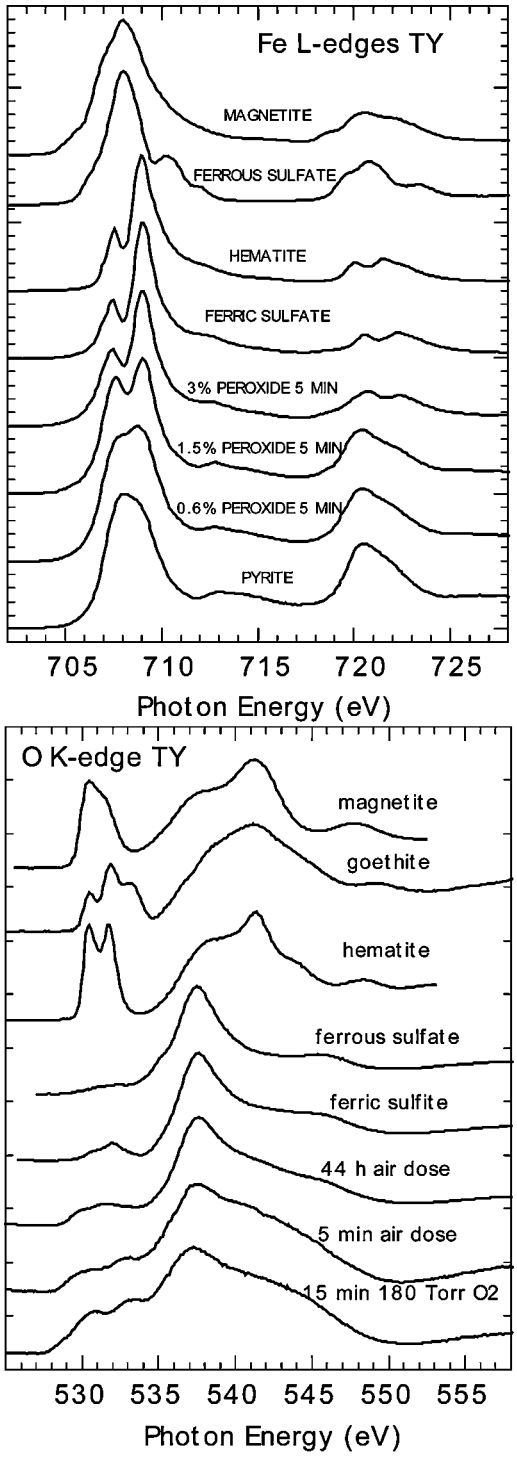

Fig. 5. Fe L_{III}-edge and O K-edge XANES spectra of a fracture surface of pyrite before and after exposure to various inorganic oxidants (O_2, air, and peroxide solutions) compared with XANES spectra of several Fe-containing model compounds (from [85]).

6. XAFS Studies of Metal Speciation in Contaminated Environmental Samples

One of the growing uses of XAFS and μ-XAFS spectroscopy is determination of the major metal and metalloid species present in complex environmental samples (see [4] for recent review). Such contaminants are typically at such low concentrations that conventional XRD (assuming they are in crystalline forms) and spectroscopic methods are of little use in determining their speciation. Here we focus on two recent studies – one on the speciation of zinc in smelter-impacted soils in northern

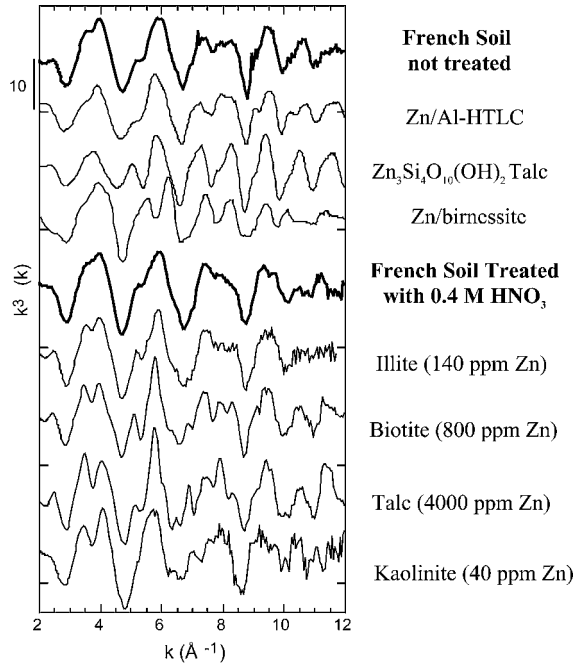

Fig. 6. Zn K-edge EXAFS spectra (background-subtracted and k^3-weighted) of a Zn-contaminated French soil (600 ppm Zn) before and after treatment with 0.4 M HNO_3, compared with EXAFS spectra of various Zn-containing model compounds (after [23]).

France and one on the speciation of uranium in vadose zone sediments beneath high-level waste tanks at the Hanford, WA (USA). In the case of the Zn-contaminated soils from northern France, the study by Juillot *et al.* [23] used a combination of EXAFS spectroscopy, μ-SXRF, XRD, and selective chemical extractions to show that Zn is present as sphalerite (and wurtzite) and Zn(II)-bearing magnetite in the dense soil fraction, whereas it is associated with soil organic matter and present as Zn(II)/Al(III)-hydrotalcite (Zn/Al-HTLC), Zn(II)-bearing phyllosilicate, and Zn(II)-bearing magnetite-franklinite solid solution in the clay fraction (see Figs. 6 and 7). A study by Manceau *et al.* [87] of Zn-contaminated soils from the same locality concluded that Zn is present in the high-temperature phases franklinite ($ZnFeO_4$), willemite (Zn_2SiO_4), hemimorphite ($Zn_4Si_2O_7(OH)_2 \cdot H_2O$), and Zn-containing magnetite-franklinite solid solution based on EXAFS (both powder and polarized) and powder XRD analysis. They also concluded that zinc released during the weathering of these phases is present in the clay soil fraction as "neoformed" Zn(II)-phyllosilicate, Zn(II) incorporated in Fe-(oxyhydr)oxides, and Zn(II) sorbed onto birnessite.

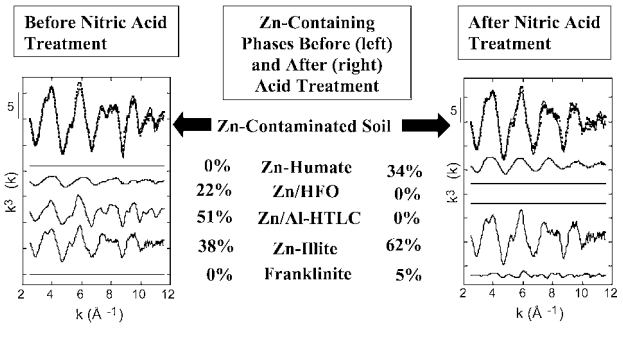

Fig. 7. Results of linear combination fitting of Zn K-edge EXAFS spectra of a Zn-contaminated French soil, showing fit components and the estimated percentages of each component present in the soil before and after nitric acid treatment (after [23]).

The differences in Zn(II) phase association determined in these two studies of smelter-contaminated soils show that in complex phase assemblages, EXAFS data alone may not be sufficient to uniquely identify the types of phases with which a contaminant is associated. In these cases, other complementary methods, such as selective chemical extraction, μ-XRD, and TEM, are needed in combination with EXAFS spectroscopy. For example, EXAFS spectra of these Zn-contaminated soils taken before and after nitric acid treatment are consistent with the presence of a significant amount of Zn/Al-HTLC, in addition to less acid soluble phases such as Zn-containing illite and Zn adsorbed to humic material (Fig. 7) [23].

A recent XAFS study by Catalano *et al.* [88] of uranium speciation in vadose zone sediments beneath the high-level waste tank BX-102 at the Hanford Site in Washington State, USA, where seven to eight metric tons of uranium have been spilled, revealed the dominant U species present. The U L_{III}-edge XANES data clearly show that uranium is in the uranyl form. The corresponding EXAFS spectra of all samples studied are very similar to those of the uranophane group minerals (see Fig. 8 and Table I). However, it was not possible using EXAFS spectroscopy alone to uniquely determine which member or members of this mineral group were present, as the minerals from this group have nearly identical EXAFS spectra. Micro-XRD data taken at the Advanced Photon Source (BL-ID-20) on μm-sized crystals in quartz veins clearly showed that the dominant phase is sodium boltwoodite, which should be less soluble than uranophane in Na-rich Hanford Tank leachates.

7. Conclusions

Synchrotron-based XAFS spectroscopy and related SR methods are contributing a great deal to our understanding of chemical processes that affect the environment, including the speciation of metal and metalloid pollutants, the types of sorption products they form at aqueous solution/solid interfaces, their redox transformations, and their interactions with microbial

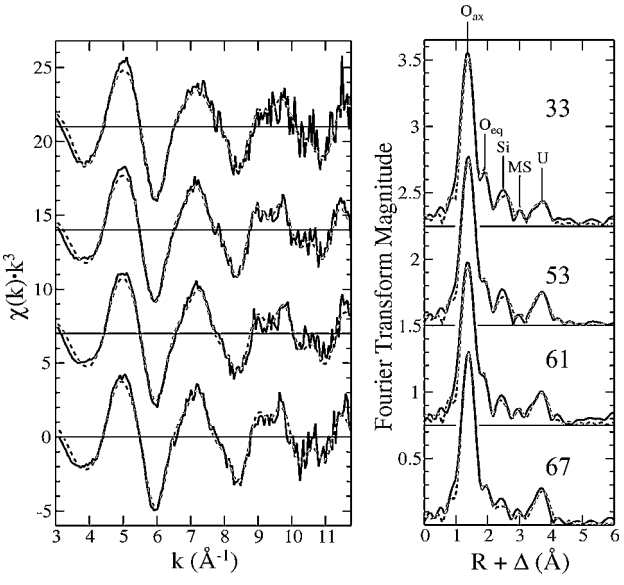

Fig. 8. U L_{III}-edge EXAFS spectra (k^3-weighted) and Fourier transforms for four U-contaminated samples from a borehole drilled beneath Hanford HLW Tank BX-102, showing fits to the data (dotted lines) (from [88]).

Table I. *EXAFS fit results for Borehole 102 sample 61A compared with fit results for boltwoodite [$(K,Na)_2(UO_2)_2(SiO_3OH)_2 \cdot 3H_2O$)] and uranophane [$Ca(UO_2)_2(SiO_3OH)_2 \cdot 5H_2O$], two members of the uranophane group (from [88]).*

Sample	U=O_{ax}	U-O_{eq1}	U-O_{eq2}	U-Si	U-U
61A	2–1.81 Å	2.9–2.29 Å	1.8–2.46 Å	0.9–3.17 Å	1.8–3.94 Å
Boltwoodite	2–1.81 Å	3–2.30 Å	2–2.45 Å	1–3.15 Å	2–3.95 Å
Uranophane	2–1.81 Å	3–2.28 Å	2–2.46 Å	1–3.16 Å	2–3.93 Å

cells, microbial biofilms, natural organic matter, and plants. Micro-XAFS methods are contributing unique insights about the association of heavy metal and metalloid pollutants with environmental materials. With the increasing availability of high brightness synchrotron X-ray sources, it is likely that information on molecular-level speciation of environmental pollutants will be increasingly utilized in making decisions about environmental remediation.

Abstract

We have recently developed a new type of near-edge X-ray absorption fine structure (NEXAFS) technique, "dispersive-NEXAFS" by using energy-dispersed X-rays and a position-sensitive electron-energy analyzer. With this technique a NEXAFS spectrum is taken in a one-shot manner without scanning photon energy resulting in a typical data acquisition time of several tens seconds. This enables to monitor the dynamic surface processes such as film growth and surface reaction. As examples of such applications, we present kinetics studies of catalytic oxidation reactions on the platinum (111) surfaces. Future possible improvements of this technique are also addressed.

1. Introduction

Studies of dynamic molecular processes on solid surfaces have attracted much interest for the fundamental understanding of the phenomena such as surface diffusion, surface chemical reaction and molecular self-assembly formation on substrates, which are closely related to the development of actual systems like catalysts and sensors. A number of time-resolved surface science techniques have been developed in this decade. Fast scanning tunneling microscopy (STM) has successfully provided microscopic information on dynamic surface processes such as diffusion of adsorbates and reaction between adsorbates [1–3]. Vibrational spectroscopies have also contributed to kinetics study on catalytic surface reactions [4, 5]. Furthermore, recent time-resolved experiments using short-pulse lasers have revealed (sub) picosecond reaction dynamics of adsorbates [6, 7].

As for X-ray spectroscopies, combined use of high-flux X-rays from an undulator and the multi-channel electron detection system has enabled X-ray photoelectron spectroscopy (XPS) to apply real time monitoring of surface processes for submonolayer adsorbates in several tens seconds [8–10]. On the other hand, for X-ray absorption fine structure (XAFS) spectroscopy, "energy dispersive XAFS" has been developed by using a curved crystal and a position-sensitive X-ray detector [11]. However, it is a transmission type not applicable to solid surfaces. For surface XAFS, we have to exploit a new method for the study of dynamic phenomena.

Near edge X-ray absorption fine structure (NEXAFS) is a kind of XAFS spectroscopy in the near edge region, mostly applied for the study of surface adsorbates. This is similar to XPS and contains additional information about geometric and electronic structures such as molecular orientation and unoccupied local density of states.

We have recently developed a new version of the NEXAFS technique by combining energy-dispersed X-rays with a position-sensitive electron energy analyzer [12, 13]. With this technique we can measure a NEXAFS spectrum within several tens seconds without scanning the monochromator. Here we present a couple of the applications on dynamic surface processes to demonstrate the potential of this novel technique.

2. Energy Dispersive NEXAFS technique

The energy-dispersive NEXAFS technique has been developed at a soft X-ray bending-magnet beamline BL-7A at the Photon Factory of High Energy Accelerator Research Organization (KEK-PF, Tsukuba). At this beamline, varied-line-spacing gratings are used with a Hettrick-type mount and energy-dispersed X-rays can be obtained by simply opening the exit slit. The energy width of the dispersed X-rays is approximately 12 eV at the sample position around the C K edge with a 150-l/mm grating and 20 eV for the O K edge with a 300-l/mm grating. By combining the energy dispersed X-rays with a position sensitive electron analyzer (GAMMADATA-SCIENTA SES-2002), the energy-dispersive NEXAFS spectra are measured, with which dynamic surface processes can be directly monitored as schematically illustrated in Fig. 1. X-ray absorption-induced Auger electrons are emitted from each position on the sample. Since the Auger electrons are collected on a two-dimensional (2D) detector with distinguishing where they are emitted along the spatially-resolved direction (in our case a horizontal axis), raw data are acquired at once in the form of a 2D image with axes of kinetic-energy vs. position on the sample, that is, photon energy. Integrating the electron counts for a particular Auger-electron energy region and plotting them as a function of photon energy, we can obtain an Auger-electron-yield NEXAFS spectrum in the one-shot manner. By continuous acquisition of the dispersive-NEXAFS spectra, the surface processes are monitored every several tens seconds.

As a typical example of such a monitoring, we present a series of C K-edge dispersive NEXAFS spectra taken during

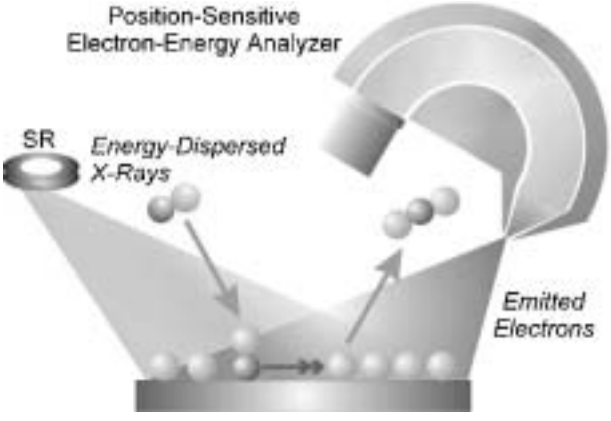

Fig. 1. Schematic illustration for the monitoring of a dynamic surface process with the dispersive-NEXAFS method. The substrate surface is irradiated by energy-dispersed X-rays from the synchrotron ring (SR) and electrons emitted from the surface are analyzed by a position-sensitive electron-energy analyzer with a spatial resolution along one direction on the surface which is parallel to the X-ray energy-dispersed direction.

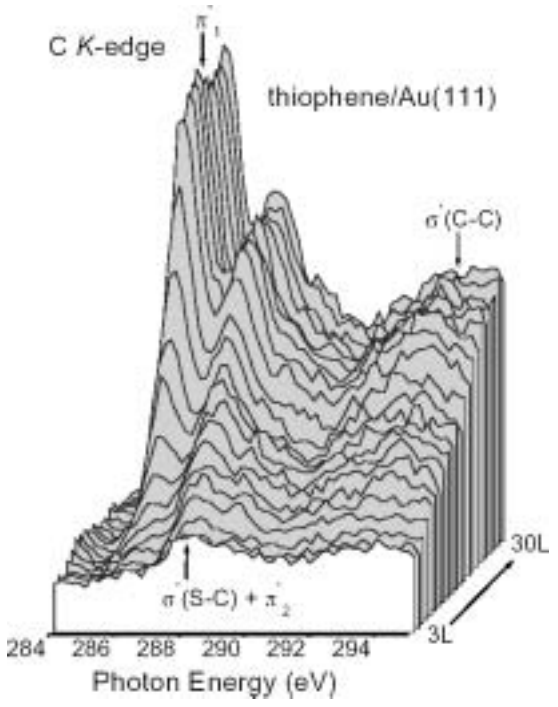

Fig. 2. Time-evolution of C K-edge dispersive-NEXAFS spectra for film growth of thiophene on a Au(111) surface at 140 K under an ambient thiophene pressure of 3×10^{-9} Torr. The accumulation time for each spectrum was 30 s.

thiophene (C_4H_4S) exposure onto a Au(111) surface in Fig. 2. The spectra were taken at the normal-incidence geometry and the accumulation time was 30 s for each spectrum. They were divided by the spectrum from the clean surface taken just before exposure to thiophene to cancel out the effect of inhomogeneous sensitivity of the 2D detector. Two prominent peaks are observed at around 286 and 288 eV, which are assigned to the C1s $\rightarrow \pi_1^*$ and $\sigma^*(C\text{-}S) + \pi_2^*$ transitions, respectively. The ratio between the two peaks changes as exposure increases; the π_1^* resonance is not found at the initial stage, but later it starts to grow and overtakes the $\sigma^*(C\text{-}S) + \pi_2^*$ with increasing exposure. This is because thiophene adsorbs with its molecular plane parallel to the surface until a flat-lying monolayer completes, and then gradually stands up as exposure increases. This adsorption behavior is consistent with results of conventional static NEXAFS measurements [14]. However, it is more clearly seen in the dispersive spectra that the change from the flat-lying configuration to the standing-up one is not like a sudden phase transition but a gradual transformation.

3. Application to dynamic surface processes

3.1. *Catalytic CO oxidation reaction on a Pt(111) surface*

The CO oxidation reaction on oxygen-precovered Pt(111) surfaces ($O_{ad} + CO_{ad} \rightarrow CO_2 \uparrow$) has been considered to be a prototypical example for the site-specific reaction, which shows significant deviations from simple collision theory for a homogeneous mixture of adsorbates. Two distinct models for the active sites in this reaction have been proposed; peripheral sites of 2D islands of oxygen [15] and interior sites of the islands [16]. Atomically-resolved scanning tunneling microscopy (STM) observations supported the former island-perimeter model [2]. Subsequent Monte-Carlo simulations assuming an attractive interaction between adsorbed oxygen atoms [17] successfully reproduced the formation of the oxygen 2D islands and the reaction kinetics obtained from the STM study. From the comparison between the STM and the simulated results, the perimeter-specific reaction was explained in terms of relative destabilization of the peripheral oxygen atoms due to lower coordination numbers of surrounding oxygen atoms compared with the interior oxygen atoms, which decreases the activation-energy barrier resulting in higher reaction probability [17]. This explanation, however, fails to rationalize the presence of "induction period" before the commencement of the oxidation reaction proposed by the STM observations [2], because at the initial stage not a negligible amount of isolated oxygen atoms are diffusing between the 2D islands which should be more reactive due to absence of surrounding oxygen atoms. Although STM provides quite rich information on distribution of adsorbates and their local electronic structures, motions and chemical reactions, it is a drawback that fast diffusing species are often invisible. To elucidate the mechanism of the CO oxidation reaction on the O-precovered Pt(111) surfaces, we have conducted real-time monitoring of this reaction with the dispersive-NEXAFS.

The oxygen-precovered Pt(111) surfaces were exposed to CO at constant surface temperatures to proceed the reaction. By continuous acquisition of the dispersive-NEXAFS spectra for the reacting surfaces, the progress of the reaction was monitored every 37 s. Figure 3 shows a data set of O K-edge dispersive-NEXAFS spectra for the CO oxidation reaction on an oxygen-precovered Pt(111) surface at 240 K under an ambient CO pressure of 1×10^{-8} Torr, which is almost the same experimental condition as used in the STM study [2]. Atomic oxygen and CO give peaks at 530 and 534 eV, respectively, the latter of which increases with time at the expense of the former peak. Time-evolution of both O and CO coverages for the O/Pt(111) surface is shown

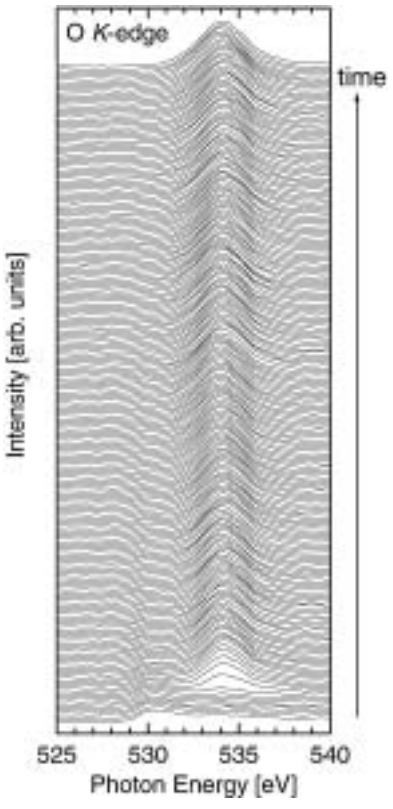

Fig. 3. A data set of O K-edge dispersive-NEXAFS spectra taken for an O-precovered ($\theta_O = 0.13$ ML) Pt(111) surface at 240 K under an ambient CO pressure of 1.0×10^{-8} Torr. The accumulation time was 30 s for each spectrum.

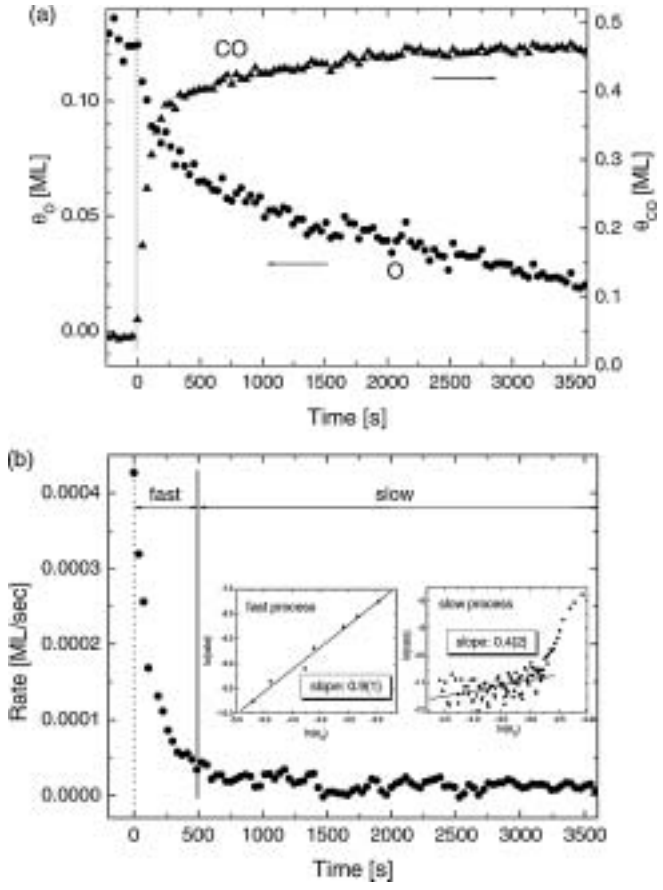

Fig. 4. (a) Coverage change of O (circles) and CO (triangles) as a function of time during the CO oxidation reaction on a O-precovered Pt(111) surface at 240 K. CO exposure was started at $t = 0$ s with an ambient CO pressure of 1.0×10^{-8} Torr. There is no induction period observed at the beginning of CO exposure. (b) Time-dependence of reaction rate. Initially quite a fast process is observed until 500 s, which is followed by a slow process. As shown in the Inset, the former process obeys almost the first-order kinetics with respect to the oxygen coverage, while the latter process exhibits approximately the 1/2nd-order kinetics.

in Fig. 4(a). Contrary to the previous STM results, no induction period is seen at all. The reaction proceeds at the maximum rate at the beginning of CO exposure, which is more evident from the rate vs. time plot shown in Fig. 4(b). The reaction rate rapidly decreases initially and reaches an almost constant rate at around 300 s. Thus, the reaction can be divided into two processes; that is, the initial fast process ($t = 0$–300 s) and the following slow process ($t > 300$ s). In the insets of Fig. 4(b) are depicted results of analyses of reaction order for the two processes. From the slope of the ln$v$ vs. lnθ_O plot the former process can be regarded as the first-order reaction with respect to the oxygen coverage θ_O, while the latter slow process is the 1/2-order reaction. Thus, two distinct processes with different reaction orders operate sequentially. The latter process corresponds to the previously reported perimeter-specific reaction process [17], since the rate of the perimeter-specific reaction should be proportional to the square-root of the oxygen coverage. The former process was newly found by the present in-situ monitoring. The first-order kinetics seen for this process suggests that the reactive species is isolated oxygen or interior oxygen of the islands.

In order to judge which oxygen species contributes to the this process, we have conducted a similar experiment for a O/Pt(111) surface with a different average size of the oxygen islands formed by pre-annealing at 350 K (not shown). The pre-annealed surface exhibited more sharp and intense p(2 × 2) LEED spots indicating a larger average size of the oxygen islands. Compared to the results for the non-annealed surface, the first process is obviously shortened and a smaller amount of oxygen is consumed in this process. The significant suppression of the first process by the pre-annealing indicates that this process is not associated with the interior oxygen but with the isolated oxygen, because such annealing causes an increase in the island size and a reduction of the isolated oxygen. It was confirmed that the reaction order keeps unchanged for the annealed surface.

To get more information about difference between the two processes, activation energies were obtained from temperature dependence of the rate constant. The activation energy for the first process was estimated to be 0.22 ± 0.03 eV, while for the second process 0.32 ± 0.01 eV. The first process exhibits the lower activation energy by 0.1 eV with respect to that for the second process. If the transition states of the both processes are the same, the difference in activation energy is associated with the difference in the initial adsorption energy. Since the interatomic interaction between the oxygen adatoms is known to be attractive [17], the adsorption energy of an oxygen atom is stabilized by coordination of surrounding oxygen atoms, meaning that the difference in effective coordination number causes a difference in adsorption energy. The effective coordination numbers for the island-perimeter atoms is obviously higher than that for the isolated atoms, which results in the lower adsorption energy for the island-perimeter atoms. Thus, the observed difference in the activation energy can be attributed to the difference in coordination number between the isolated atoms and the island-perimeter atoms.

From all the results mentioned above, we conclude that the initial fast process corresponds to the reaction of isolated oxygen atoms whereas the following slow process is the island-perimeter reaction. This reaction mechanism was confirmed by kinetic Monte-Carlo simulations that take accounts of the adsorbate-adsorbate interactions [18]. The former process was found for the first time with the present dispersive-NEXAFS monitoring. The isolated oxygen atoms are diffusing so fast that they might be invisible in the STM observation.

3.2. *Water formation reaction on a Pt(111) surface*

The water formation reaction on Pt(111) is a model reaction for a fuel cell. Adsorbed hydrogen is oxidized by pre-adsorbed oxygen to give H_2O. Although this reaction seems rather simple, interesting findings have been reported for this reaction [3]: First, this reaction is auto-catalytic in the presence of H_2O. Secondly domains of intermediate OH are traveling on the surface during the reaction, which was evidenced by previous STM observations [3, 19]. However, drawbacks in the STM observations are that not all surface species are visible and it provides only information of a limited area. We conducted dispersive-NEXAFS experiments for this reaction to get information on behavior of O, OH, and H_2O on a macroscopic scale, particularly focusing on quantitative detection of the intermediate OH coverage during the reaction [20].

Figure 5 shows oxygen K-edge dispersive-NEXAFS spectra taken for an oxygen-precovered Pt(111) surface with exposing to H_2. The experimental conditions were similar to those used in the STM observation. The oxygen peak decreases with H_2 exposure and instead a broad peak, which comes from both OH and H_2O, grows. Each spectrum was curve-fitted by summation of standard spectra of the three species to estimate the coverages. Coverage

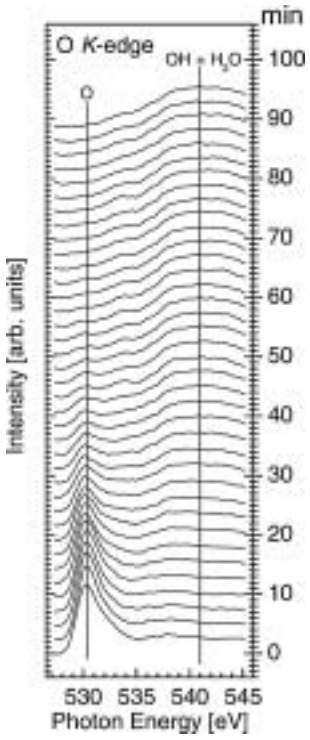

Fig. 5. A data set of O K-edge dispersive-NEXAFS spectra taken for an O-precovered ($\theta_O = 0.25$ ML) Pt(111) surface at 130 K under an ambient H_2 pressure of 5.0×10^{-9} Torr. The accumulation time was 30 s for each spectrum.

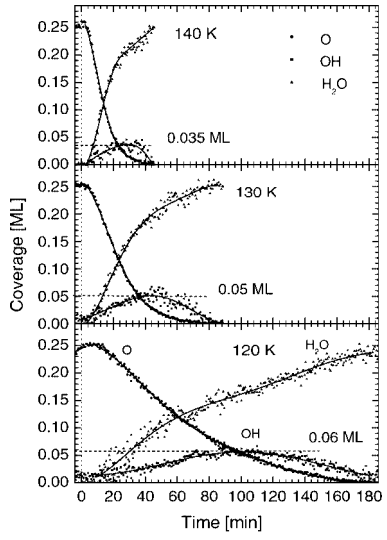

Fig. 6. (a) Coverage changes of O (circles), OH (squares) and H_2O (triangles) as a function of time during the hydrogen oxidation reaction on a O-precovered Pt(111) surface at 140 K (top), 130 K (middle) and 120 K (bottom). H_2 exposure was started at $t = 0$ s with an ambient H_2 pressure of 5.0×10^{-9} Torr.

changes of O, OH and H_2O thus obtained at different temperatures are shown in Fig. 6. The OH coverage gradually increases with time and after passing through a maximum decreases to zero. The total coverage of O, OH, H_2O always keeps constant, indicating that this analysis appears self-consistent. This is the first case that the time-evolution of all the surface species including the reaction intermediate is quantitatively estimated at several temperatures. It is interesting to note that the maximum coverage of OH increases with decreasing temperature.

In order to understand this trend, we performed simulations based on the reaction diffusion model. The elementary steps of the water formation reaction are described as follows:

$$O + H \xrightarrow{k_1} OH, \tag{1}$$

$$OH + H \xrightarrow{k_2} H_2O, \tag{2}$$

$$O + 2H_2O \xrightarrow{k_3} 3OH + H. \tag{3}$$

Since k_1 is very small, the first step can be neglected. The cycle of the second and the third step acts as an autocatalytic cycle which yields one H_2O molecule per cycle. This cycle is driven by diffusion of H_2O to a reaction front. Based on these elementary steps, rate equations are numerically solved using a grid with an assumed initial configuration where a certain number of H_2O nuclei are randomly distributed on the oxygen-saturated surface. A small amount of H_2O molecules are inevitably adsorbed from residual gas [3]. To conduct this simulation, we needed a couple of kinetic parameter values, the rate constants k_2, k_3 and the diffusion coefficient of H_2O D. k_2 and k_3 were estimated by separate dispersive-NEXAFS experiments to be $k_2 = 1.2 \times 10^{-4}$, 4.1×10^{-4} and 1.1×10^{-3} [$ML^{-1}s^{-1}$] and $k_3 = 3.5 \times 10^{-3}$, 1.1×10^{-2} and 3.1×10^{-2} [$ML^{-1}s^{-1}$] at 120, 130 and 140 K, respectively [20], and as for D we referred to the previous STM study [3]. From reaction diffusion simulations using these kinetic parameters, we obtained coverage changes of O, OH and H_2O as a function of time. Simulated results at different temperatures with a fixed number of H_2O nuclei showed no apparent temperature dependence except for differences in overall reaction time (not shown). On the other hand, nucleus-number dependence at a fixed temperature is significant; the higher nucleus number causes the higher OH maximum coverage as shown in Fig. 7. Considering these simulated results, we interpret the temperature dependence of the OH maximum coverage by the difference in initial nucleus density that depends on surface temperature. At the lower temperature the larger number of the H_2O nuclei are

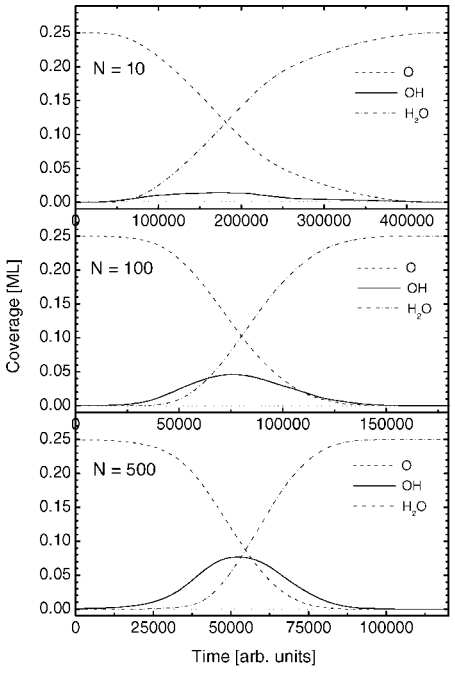

Fig. 7. Simulated coverage changes of O (circles), OH (squares) and H_2O (triangles) as a function of time based on the reaction diffusion model. The temperature was fixed at 130 K, while the number of the initial H_2O nuclei (N) was assumed to be 10 (top), 100 (middle) and 500 (bottom).

formed due to a limited diffusion of H_2O. It is emphasized here that the combination of the dispersive-NEXAFS and the kinetic simulations is a powerful tool to study the mechanism of the surface non-linear reactions as described above.

4. Future improvements

Finally, we discuss future possible improvements of the dispersive-NEXAFS technique. It is necessary for the fast XPS to use the undulator beamline, while the present dispersive-NEXAFS is set up at the bending magnet beamline with a similar performance. If we use a tapered undulator as a light source of the dispersive NEXAFS, we can expect two orders of magnitude higher intensity. Another possible improvement is to optimize the electron analyzer system. The present system uses a commercial electron analyzer which has a high energy resolution, but a small acceptance angle ($\pm 5^\circ$). In fact, we do not need any high energy resolution but need a large acceptance angle. By using an electron energy analyzer fully optimized to this technique, the detection efficiency will be improved by two orders of magnitude. Combined improvement of the photon flux and the detection efficiency will lead to a milli-second order acquisition of a NEXAFS spectrum.

Furthermore, if the improved technique is combined with a chopped X-ray or a gated-ICCD camera and applied to repeatable fast surface phenomena triggered by an arrival of a pulsed molecular beam or other external stimuli such as pulsed light and pulsed electric field, time-resolved NEXAFS experiments will be able to be performed with a microsecond-order resolution. Such a time-resolved NEXAFS technique will provide information on dynamics of surface species such as a transient reaction intermediate, an adsorption precursor and a photosensitive organic molecule adsorbed on a substrate.

Abstract

The timing structure and the high photon flux of X-ray pulses from the Advanced Photon Source permit pump-probe techniques widely used in ultrafast laser spectroscopy to be extended into the X-ray regime. The intrinsic time resolution of the experiments is determined by the FWHM of the single pulses from the synchrotron at 70–100 ps. The challenges and the solutions in such experiments will be discussed. Using laser pulse pump, X-ray pulse probe XAFS, several excited state molecular structures in solutions were studied. We will mainly describe molecular structures of the photoexcited metal-to-ligand-charge-transfer state of $[Cu^{I}(dmp)_2]^+$, where dmp is 2,9-dimethyl-1,10-phenanthroline, in toluene and acetonitrile. The experimental results indicated that the copper ion in the thermally equilibrated MLCT state in both solvents had the same oxidation state as the corresponding Cu(II) complex in the ground state and was found to be penta-coordinate with an average nearest neighbor Cu-N distances 0.04 Å longer in toluene and 0.04 Å shorter in acetonitrile than that of the ground state $[Cu^{I}(dmp)_2]^+$. The results further revealed that what distinguishes the MLCT state structures in non-coordinating and coordinating solvents is not the "exciplex" formation, but the strength of the interactions between the solvent and the Cu(II)* species at the MLCT state. In addition, future direction of time-resolved XAFS will be discussed.

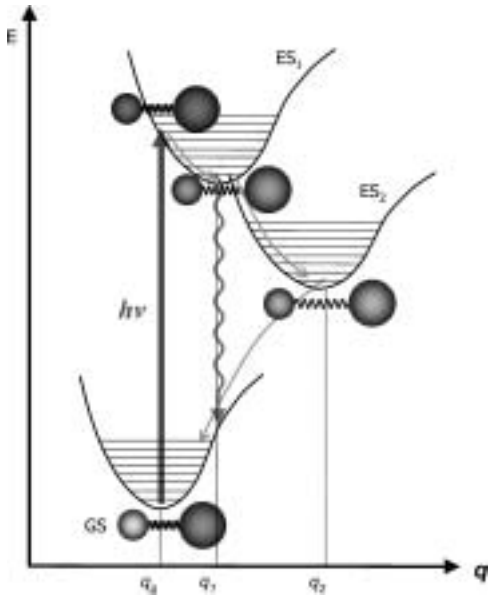

Fig. 1. Interactions between light and molecule. The potential energy E vs. reaction coordinates as the reaction proceeds from excited state 1 (ES_1) to excited state 2 (ES_2). The pump-probe XAFS with 100-ps resolution will capture the thermally equilibrated excited states with the coordinates at the bottom of the potential wells.

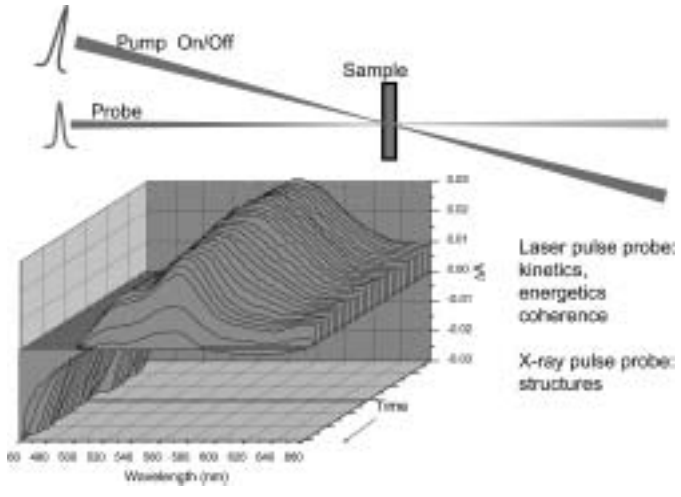

Fig. 2. Illustration of the pump-probe approach. Using laser pulse as a probe, the kinetics, energetics and coherence of the excited state molecules can be obtained. Using X-ray pulse as the probe, we can obtain the direct structural information of the excited state molecules.

Photoexcited molecules are key ingredients for photochemical processes that are important to natural and artificial photosynthesis, photocatalysis, molecular photonics, and devices [1]. In these processes, the excited state molecules are reactants generated by light and are either transformed into products or are vehicles for converting light energy into other forms of energy. The fundamental aspect of the reaction can be understood by the interactions between molecules and light. When a molecule absorbs a photon with energy ranging from ultra-violet to near infrared, its valence electron density is redistributed, and its nuclei experience a new field while retaining the same configuration as the ground state (Fig. 1) [2]. However, within femtoseconds (fs) to a few picoseconds (ps) of the excitation, nuclei of the excited molecule will rapidly adjust themselves to accommodate the new field via structural relaxation to a configuration corresponding to that at the bottom of the potential well in Fig. 1, which differs from the ground state and retains this thermally equilibrated configuration for ps to ms. The pump-probe approach is most commonly used in ultrafast laser spectroscopy, where a laser pulse creates the excited state molecules and another laser pulse probes the optical absorption change due to the pump laser pulse as a function of time delay between the pump and the probe (Fig. 2) [3]. Such an approach allows us to obtain the kinetics, energetics and coherence of the excited states. However, the excited state structures remain elusive, which severely hinders advances in photochemistry.

The Advanced Photon Source (APS) at Argonne provides unprecedented photon flux in each X-ray pulse and timing structures of X-ray pulses [4], which enable the transient structure of the excited state molecules to be probed with an intrinsic time resolution only limited by the pulse duration of the pump or the probe pulse, whichever is longer. In most of the cases, that is the limit of the X-ray pulse duration of ∼30–100 ps. Although it is still too slow for following actual atomic movements from

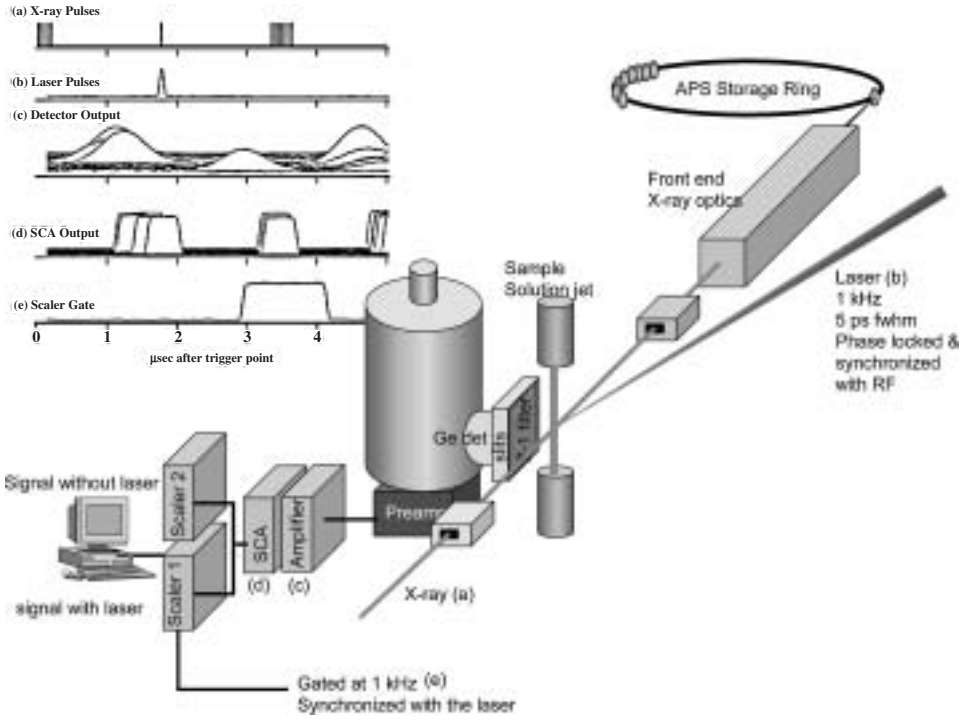

Fig. 3. Illustration of the experimental setup for the pump-probe XAFS. The signals shown in the upper left are marked at corresponding points with the same letter.

the initial Franck-Condon state to the structural relaxed excited state, 100-ps resolution is sufficient for capturing the thermally equilibrated excited state structures with lifetimes from hundreds of ps to ms. Currently, limited information on these excited state structures is available. Because most photochemical reactions take place in disordered media, our studies has been focused on X-ray absorption spectroscopy [5, 6].

Challenges were encountered by the pump-probe XANES and XAFS measurements due to the mismatches in 1) repetition rates of the laser pump and the X-ray probe pulses, 2) the absorption coefficients for optical and X-ray photons, 3) sample concentration preference by XAFS and photochemistry, as well as 4) response times of detectors and the intrinsic time resolution provided by 100-ps X-ray pulses [7]. In addition, the partial conversion of the ground state to the excited state in almost all cases imposes difficulties in extracting an excited state spectrum as indicated by Equation (1),

$$\mu(E,t) = \left[1 - \sum_j f_{es_j}(0)\mathrm{e}^{-k_j t}\right]\mu_{gs}(E) + \sum_j f_{es_j}(0)\mathrm{e}^{-k_j t}\mu_{es_j}(E) \tag{1}$$

where $\mu(E,t)$ is the total X-ray absorption signal, E and t are X-ray photon energy and time, respectively. The subscripts *es* and *gs* stand for the excited and the ground states, and j is the index for the excited states. f_{esj} is the fraction of the jth excited state, and k_j is the decay time constant for the jth excited state. Assuming there is only one excited state and the time of the measurement is zero from the pump, Equation 1 can be further simplified as below,

$$\mu(E) = [1 - f_{es}(0)]\mu_{gs}(E) + f_{es}(0)\mu_{es}(E)$$

where $f_{es}(0)$ is the fraction of the excited state at zero delay between the pump and probe pulses. Therefore, the excited state molecular structure at the optimal concentration can be probed.

In spite of experimental challenges mentioned above, pump-probe XAFS experiments have been carried out at the beamline 11ID-D under the hybrid timing operation mode (Fig. 3), where a single electron bunch or bunch cluster is separated in time from the rest of the electron bunches in the storage ring to satisfy time domain studies and other studies concerning the average X-ray photon flux only. In the first pump-probe XAFS, the structure of a photodissociation intermediate of nickeltetraphenylporphyrin (NiTPP) with two axial piperidine ligands was captured in solution within its lifetime of 28 ns by a sextuplet X-ray pulse cluster with a 14 ns time resolution at 1 mM concentration. The results indicated that the recombination of the ligands was concerted within the time resolution of the experiment and about 30% of the molecules underwent photodissociation. The structure of the photodissociation intermediate had a structure resembled that of the ground state NiTPP without the axial ligands [8].

Following the initial success, we expanded our interests to the real photoexcited state molecules other than reaction intermediates. The metal-to-ligand-charge-transfer (MLCT) states of metal complexes are essential for many photochemical reactions, where the electron is depleted from the metal center and transferred to the ligands upon absorbing light by the molecule. Such an intra-molecular electron transfer creates transient change in the oxidation state of the metal. Consequently, such an electron movement could induce nuclear rearrangement in the MLCT state. Pump-probe XAFS measurements with 100-ps time resolution obtained by using single X-ray pulses from the APS during the hybrid fill operation were conducted to investigate structural origins of the MLCT excited state behavior of $[Cu^{I}(dmp)_2]^+$ (dmp = 2,9-dimethyl-1,10-phenanthroline), which is strongly solvent dependent [9, 10]. Absorption of a visible photon promotes an electron from Cu^{I} to one of the ligands, achieving an intra-molecular charge separation with a Cu^{II*} center coordinated to one reduced and one neutral dmp ligand. The initial Franck- Condon MLCT state has an identical pseudo-tetrahedral

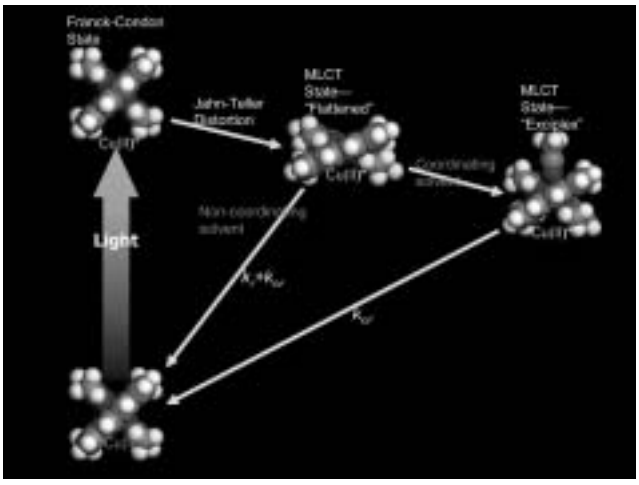

Fig. 4. Previously accepted photoexcitation pathway for $Cu^{I}(dmp)_2{}^{+}$, where only a coordinating solvent molecule would form "exciplex" that causes quenching of room temperature luminescence and shortened lifetime for the MLCT state, but a non-coordinating solvent molecule would not form the complex with copper resulting in a much longer lifetime of the MLCT state and room temperature luminescence.

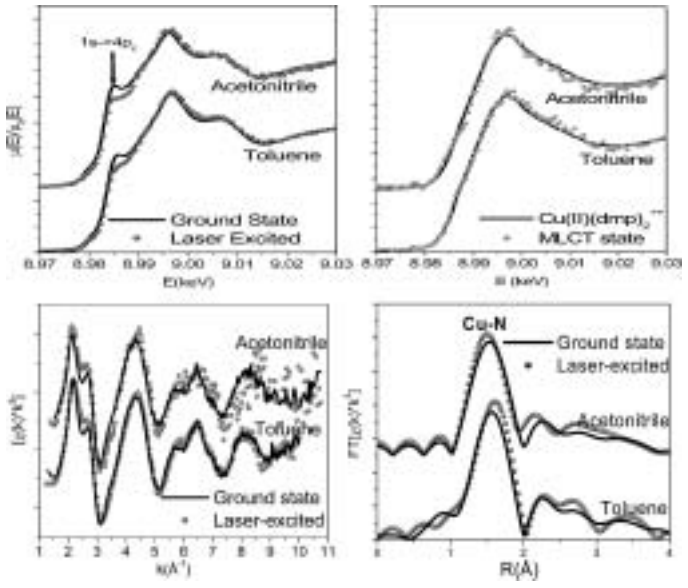

Fig. 5. XANES and XAFS of $Cu^{I}(dmp)_2{}^{+}$ in coordinating solvent acetonitrile and non-coordinating solvent toluene, with and without laser excitation.

coordination geometry as the ground state, but the Cu^{II*} center with a d^9 electronic configuration is susceptible to a Jahn-Teller distortion resulting in a MLCT state with flattened tetrahedral coordination (Fig. 4). In non-coordinating solvents, such as toluene, the MLCT state is luminescent at room temperature and has lifetimes up to 100 ns. In contrast, the MLCT state is almost non-luminescent and has lifetimes as short as 1–2 ns at room temperature in strongly coordinating solvents, such as acetonitrile. The large "Stokes-like" shift observed between the absorption and emission is consistent with significant structural changes in the MLCT state that either returns to the ground state via a radiative decay pathway in non-coordinating solvents, or forms a penta-coordinate complex with a strongly coordinating solvent molecule, resulting in the "exciplex" quenching.

Transient optical spectra with fs time resolution were also measured in a coordinating solvent acetonitrile and in a non-coordinating solvent toluene respectively, revealing three time constants in the excited state dynamics in each solvent. The first two fast time constants of 500–700 fs and 10–20 ps are similar in both solvents, but the third time constants are 1.7 ns in acetonitrile and 100 ns in toluene, about 60-fold difference! The optical transient absorption data suggest that the sub-ps time constant is due to the formation of the triplet state via the inter- system crossing and the 10 ps time constant is due to the structural flattening of the tetrahedral coordination in the excited state. Because these two time scales are beyond reach of the current X-ray probe with single pulses, the pump-probe XAFS was carried out to investigate the structures of the thermally equilibrated MLCT state with 1.7 and 100 ns lifetimes, respectively.

Laser pulses at 527 nm were used to excite the copper complex, and differences between the XANES spectra of the ground state and the laser excited $[Cu^{I}(dmp)_2]^{+}$ in acetonitrile and in toluene are clearly visible in Fig. 5. The shoulder feature at 8.985 keV was reduced upon laser excitation, accompanied by a slight increase of the peak intensity at 8.996 keV. After subtracting the 80% remaining ground state spectrum respectively from the laser illuminated sample spectra in both solutions, the MLCT state XANES spectra were extracted in both solvents. In both cases, the shoulder feature for the ground state $[Cu^{I}(dmp)_2]^{+}$ is missing in the MLCT state, and the transition edge is shifted by about 3 eV to the same edge energy as the ground state $[Cu^{II}(dmp)_2]^{2+}$ obtained via *in situ* electrolysis of $[Cu^{I}(dmp)_2]^{+}$ in acetonitrile. The shoulder feature at 8.985 keV is due to the $1s \rightarrow 4p_z$ transition that is pronounced in $[Cu^{I}(dmp)_2]^{+}$ and missing from $[Cu^{II}(dmp)_2]^{2+}$. This is a typical observation for transformation from 4- to 5- or 6-coordinate geometry.

The copper coordination number and the Cu-to-ligand bond lengths for the MLCT state of $[Cu^{I}(dmp)_2]^{+}$ were extracted from the XAFS data. Interestingly, the Cu-N peak shifts to a shorter distance in acetonitrile, but to a longer distance in toluene, compared to the average Cu-N distance at 2.07 Å for the ground state. The average Cu-N distance for the laser-excited sample in acetonitrile fits distances of 2.07 and 2.03 Å, whereas that in toluene fits distances of 2.06 and 2.11 Å, while keeping the relative ratio of the two distances to 4:1. Clearly, the first Cu-N distance is from the ground state, and the second, the MLCT state. The results of the experiment demonstrated: 1) light excitation generated a formally Cu^{II*} center, 2) the inner-sphere reorganization changed the coordination number of the MLCT state from four to five in presumed non-coordinating toluene, and 3) the average Cu-ligand bond distances lengthened in the MLCT state in toluene, but shortened in acetonitrile.

The XANES spectra provided strong evidence for the penta-coordinate Cu^{II*} in both acetonitrile and toluene. These results are in accordance with the fact that Cu^{II*} in the MLCT excited state is formally a 17 electron d^9 system prone to the addition of a fifth ligand. It is well-known that MLCT excited states in general follow the energy gap law that the non-radiative rate constant increases exponentially with decreasing energy separation between the ground state and the excited state. The formation of the "exciplex" stabilizes the MLCT state, reducing the energy gap between the ground state and the MLCT state. As the energy gap becomes small enough due to the strong interaction of the Cu center with the ligand, the non-radiative decay dominates the relaxation pathway and no emission is detected (*e.g.*, as in the acetonitrile solution case). However, the above statements are unable to explain the solvent dependency of the MLCT state behaviors.

The XANES results for $[Cu^{I}(dmp)_2]^+$ in both toluene and acetonitrile solutions support the formation of a penta-coordinated Cu^{II*} center in the MLCT state based on the attenuation of the shoulder feature in the transition K-edge of copper in the spectra. However, a broad range of the Cu-to-ligand bond distances for the fifth ligand could smooth the transition edge as seen in previous studies. The respective elongation and the shortening of the average Cu-N bond distance for the MLCT state of the $[Cu^{I}(dmp)_2]^+$ in toluene and in acetonitrile signal the difference in the interactions of the copper with the fifth ligand. Such variation was also seen by a broad range of the MLCT state lifetimes in various Lewis base solvents with different electron donating capabilities. The variation of the MLCT state structure in different solvents confirmed that the origin of distinctly different excited state behavior is due to formation of MLCT state-solvent complexes with different electronic interactions. When the interaction is strong, the MLCT state lifetime is shortened significantly and the luminescence is quenched, which has been characterized by the "exciplex" formation in previous literature. Therefore, the pump-probe XAFS measurements in the time domain provide new insights into the fundamental aspects of structural factors that may influence photoinduced electron and energy transfer processes.

Abstract

For local structure and electronic state analyses of electron trapping centers, we developed a site-selective X-ray absorption fine structure (XAFS) measurement, i.e., the capacitance XAFS method. The concept of the capacitance XAFS measurement is based on the fact that the X-ray absorption of trapping centers, not the bulk, can be evaluated from the capacitance change due to X-ray induced photoemission of a localized electron. With this method, micro spectroscopy can be achieved by scanning probe detection of the capacitance. Moreover, trapping centers with a specific eigen-energy can be selectively observed by controlling the sample bias voltage. We tested these advantages in detail for two typical metal and semiconductor systems. (1) The capacitance XAFS spectrum of Cu indicated two-dimensional (2D) electronic states at a hetero interface between native oxide (Cu_2O) and bulk Cu; the Cu 4pπ states of the electron trap were confined into a 2D plane. (2) The capacitance XAFS spectrum of GaAs depends on the sample bias voltage and on selectively indicated electronic states of surface trapping center due to Ga oxide, which captures electrons at a positive bias voltage.

1. Introduction

X-ray absorption fine structure (XAFS) measurement [1, 2] has already been established as an experimental technique for analyzing local structures and electronic states. One advantage of this method is that local information of a specific atom can be obtained even when the atom is incorporated into a compound, because XAFS oscillation appears around the inner-shell absorption-edge energy intrinsic to individual atoms. However, the fact that local information is derived from macroscopic absorption implies the structural homogeneity of the sample. When the sample is heterogeneous with various local structures dependent on their chemical environments, only rarely can the spectrum be deconvoluted into spectra of common structures, so a significant analysis is generally impossible. However, heterogeneous systems are not only common but also of interest to current material science. For instance, defect, hetero interfaces or nanometer-scale quantum structures provide optical luminescence at industrially profitable wavelengths and a high electron mobility applicable to active devices in a central processing unit [3–5]. Therefore, many efforts have been made to fabricate well-defined heterogeneous structures with nanometer-scale precision [6]. Obviously, the applicability of the XAFS measurement method to nanotechnology is restricted if the sample needs to be homogeneous.

High spatial resolution measurements are one candidate for evaluating heterogeneous systems. However, generally speaking, the X-ray beam size and the emittance are large, and focusing on a nanometer-scale object is not easy because of the high transmittance and low refractive index of the X-ray [7]. Though precise focusing optics represented by a Fresnel zone plate have been developed for X-ray microscopy [8], they are not suitable for spectroscopy accompanied with photon energy scanning.

Recently, we proposed a new XAFS measurement method, called capacitance XAFS [9, 10]. Since in this method X-ray absorption is evaluated by a capacitance change caused by X-ray induced photoemission of a localized electron, it can achieve a site-selective XAFS analysis of the specific atoms with the localized electron. Considering that the target characteristics of the heterogeneous system are obtained by confining electrons in a nanometer-scale region, the capacitance XAFS measurement method has the potential for selectively observing optically and electronically active sites in heterogeneous systems [11, 12].

Moreover, we can take microspectroscopic measurements by using the capacitance XAFS method with a metal scanning probe as the electrode facing a sample becomes a local capacitor. The observation area can be conceptually narrowed down to the probe size rather than the X-ray beam size; the focusing optics is not necessary.

In this report, we discuss two experimental results of capacitance XAFS measurements of a nanometer-scale thickness native oxide layer (1) on a metal (Cu_2O/Cu) and (2) on semiconductor (GaO/GaAs). Though the basic idea for the measurements is the same in both systems, the photoemission process of the localized electron depends on their valence states. We propose electron transition models for the site selectivity in metal and semiconductor systems, and we discuss the chemical properties of the trapping centers obtained by the site selectivity.

2. Capacitance XAFS measurement of a Cu_2O/Cu system

2.1. *Experiments*

Figure 1(a) shows the schematic diagram of an experimental apparatus for the capacitance XAFS measurement of metals. A sample is mounted in an insulator cell, and it is also electrically isolated by a polymer film (poly vinylidene chloride) and a glass plate each on the front and the rear surfaces. A capacitor was formed by placing grounded Al foil parallel to a metal electrode on a capacitance detector. A synchrotron radiation (SR) beam was irradiated into the sample surface through the Al foil and the poly vinylidene chloride film. The films were 15 and 10 μm thick, respectively; any attenuation of the SR beam by these layers is negligible. The incidence angle of the SR beam was normal to the sample surface ($\theta = 90^\circ$), and the electric and magnetic fields were polarized in the sample surface plane. The experimental

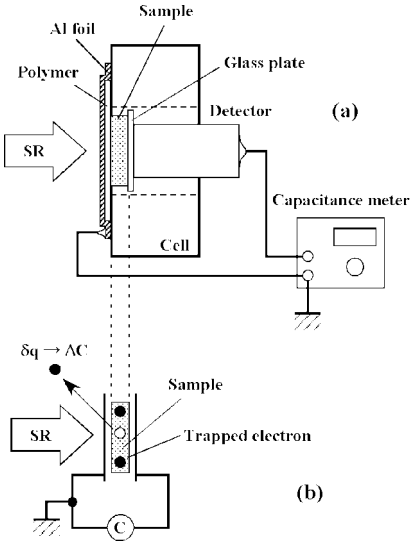

Fig. 1. (a) Schematic diagram of experimental apparatus for a capacitance XAFS measurement of metals. (b) Equivalent circuit of (a).

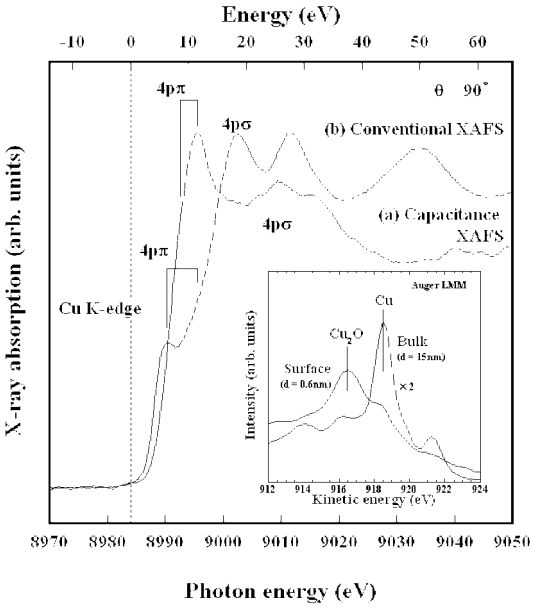

Fig. 2. Capacitance XAFS spectrum of Cu sheet at K-edge (8984 eV) and XAFS spectrum of reference Cu foil measured by using the conventional transmission XAFS method. The inset shows a Cu Auger *LMM* transition peak at the bulk and the surface of the Cu sheet.

setup including the sample made up an electric circuit, which can be equivalently expressed by Fig. 1(b). The sample can be considered as an insertion in the capacitor. Therefore, the electric charge on the sample can be detected by a capacitance meter. In this study, a 500 µm thick polycrystalline Cu sheet was used as the sample. The X-ray induced photoemission of the electron from a trapping center, δq, resulted in a capacitance variation, ΔC. The trapping center is not specified in this figure. However, considering that free charge compensates δq in the Cu bulk, ΔC with respect to the X-ray photon energy indicates the XAFS spectrum of the trapping center. The detailed electron transition process dependent on the sites in the sample is discussed in sections 2.2 and 2.3.

The capacitance XAFS experiments were performed at SPring-8 BL10XU High-Brilliance XAFS Experimental Station [13, 14] in Hyogo Prefecture, in Japan. In this beamline, a high-intensity and quasi-monochromatized SR beam can be obtained from an in-vacuum undulator [15] set in a storage ring. A Si (111) double crystal was used to monochromatize the SR beam. The undulator gap was controlled synchronized with the Bragg angle of the monochromator to maintain the high-intensity SR beam over the wide photon energy range for the XAFS measurements. A rhodium-coated double-mirror positioned after the monochromator eliminated the higher-order X-rays such as third harmonics. The X-ray incidence angle to the double-mirror was fixed at 3 mrad.

2.2. *Results*

Figure 2(a) shows the capacitance XAFS spectrum of the Cu sheet at Cu K-edge (8984 eV). As a reference, an XAFS spectrum of Cu foil evaluated by a conventional transmission XAFS method is also indicated in Fig. 2(b). The spectroscopic structure at the edge energy is mainly caused by resonant electron excitations from the Cu 1s inner-shell to Cu 4p unoccupied states, and it thereby reflects the chemical bonding states such as 4pπ and 4pσ. As shown in this figure, the capacitance XAFS spectrum is obviously different from a conventional one. The absorption edge is shifted to a higher energy side by approximately 2 eV in the capacitance XAFS spectrum. Moreover, resonant peaks related to 4pπ in the capacitance XAFS spectrum are significantly enhanced, while another resonance produced by 4pσ is relatively suppressed. These results strongly suggest that the spectrum (a) shows electronic states of a specific site different from the Cu bulk, because the reference spectrum (b) indicated a Cu bulk site.

We used X-ray photoelectron spectroscopy (XPS) employing ESCALAB 250 produced by VG for a more detailed characterization of the sample. Al Kα (1453.6 eV) was used for sample surface excitation. The depth profile of the chemical composition was measured by in-situ Ar ion sputtering during the XPS measurement. The inset of Fig. 2 is the XPS spectra of the sample Cu sheet. We found that the Cu Auger *LMM* transition peak depends on the depth from the sample surface. An intense peak at a kinetic energy of approximately 919 eV is obtained at depth $d = 15$ nm, which originates from the Cu bulk. However, another peak at approximately 917 eV indicating that Cu_2O is dominant at the sample surface ($d = 0.6$ nm). These results indicate that Cu_2O covers the sample surface as a native oxide. CuO, which can be identified by a Cu $2p_{3/2}$ XPS peak, was not found in our sample. The thickness of the surface Cu_2O is estimated to be approximately 3 nm from a detailed depth-profile measurement. This result provides another possibility that the capacitance XAFS spectrum in Fig. 2(a) corresponds to Cu_2O. However, the capacitance XAFS spectrum indicated by Fig. 2(a) is also different from the previously reported Cu_2O XAFS spectrum [16], which has a sharp pre-edge peak of 4pπ and strong absorption of 4pσ at approximately 20 eV above the K-edge energy.

The capacitance XAFS spectrum that is not a result of either bulk Cu or surface Cu_2O is considered to indicate the local electronic state of the Cu/Cu_2O interface. The electron trapping center is formed at this Cu/Cu_2O hetero interface because an electron lone pair is produced. In this two dimensional (2D) trapping center, the strong σ-bond in the vertical direction cannot be formed by discontinuous atomic arrangement. Consequently, Cu $4p_z$ orbital tends to be confined into the 2D plane, and the π-bond, not the σ-bond, becomes dominant. Confining $4p_z$ should also enhance the degeneracy with the $4p_x$ and $4p_y$ orbitals in the plane, yielding the intense 4pπ peak as shown in Fig. 2(a).

Moreover, the absorption edge shift of by approximately 2 eV to the higher energy in the capacitance XAFS spectrum indicates an increase in the ionic number of Cu. We know that though the absorption edge energy of Cu^0 and $Cu^{1+}{}_2O$ is almost the same, that of $Cu^{2+}O$ is abruptly shifted to higher energy [16]. It is consistent with the 2D trapping center model, because a CuO-like structure is expected to form at the Cu/Cu_2O hetero interface. Therefore, we can conclude that the capacitance XAFS spectrum shows the CuO-like structure as the origin of the trapping center.

Note that the Cu atom is included in all areas, i.e., the Cu bulk, the CuO-like trapping center, and the Cu_2O native oxide. The conventional XAFS measurement using a normal X-ray incidence gives local information of the dominant absorption area, i.e., the Cu bulk. The capacitance XAFS method can only observe a specific site, the Cu-O like trapping center with a sub-atomic layer thickness. The electron transition process in the capacitance XAFS measurement of this CuO-like trapping center at the Cu/Cu_2O interface is as follows.

2.3. *Electron transition model*

Figure 3 shows a band diagram of the sample and the expected electron transition process of the Cu sheet sample under X-ray irradiation. This figure simultaneously indicates the valence and inner-shell states at the front side of the sample to discuss the electron transition process of the 2D electron trapping center at the Cu/Cu_2O interface. In this experiment, the Fermi energy E_F of the Al electrode and the Cu sample was not equal because the sample was electrically isolated. The isolation is indicated by a space between the Al electrode and the sample, which corresponds to the poly vinylidene chloride insulator film in the actual system. The Cu_2O native oxide is a semiconductor, and it is connected to the Cu bulk. The band pinning of thin Cu_2O is superior to the floated E_F of the Cu bulk, resulting in band bending in the Cu bulk.

At the Cu bulk site [Fig. 3(b)], (1) a core-hall produced by the X-ray excitation is immediately occupied by the relaxation of a free electron in the conduction band (2). In this case, the electronic state rapidly returns to the initial state because the conduction band is filled sufficiently with free electrons (3). Therefore, there is no effective X-ray induced photoemission of the localized electron ($\delta q = 0$) resulting in no ΔC. This is the reason why the capacitance XAFS spectrum does not indicate the XAFS spectrum of the Cu bulk as shown in Fig. 2.

As discussed in 2.2, the CuO-like structure is considered to form an electron trapping level and capture electrons at the Cu/Cu_2O hetero interface [Fig. 3(a)]. If the inner-shell excitation of the trapping center atom ($1'$) and the following electron relaxation from the trapping level ($2'$) produce an unoccupied level, this transition induces δq, i.e., Δc. Consequently, ΔC with respect to the X-ray photon energy selectively indicates the XAFS spectrum of the trapping center. Obviously, a lifetime of unoccupied trapping level after the relaxation ($2'$) in Fig. 3(a) is crucial for the ΔC observation. If this level is immediately occupied by a free electron from Cu as well as (3) in Fig. 3(b) ΔC cannot be observed. The electrically floating sample can locally produce an unoccupied level with a longer lifetime. In fact, when the potential in the sample is fixed by a bias voltage applied to the sample, the capacitance XAFS spectrum cannot be obtained. The isolation of the trapping center from the free electrons is realized by a band bending in this figure. However, the free electron can easily fill the trapping level under the fixed bias condition that the band in the Cu bulk is flattened. Though this band bending model is only a speculation, a similar theory can explain a site-selection of a trapping center with a specific eigen-energy in semiconductors as discussed below.

3. Capacitance XAFS measurement of a GaO/GaAs system

3.1. *Experiments*

Figure 4(a) shows the schematic diagram of an experimental apparatus for capacitance XAFS measurements of semiconductors. In the developed system, a scanning capacitance microscopy (SCM) with an Au coated Si microprobe was used for detecting the capacitance in a random area. This combination of XAFS and SCM techniques aims at concluding micro spectroscopy and is called the SCM-XAFS method [17]. A piezoelectric scanning stage with an Al sample holder was used to

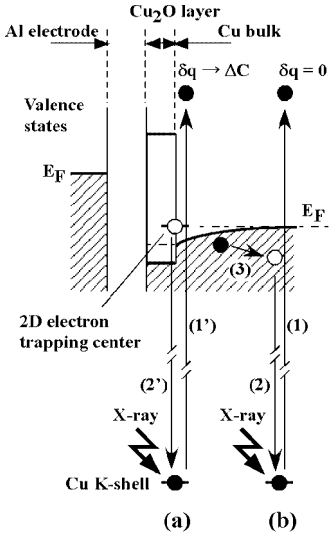

Fig. 3. Band diagram of the Cu sheet and electron transition models at (a) CuO-like trapping center and at (b) Cu bulk site.

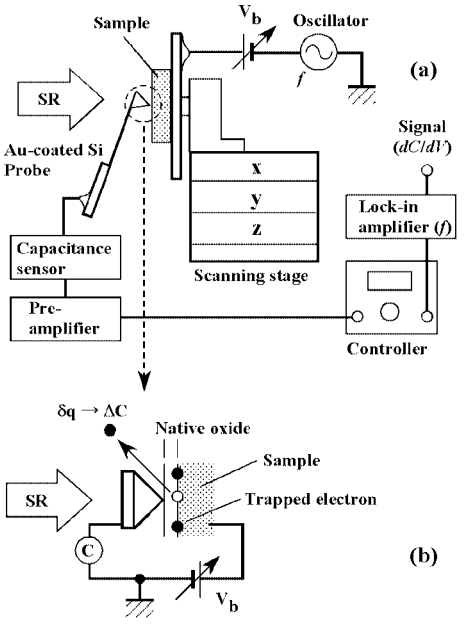

Fig. 4. (a) Schematic setup for SCM-XAFS measurement of a semiconductor. (b) Microscopic MOS capacitor formation by point contact of an Au probe to the semiconductor.

control the position. A semiconductor was attached to the sample holder with conductive silver paste. A voltage variable DC power supply and an AC oscillator were serially connected to the sample holder. So a modulated bias voltage can be applied to the sample. The point contact of the Au microprobe with the semiconductor locally formed a metal-oxide-semiconductor (MOS) capacitor due to a native oxide on the sample surface, as shown in Fig. 4(b). The capacitance of the MOS capacitor was measured by a capacitance sensor, which was a videodisc capacitance pickup circuit developed by RCA [18]. The electronic property of this microscopic MOS capacitor can be evaluated by regarding the capacitance–bias voltage (C-V) characteristics. We can analyze the trapping centers based on the C-V characteristics, as discussed in 3.2. For the capacitance XAFS measurements, we adopted a lock-in amplifier technique using the sample bias modulation for sensitive signal detection. The modulation frequency was fixed at 131 Hz.

The semiconductor sample used in this study was Sn-doped n-type GaAs grown by liquid phase epitaxy. The GaAs surface was covered by a few nanometers thick native oxide layer [19] as well as a Cu_2O/Cu sample, and the electron trapping centers were considered to form at the interface between the GaAs and the native oxide. The SR beam was irradiated into the trapping center under the SCM microprobe and induced the photoemission of localized electrons, δq, resulting in ΔC of the MOS capacitor. The incidence angle of the SR beam was fixed at 45°. The SCM-XAFS experiments were also performed at SPring-8 BL10XU. The X-ray source and the optics of this beamline were the same as those described in section 2.1.

3.2. *Results*

Figure 5 indicates the SCM-XAFS spectra at Ga K-edge (10375 eV). In this experiment, bias voltage V_b was varied from -0.4 to $+0.4$ V. These spectra are normalized by edge jump. As shown in the figure, in the positive V_b region the intensity of a resonant absorption peak at ∼10378 eV gradually increased with increasing V_b. However, the intensity was almost constant in the negative V_b region. This unique dependence on V_b suggests the site of the trapping center with a specific eigen-energy can be selected by controlling V_b. The sharp resonant peak at the absorption edge can be identified as a "white line" produced by Ga oxide. Moreover, an XPS analysis of this GaAs sample found a thin GaO surface layer as a native oxide containing Ga. Therefore, we can conclude that the SCM-XAFS spectra in the positive V_b region indicates a specific trapping center caused by Ga oxide at the GaO/GaAs interface.

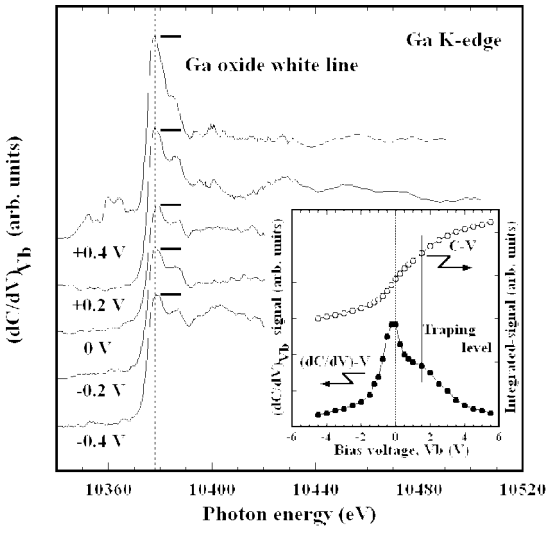

Fig. 5. SCM-XAFS spectra. Inset indicates C-V and $\mathrm{d}C/\mathrm{d}V$ V characteristics of the MOS capacitor.

The C-V characteristics of this GaAs sample measured by SCM is shown in the inset of Fig. 5 (open circles). A sigmoid property typical of MOS capacitors was obtained. However, the $\mathrm{d}C/\mathrm{d}V$-V curve (closed circles) for a more detailed analysis of the C-V characteristics is not symmetrical; it has a broad peak in the $V_b > 0$ region. This finding means that some trapping center in the sample captures electrons, and the electron emission from the trapping center can be detected by ΔC in the $V_b > 0$ region. Note that this V_b region corresponds to that for the selective observation of the Ga oxide trapping center in the capacitance XAFS measurement discussed above. Hence, the trapping center found in the C-V characteristics is caused by the Ga oxide trapping center, and its local electronic states and structure are selectively obtained by the capacitance XAFS measurement under the $V_b > 0$ condition because the X-ray-induced photoemission of the localized electron can be precisely detected.

Though the XPS analyses obtain the chemical information on the sample surface, they cannot clarify the electric characteristics of the surface species. On the other hand, though the electric properties of the microscopic MOS capacitor can be analyzed by regarding the C-V characteristics, the chemical information of the trapping centers cannot be obtained in the electric measurements. In general, microscopic chemical and electric properties have been independently analyzed. In nano structures, the microscopic chemistry at atomic level determines the electronic characteristics of the device, so these properties need to correlate. Based on selecting the sites by controlling V_b, the SCM-XAFS method is a powerful tool for this purpose.

Though the SCM-XAFS spectra in Fig. 5 conceptually indicate a potential for concluding micro spectroscopy, an experimental evaluation of spatial resolution is necessary. Unfortunately, various unpredictable factors such as the moisture between the probe and the substrate and vibration in the experimental station, obstruct an accurate evaluation of the spatial resolution at that time. However, selective observations of the trapping centers at hetero interfaces indicate the spatial resolution of the atomic level in vertical direction. Therefore, an isolated trapping center on the sample surface should be distinguished from other sites by applying site selectivity, and site selectivity should equivalently improve the spatial resolution.

3.3. *Electron transition model*

Figure 6 shows an electron transition model in the SCM-XAFS method. The band diagram of the microscopic MOS structure is illustrated in Fig. 6(a). The E_F of the Au probe equals to that of the GaAs sample without the bias ($V_b = 0$), while the bias forms an E_F step of eV_b as shown in this figure. Therefore, the absolute energy level of the Au probe and the GaAs sample is determined by E_F and V_b, which is different from the electrically floated Cu_2O/Cu system in Fig. 3. In this diagram, a trapping level in the GaAs band gap is assumed at the interface of GaO/GaAs. The X-ray absorption of the trapping center excites the inner-shell electron (1). Following that, the localized electron from the trapping center is relaxed into the core hole (2). This sequential process corresponds to the photoemission of δq and is detected

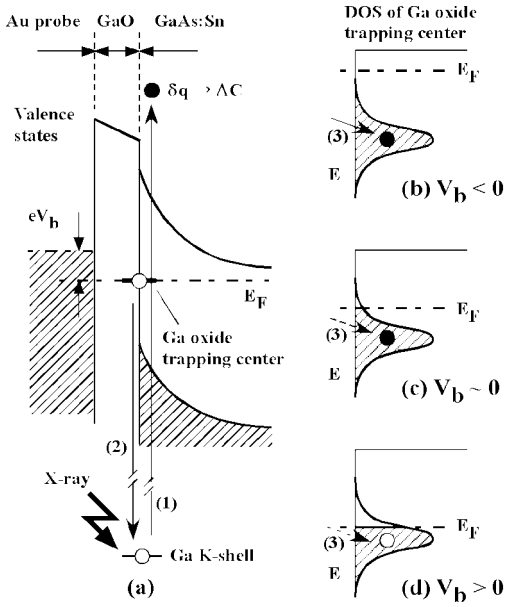

Fig. 6. (a) Band diagram of microscopic MOS capacitor and electron transition model under X-ray irradiation. Electron filling model at various V_b; (b) $V_b < 0$, (c) $V_b \sim 0$, and (d) $V_b > 0$.

by ΔC. Though this electron transition process is similar to that in Fig. 3(a), electric isolation of the trapping level in the GaAs band gap can realizes an unoccupied state with a relatively long lifetime under specific V_b conditions. By taking the variable lifetime into account, the capacitance XAFS spectrum dependent on V_b can be explained as follows. Figures 6(b)–(d) are schematic density of stats (DOS) diagrams of the trapping center. Under the condition of $V_b < 0$, E_F of the semiconductor is considered to be higher than the trapping level of Ga oxide as shown in Fig. 6(b). In this case, the trapping level is immediately filled by free electrons (3). As discussed in the Cu_2O/Cu system, this short lifetime immediately restores the electronic state to the initial state resulting in no effective ΔC [Fig. 3(b)]. However, E_F begins to cross the trapping level when V_b is approximately 0 [Fig. 6(c)]. The lifetime increases too much because the electron transition (3) is suppressed. Accordingly, a ΔC corresponding to the X-ray absorption of the trapping center can be observed. The ΔC increases with increasing V_b [Fig. 6(d)]. Finally, when the E_F becomes equal to the trapping level with the maximum DOS, the ΔC is expected to become the strongest. This is the reason why the Ga oxide trapping center is selectively observed in the $V_b > 0$ region in Fig. 5. Obviously, this model demonstrates site selectivity of a trapping center with a specific eigen-energy by controlling V_b. Moreover, as illustrated in Figs. 6(b)–(d), it also indicates a possibility of new capacitance spectroscopy of the valence states using a resonant inner-shell absorption, such as double resonance capacitance spectroscopy (DORCAS) [20] because the dependency of ΔC on V_b reflects the DOS of the trapping center.

4. Conclusion

We propose a new site-selective and microscopic X-ray absorption fine structure (XAFS) technique called capacitance XAFS method. In this technique a XAFS spectrum can be obtained by regarding the capacitance change with respect to the X-ray photon energy. An electron trapping center can be selectively analyzed because the X-ray induced photoemission of localized electrons is detected by the capacitance. This basic idea was experimentally demonstrated in both a metal and a semiconductor system. We proposed an electron transition model for each system; the inner-shell absorption of the trapping center and the following relaxation of the localized electron into the core-hall produced an unoccupied valence level with a relatively long lifetime. In the semiconductor system, the lifetime can be controlled by applying a bias voltage to the sample. When the Fermi energy is sufficiently higher than the trapping level, the unoccupied level is immediately filled by free electrons resulting in a short lifetime. The short lifetime cannot produce the capacitance XAFS spectrum. Based on this lifetime control, a trapping center with a specific eigen-energy can be selectively observed. Moreover, detecting the capacitance by scanning the microprobe indicated a potential for concluding micro spectroscopy with this method.

Abstract

We describe an experimental setup, which measures transient chemical changes of photoexcited solutes in disordered systems via time-resolved X-ray Absorption Spectroscopy (XAS) with picosecond temporal resolution. The setup combines a femtosecond amplified laser with picosecond X-ray pulses at beamline 5.3.1 at the *Advanced Light Source* in Berkeley, USA. New results on time-resolved XAS used for probing both the electronic and the geometric modifications of a photoexcited tris-(2,2′-bipyridine) ruthenium (II), $[Ru^{II}(bpy)_3]^{2+}$ in water solution are presented.

1. Introduction

With the advent of time-resolved optical spectroscopy and the rapid development of femtosecond lasers, it has become possible to monitor the transient chemical changes occurring during an ongoing chemical reaction on fundamental timescales, which range from femtoseconds for molecular vibrational motions up to nanoseconds and microseconds for slower diffusion-controlled processes. In addition, since all chemical reactions take place on the atomic level, the complete study of transient chemical structures requires both ultrafast temporal resolution and atomic-level spatial resolution, usually in the picometer range. Femtosecond laser spectroscopy provides the necessary time-resolution to observe fully the photoinduced time evolution of a chemical system under investigation however it is less sensitive in detecting transient molecular structures.

On the other hand, there are many well-established structure-sensitive experimental techniques, such as Electron Diffraction, X-ray Absorption Spectroscopy (XAS) and X-ray or Neutron Diffraction, which are useful in determining the structures of complex many-body systems with atomic-level spatial resolution. Therefore, combining the advantages of ultrahigh atomic-level resolution and ultrafast temporal resolution of these techniques, one could visualize nuclear and electronic motions during the chemical reaction and capture the transient molecular structures. Among these structural tools, XAS offers distinct advantages, when applied to chemical and biological systems in the condensed phase. It is element specific and allows the measurement of the local electronic structure of an atom of interest in a disordered medium, such as a liquid, by X-ray Absorption Near Edge Structure (XANES) and the local geometric structure, including nearest neighbor distribution and relevant bond distances, by Extended X-ray Absorption Fine Structure (EXAFS).

Ultrafast Time-Resolved X-Ray Absorption Spectroscopy is a novel experimental technique which has not found wide-spread use yet. Although this scheme was originally proposed many years ago [1–3], up to now, only a few time-resolved XAS measurements were carried out successfully, both in liquid [4–9] and gas phase systems [2] with nanosecond or longer temporal resolution. Only recently, Chen *et al.* [10] carried out a sub-nanosecond measurement of structural dynamics of an excited Copper (I) Diimine complex using both XANES and EXAFS and we reported on picosecond time-resolved XANES studies of a Ruthenium (II) tris-bipyridine complex in water solution reaching the sub-100 picosecond pulse-limited time resolution [11].

In our laser-pump X-ray-probe experiment, a femtosecond laser pulse starts a chemical reaction and a delayed X-ray pulse probes the photoinduced changes in a system. In full analogy to a laser-only experiment, by scanning the time delay between pump and probe pulse one can observe the time evolution of the transient chemical species. Synchrotrons are currently the brightest and the most stable pulsed X-ray sources. Moreover, they produce radiation that can be tuned over an extremely broad range up to the hard X-ray regime, e.g. hundreds of keV, however, the delivered X-ray pulse widths are usually limited to the tens of ps range, except for recent breakthrough experiments carried out by Schoenlein *et al.*, where a successful experimental scheme providing femtosecond synchrotron pulses was realized [12].

The feasibility of time resolved XAS depends on the number of available X-ray photons per data point. This depends on the X-ray pulse intensity and on the repetition rate of the measurement, which is typically in the 1 kHz range, when using femtosecond amplified lasers. On the other hand, synchrotrons operate at much higher repetition rate of usually 100–500 MHz, which means that after synchronization of both sources we reduce the available X-ray photon flux by more than 5 orders of magnitude. Therefore, these experiments require a very sensitive detection scheme given that the X-ray pulse intensity at 3rd generation X-ray beamlines is rather weak, i.e. 10^4–10^6 photons/pulse. Furthermore, there are other experimental challenges imposed by the nature of the experiment itself and a careful optimization of the sample geometry is required. The details on both sample and detection scheme optimization can be found elsewhere [13].

2. Experimental Setup

The experiments are carried out at bend magnet beamline 5.3.1 of the *Advanced Light Source* in Berkeley, USA, which operates between 2.5 and 12 keV. We use a special filling pattern of the storage ring called *camshaft mode* (Fig. 1). It consists of a close-packed multibunch train followed by a 100 ns empty section, in which a ten-fold more intense single electron bunch is placed, whose radiation we use in the pump-probe measurement. The beamline provides a hard X-ray photon flux of about

*E-mail: Christian.Bressler@epfl.ch

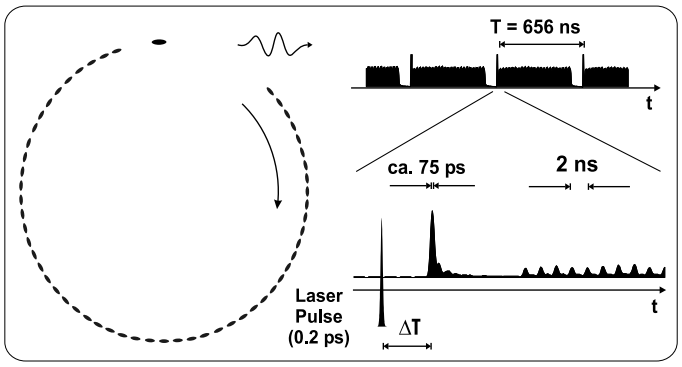

Fig. 1. The ALS storage ring filling pattern (left). The single electron bunch, so called *camshaft pulse*, is placed in a 100 ns empty section and thus is well separated from the 600 ns long multibunch. The X-ray radiation resulting from this bunch provides us with 60–80 ps single X-ray pulses at 1.52 MHz repetition rate used in our experiments (top right). The 200 fs laser pulse at 1 kHz repetition rate is synchronized to one of these camshaft pulses with fixed time delay (bottom right).

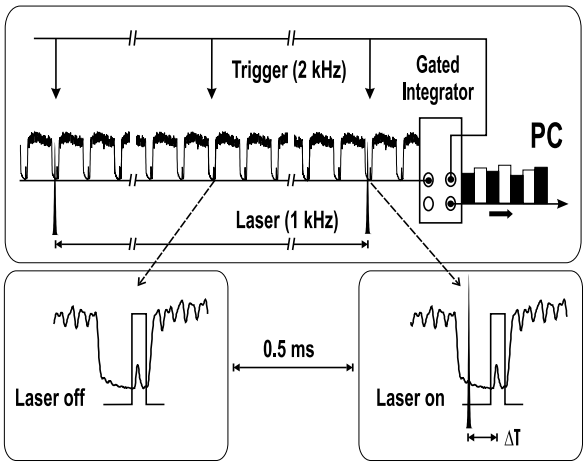

Fig. 2. Data acquisition scheme for recording time-resolved XAS. The X-ray pulses are recorded with a sensitive and suitably fast X-ray detector, i.e. avalanche photodiode, at 2 kHz repetition rate, which permits us to record *in situ* the unexcited and photoexcited sample on a shot-to-shot basis. The measured single X-ray pulse intensities are then fed into the gated integrator. The pair-wise subtraction of adjacent pumped (black) and unpumped (white) intensities yields the transient difference XAS spectra. The PC sorts the recorded data and controls both the X-ray monochromator and the laser-X-ray time delay settings.

10^{12} photons/s (corresponding to ca. 10^4 photons/single X-ray pulse) with a spectral resolution of $3 \cdot 10^{-4}$ bandwidth around 3 keV energy range. The bend magnet radiation is imaged 1 : 1 via a grazing incidence Pt-coated mirror (5 mrad deflection) into the experimental X-ray hutch. A Ge (111) double monochromator with fixed output height selects X-ray photon energies between 2–12 keV. An X-ray chopper in front of the monochromator is set to 2 kHz repetition rate reducing the heat load on the first monochromator crystal. The experimental chamber is filled with atmospheric He gas in order to minimize transmission losses for radiation below 7 keV.

The laser source is a Ti: sapphire based amplified femtosecond laser system, which delivers 1.8 mJ, 200 fs, 800 nm laser pulses at a repetition rate of 1 kHz. Both sources, i.e. the laser and the storage ring, require stable and precise synchronization. The key factor in the synchronization scheme is locking of the laser oscillator frequency to the radio frequency (RF) of the storage ring with a stable phase. The oscillator timing is the most important step in this process, because its temporal precision defines the relative jitter between laser and X-ray pulses. Once the complete synchronization between laser pump pulses and camshaft probe pulses is properly set, the relative time delay between them can be kept fixed in order to scan the energy spectra at a given time instant after the photoexcitation or alternatively we can scan the time delay electronically (at a fixed X-ray energy) to record the temporal evolution of the transient X-ray absorption. The sample consists of a free-flowing liquid jet with a thickness of 100 μm. The amplified femtosecond laser pulses provide the photoexcitation source and they can be delivered at the fundamental wavelength of 800 nm, or frequency-doubled and trippled, namely 400 nm and 266 nm respectively. The amplified and frequency-doubled Ti: Sapphire laser at 1 kHz can currently deliver up to 550 μJ pulse energy at 400 nm.

The laser is focused on the sample down to ca. 300 μm diameter with its beam size being slightly larger than the X-ray focal size, which is 250 × 90 μm. The flow speed of the jet is adjusted in a way that we can always provide a fresh sample solution at the site where the photoexciting laser pulse arrives, i.e. the jet flow speed of 5 m/s ensures that after 60 μs the sample will move out of the probe focus. Spatial and temporal overlaps are secured in two steps. Initially, we align both X-ray and laser beams through a 50 mm pinhole at the sample position. Then we monitor at the sample position both pulses individually with a fast photodiode. This allows us to set the timing with a precision around 100 ps by comparing the rise times of both signals. After this procedure, we place the sample within both beams and measure a photoinduced signal to fine tune both spatial and temporal overlap.

The transmitted X-ray pulse train is detected using an avalanche photodiode (APD) as an X-ray detector, which resolves the single X-ray pulse intensities and camshaft pulses can be resolved and detected yielding the output signal of about 10 ns (FWHM), as shown in Fig. 2. The APD signal is amplified by a fast pre-amplifier and subsequently plugged into a gated integrator. The gate of the integrator is set to this 10 ns width for an optimum signal-to-noise ratio. The single X-ray pulse intensities are then recorded at twice the laser repetition rate, i.e. 2 kHz, which means that we acquire simultaneously transmitted camshaft pulse intensities originating from laser-pumped and unpumped species. Later on, the subtraction of adjacent pairs of X-ray pulse intensities yields the transient difference XAS in transmission mode. Using the described data acquisition strategy cancels out any noise contributions and electronics drifts at frequencies lower than 1 kHz for a given pump-probe difference signal. Moreover, this difference detection scheme reduces our susceptibility towards gradual sample deterioration due to extended exposure to radiation, since we always measure the unexcited sample every 0.5 ms before probing the photoinduced changes and thus long-term changes in the sample do not contribute to our difference signal. One interesting prospect of our detection scheme is that we can envision studying of non-cyclic photochemical reactions without contaminating our pump-probe spectra with the overall change in XAS due to sample degradation.

With the above-described detection strategy, we are able to record high precision and quality XAS spectra. In fact, careful noise analysis shows that our current sensitivity has reached 90% of the shot-noise limit of the X-ray source. It is illustrated in Fig. 3a, which shows the pulse height distribution of 10^4 recorded single X-ray pulse intensities. From this distribution, we can

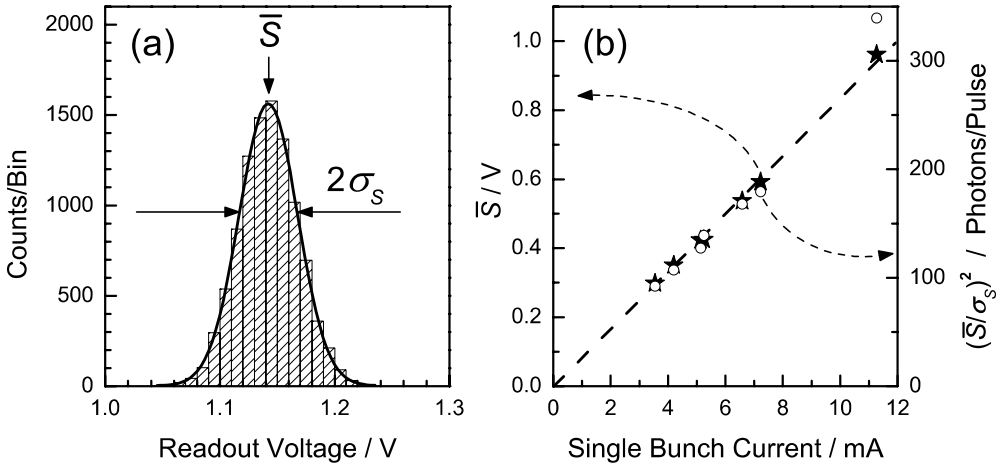

Fig. 3. a) Pulse height distribution of 10^4 recorded single X-ray pulses at a fixed energy without laser. In our data acquisition scheme we record the averaged value $\bar{S}$ together with its standard deviation σ_S for a given number of single X-ray pulses. b) On the left ordinate (stars), the averaged readout voltage is plotted as a function of stored current in the single electron pulse. The right ordinate (circles) corresponds to the effective number of recorded photons, according to relation (1), plotted as a function of the same value of the single bunch current. We find the linear response of the utilized detection scheme and very good agreement between measured pulse height distribution and the effective number of single X-ray pulse photons.

estimate an effective number of monochromatic X-ray photons per pulse, via the equation:

$$N = \left(\frac{N}{\Delta N}\right)^2 = \left(\frac{N}{\sqrt{N}}\right)^2 \geq \left(\frac{\bar{S}}{\sigma_S}\right)^2 \qquad (1)$$

with N being the average number of photons per pulse, $\Delta N = N^{1/2}$ being the standard deviation or shot noise distribution of the X-ray source, $\bar{S}$ denotes the averaged measured signal height (in Volts), and σ_S the measured standard deviation (in Volts) of the pulse height distribution. Of course, this relation holds only if σ_S contains no other contributions, e.g., electronic noise. On the other hand, using Eq. (1) we can estimate the number of photons per X-ray pulse and compare it to the calculated value for the beamline (at the given X-ray energy) where the experiment is carried out.

The beamline is specified to deliver ca. 1×10^{12} photons/(s $\times$ 0.1% bandwidth) at 2.8 keV for 400 mA of stored current. At this beam current value, the camshaft current amounts to 10 mA, which corresponds to 1.65×10^4 camshaft photons/pulse and 0.1% bandwidth. Due to the fact that we only use 0.03% of the available bandwidth, the corresponding number of X-ray photons on the sample scales down to ca. 5000 photons/pulse. Taking into account the transmission through the sample (10%) and through Be filters (70%), we obtain a value of 350 photons per pulse incident on the X-ray detector at 10 mA of camshaft current, and this is very close to the value measured via the pulse height distribution of single recorded X-ray pulses (Fig. 3b).

3. Results and discussion

With the above-described experimental setup, we have investigated the photoexcited Metal-to-Ligand Charge Transfer (MLCT) reaction of aqueous tris-(2,2′-bipyridine) ruthenium (II), $[Ru^{II}(bpy)_3]^{2+}$. Its excited state properties have been extensively studied with optical spectroscopy [14–18], nevertheless, still little is known about its excited state structure, which can be investigated via time-resolved XAS. The photoexcitation cycle (which is completed on a sub-microsecond time scale) is displayed in Fig. 4. Light absorption by $[Ru^{II}(bpy)_3]^{2+}$ results in the formation of a Franck-Condon MLCT singlet excited state, ^{1}(MLCT), which undergoes sub-picosecond intersystem

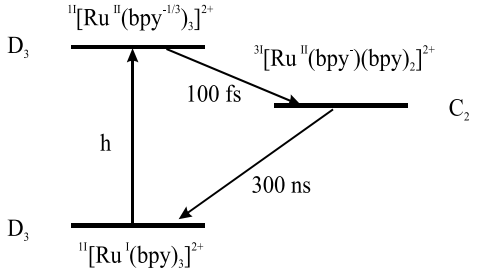

Fig. 4. Photoexcitation cycle of the solvated reactant species in its singlet ground state leads to formation of an intermediate triplet excited state of $[Ru^{III}(bpy^-)(bpy)_2]^{2+}$, which radiatively returns to the initial reactant state after ca. 300 ns.

crossing to a long-lived triplet excited state, ^{3}(MLCT) [17], with near-unity quantum yield. In the process, the D_3 symmetry of ground state $[Ru^{II}(bpy)_3]^{2+}$ is reduced to C_2 symmetry of $[Ru^{III}(bpy^-)(bpy)_2]^{2+}$ in the ^{3}(MLCT) state. This reaction involves a change of oxidation state of the Ru central atom, which can be probed by monitoring the XANES region around the ruthenium L_3-edge. Indeed, oxidation states of (ground state) Ru^{II} and (photoexcited) Ru^{III} complexes exhibit clear differences in their L-edge XANES [19–21]. This can be seen in Fig. 5a around the Ru L_3 edge. A pre edge absorption feature at 2841.0 eV (denoted B in Fig. 5a) characterizes the bivalent compounds due to the $2p_{3/2} \rightarrow 4d_{3/2}$ (e_g) transition [19], next to the weaker $2p_{3/2} \rightarrow 5s_{1/2}$ transition around 2851 eV (feature C) [20]. Removal of the weakest bound electron from the fully occupied $4d_{5/2}$ (t_{2g}) level generates a trivalent ruthenium compound [19], opening up additional absorption due to the allowed $2p_{3/2} \rightarrow 4d_{5/2}(t_{2g})$ (feature A') in addition to an oxidation state induced shift [19]. Thus we observe the appearance of the A'/B' doublet structure in the trivalent L_3 XANES together with the energetic $B \rightarrow B'$ and $C \rightarrow C'$ shift (Fig. 5a), resulting from the change of oxidation state of the Ru central atom and formation of ^{3}(MLCT) (see Fig. 4).

The recorded transient difference absorption spectrum is shown on Fig. 5b. It is plotted as a function of the X-ray probe energy E, recorded 50 ps after laser excitation (data points with error bars) for a sample containing 80 mmol/l solution of

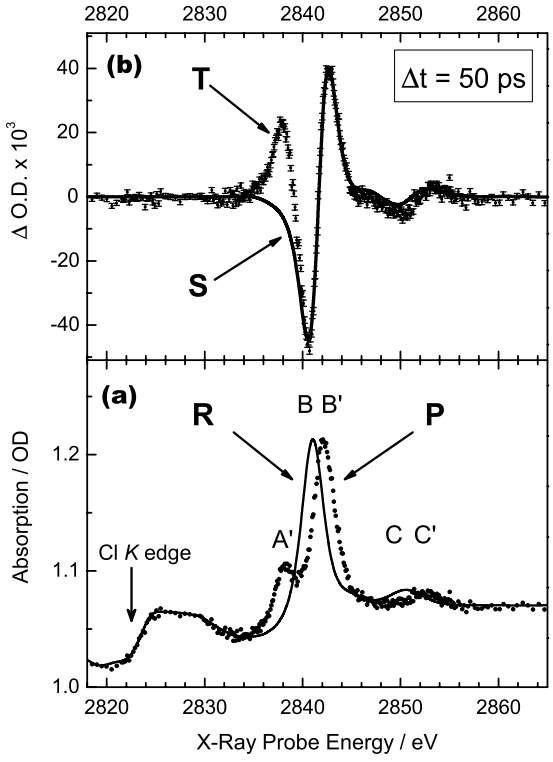

Fig. 5. (a): Static L_3-edge X-ray absorption spectrum of ground state $[Ru(bpy)_3]^{2+}$ (black trace, measured 0.5 ms before the laser strikes the sample), and excited state absorption spectrum (red dots) generated from the transient data curve T in (b) via Eq. (2). (b): Transient X-ray absorption spectrum of photoexcited aqueous $[Ru(bpy)_3]^{2+}$ measured 50 ps after laser excitation.

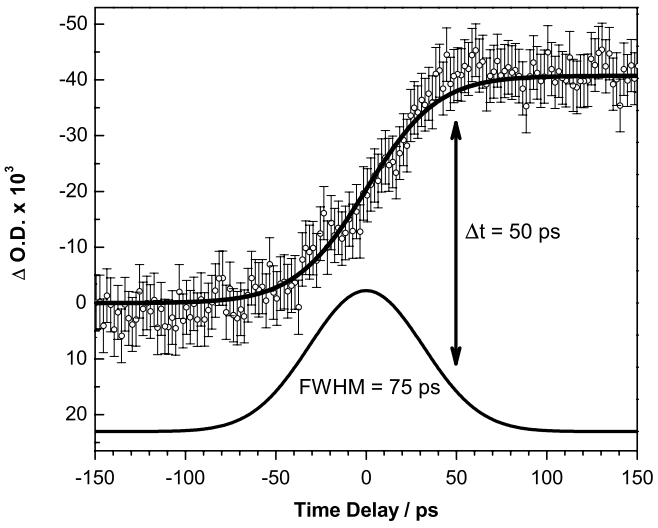

Fig. 6. Time delay scan between laser and X-ray pulses around time zero of photoexcited aqueous $[Ru(bpy)_3]^{2+}$. Cross-correlation signal recorded between the 200 fs laser pulse and the 70–80 ps long X-ray pulse can be fitted with a Gaussian error function, which derivative is a Gaussian with a FWHM around 70–80 ps, which corresponds to the single X-ray pulse width.

$[Ru^{II}(bpy)_3]^{2+}$ in H_2O. This transient contains all the electronic changes from the reactant state absorption spectrum, $R(E)$, to the product state absorption spectrum, $P(E,t)$, at the time t after photoexcitation can be expressed by the following relation:

$$T(E,t) = f(t) \cdot [P(E,t) - R(E)], \tag{2}$$

with $f(t)$ being the fraction of excited state species at time t. Therefore, one can directly access the XANES spectrum of the product state from the measured transient signal and the reactant state XAS, provided that the $f(t)$ value is known. Alternatively, one can derive $f(t)$, if the exact shape of the product state XAS, $P(E,t)$ is given. From laser-only measurements we know that the photoexcitation yield of the sample is ca. 10%, but here we have treated the data differently: Assuming no change in oscillator strength for the B feature, we have constructed the product state spectrum $P(E, \Delta t = 50\,\text{ps})$ via Eq. (2) by adjusting $f(t)$, until features B and B' have equal amplitudes. This yields a value of $f = 10.4\%$ in close agreement with our prediction from the optical-only measurements. It contains an energetic shift of all features by 1.2 eV together with the photoinduced appearance of the A' feature, as expected. The A'-B' splitting (4 eV) and the B'/A' intensity ratio (ca. 2.3) is indeed close to the values observed for $[Ru^{III}(NH_3)_6]^{3+}$ complex, which has the same valency and a similar coordination symmetry (O_h versus D_3) as the bipyridine complex. Assuming no change in oscillator strength for the B feature in the ground and photoexcited states seems plausible, since the $4d_{3/2}$ (e_g) level should remain empty in both cases. In addition, the peak intensities of the B feature of ground state $[Ru^{II}(bpy)_3]^{2+}$ and $[Ru^{III}(NH_3)_6]^{3+}$, as compared in Ref. [11], are indeed very similar.

Our experimental setup allows us also to vary the delay time between laser and X-ray pulses. As it is presented in Fig. 6, we scanned the time delay in 2 ps steps with the X-ray energy set near the maximum of feature B (ca. 2840 eV) thus allowing us to observe the appearance of the photoinduced bleach signal. Once the electron has been excited to the triplet MLCT state (in ca. 300 fs, [17]) we can observe the induced oxidation state change of the Ru central atom, and therefore the time evolution of this transient signal is entirely governed by the cross-correlation time of the laser and the X-ray pulses. Cross-correlation signal recorded between the 200 fs laser pulse and the 70–80 ps long X-ray pulse can be fitted with a Gaussian error function, which derivative is a Gaussian with a FWHM around 70–80 ps, which corresponds to the actual single X-ray pulse width provided by the ALS (depending on the stored charge in the single electron bunch). It should be stressed that our current temporal resolution is X-ray pulse-limited and our setup is prepared to be directly implemented into femtosecond-resolved XAS measurements given that ultrashort X-ray pulses could be provided. With this precise timing measurement, we can then set a fixed time delay with better than 10 ps accuracy. While this method serves as a convenient analog of conventional laser cross-correlation measurement for setting the correct time delay between the pulses, our setup can be exploited for measurements of kinetic traces out to several hundred of microseconds in a few picosecond steps.

In order to verify the limits of our experimental setup, we carried out a solute concentration dependence study. In fact, the 80 mmol/l sample concentration used to collect the data in Fig. 5 is rather high for typical photochemical studies, and gives rise to additional processes occurring on nanosecond time scales. Therefore, we decreased the concentration and repeated the measurement of its transient absorption. The results are shown in Fig. 7 for different concentrations down to 1 mmol/l and using an increased laser focus thus reducing the laser intensity (and the photoexcitation yield) in the overlap volume. The spectra represent single scans with 2 s accumulation time per data point except for the 1 mmol/l sample, which utilized 40 s. The corresponding error bars of the 1 mmol/l spectrum are ca. a factor

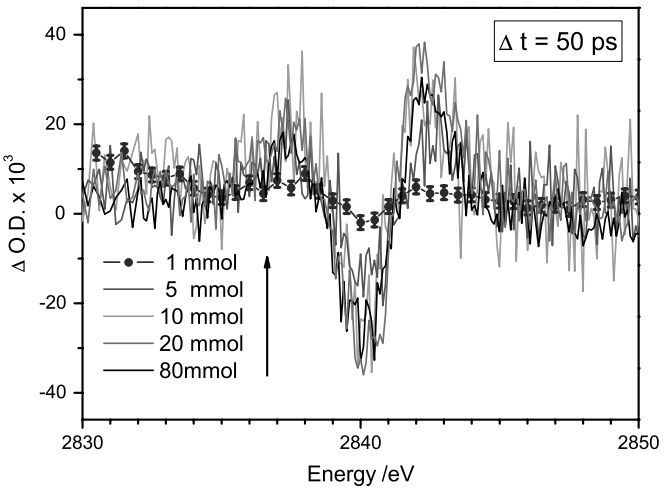

Fig. 7. Solute concentration dependence of the photoinduced aqueous $[Ru(bpy)_3]^{2+}$. All data, except for 1mM trace (solid line with open circles), were recorded at the same experimental conditions (laser intensity, data accumulation time, etc.). The arrow indicates the decreasing concentration of the sample. The lowest concentration sample was recorded at 20 times larger data accumulation time in order to improve the signal-to-noise ratio. All data were collected during single energy scan around Ru L_3-edge (feature B) and measured 50 ps after laser excitation.

of 4.5 smaller than those of the other samples, which we expect from a shot-noise limited detection scheme. These measurements prove that we are capable of descending into significantly lower concentration regions without dramatic loss of signal-to-noise ratio. These results are very promising because one can envision the study of samples for which large concentrations are impossible to prepare.

Moreover, decreasing sample concentration rules out several unwanted effects, such as proximity effects of closely-packed excited species that can influence the ongoing photochemical reaction. In addition, biologically relevant samples are usually investigated in solutions with up to 1 mmol/l concentration, and hence we can imagine such studies in the near future. Furthermore, it should be remarked that these results were obtained in transmission mode. Another possible near-future extension of our technique could be the application of X-ray fluorescence spectroscopy, which is in principle background-free, and could bring another improvement in signal-to-noise ratio.

4. Conclusion

Time-Resolved X-ray Absorption Spectroscopy is a new technique, which permits the investigation of photoinduced processes on various chemical systems on time scales down to the cross-correlation time between the laser and the X-ray pulses. We have successfully applied this technique to investigate the photoinduced charge transfer reaction of aqueous $[Ru^{II}(bpy)_3]^{2+}$ in both X-ray absorption energy and in time. This result demonstrates the utility of current pulsed X-ray sources for future ultrafast XAS studies. Furthermore, we showed the high sensitivity of our technique, which allows measurements of very weak transient XAS signals with X-ray pulse-limited temporal resolution (currently in 60–80 ps range). With only ca. 10^6 photons per data point (corresponding roughly to 1 second accumulation time per data point in the range 3–10 keV), we have achieved a signal-to-noise ratio of ca. 20 for measuring the 10% amount of transient species via time-resolved XANES with sensitivity nearly corresponding to the shot-noise limit of the source.

Particularly promising are the prospects of carrying out time-resolved structural studies via EXAFS. The modified transient structure of the MLCT species has never been directly observed in experiment. Time-resolved EXAFS exploiting our new technique are feasible and could yield the individual Ru-ligand distances of the intermediate species for the first time. Our future work will focus on exploiting this structural tool to study nuclear rearrangements with picosecond temporal resolution.

Abstract

In-situ x-ray absorption spectroscopy (XAS) was used to probe the local structure of photo-induced phase of Fe(II) spin-crossover complex. High-quality XAS data under photo-excitation were obtained *for fine powder specimen* using a novel pixel array detector (PAD). It was demonstrated that the technique can x-ray probe opaque specimen with high sensitivity (requiring less than 10^{-3} g) which is irradiated with visible photons. We find that the nearly octahedral ligand coordination (O_h) of FeN_6 cluster undergoes a significant expansion upon the diamagnetic (S = 0) ↔ paramagnetic (S = 2) transformation induced by laser light (532 nm), at much lower temperature than the critical temperature of thermally induced phase transition. Indication of symmetry breaking was observed in the distorted ligand molecules, in contrast to the relaxed undistorted structure in the thermally induced high spin phase.

1. Introduction

Recently, photo-induced phase transition attracts much attention as a novel means of nanotechnology where multistability of a ground state gives rise to a variety of nanoscale modifications of local structure with modified macroscopic properties [1]. Photo-irradiation stimulates a cooperative phase transition between a ground state and a metastable state which may not be the same phase with that of thermally excited phase transition. Photo-induced phase transitions such as ionic-neutral phase transitions in organic charge transfer (CT) crystals [2], magnetic phase transitions in spin crossover complexes [3, 4]. and photo-induced charge, spin and orbital order/disorder transitions in perovskite manganites [5.6] form rich class of multistable ground state materials where photo-stimulation eventually results in a global phase transition with pronounced changes in macroscopic physical properties. $[Fe(II)(2\text{-pic})_3]Cl_2EtOH$ (2-pic = 2-aminomethyl-pyridine), hereafter abbreviated as Fe-pic, is a typical spin-crossover complex which shows a thermally induced first-order phase transition from a low-spin (LS, S = 0) to a high spin (HS, S = 2) state.

It was shown that photo-induced magnetic transitions [7, 8] have nonlinear characteristics such as threshold light intensity, incubation period and phase separation [9]. The photo-induced phase transition is understood in terms of trapping of metastable spin state *i.e.*, light-induced excited spin state trapping (LIESST) [10]. It was pointed out that a structural relaxation in an excited state may proceed with symmetric and non-symmetric normal coordinates and therefore symmetry breaking could be observed. The excited state trapped by a metastable state may also relax to another "*false*" ground state which may not be the same with the original one. Thus the nature of photo-induced phase is still unclear. Tayagaki *et al.* recently investigated the symmetry of photo-induced phase by Raman spectroscopy and observed broken symmetry in the photo-induced phase which is distinguished from thermally induced phase [11]. The information on the local structure is essential to understand the nature of photo-induced high spin (PIHS) phase, *i.e.*, symmetry breaking. Here, we report the *in-situ* XAS study of $[Fe(II)(2\text{-pic})_3]Cl_2EtOH$ under light irradiation at low temperature.

2. Experimental

High brilliance photon sources (insertion devices) and grazing-incidence geometry have solved thickness mismatch problem [12]. Using high brilliance x-ray beam and grazing incidence fluorescence excitation geometry, an efficient optical excitation and x-ray absorption data collection with a good statistics became feasible. In our experimental set-up, fine particles mounted on a closed cycle helium cryostat rotate on a high precision goniometer (Huber 420) so that the incidence angle is controlled with a minimum step of 10^{-4} degree. The fluorescence x-ray yield is measured with a germanium pixel array detector (PAD) details of which are described elsewhere [13]. Each pixel (4.7 mm × 4.7 mm) can independently count upto 100 kcps, providing a total count rate of 10 MHz. Grazing-incidence geometry requires high brilliance x-ray beam. The wiggler x-radiation from MPW #13 of Photon Factory was used as an x-ray source. The energy and maximum positron current are 2.5 GeV and 400–500 mA, respectively. A directly water-cooled silicon (111) double-crystal monochromator [14] was used that covers the energy range between 4 keV and 25 keV. The energy resolution of XAS measurements was better than 2 eV at 9 keV, calibrated from the near-edge features of copper metal at 9.8 keV. A 100 mW CW laser (532 nm) was used as a light source.

3. Results and discussion

The Fe K-edge x-ray near-edge absorption structure (XANES) spectra and the difference spectra taking the low temperature low spin (LTLS) phase as a standard are shown in Fig. 1a. Energy shift of features B and C to higher energy upon laser light (532 nm) illumination is due to the S = 0 → S = 2 spin transformation. Photo-induced spin conversion induces stretching of R_{Fe-N} on going from a low spin state (strong ligand field) to a high spin state (weak ligand field). Thermally induced first order S = 0 → S = 2 phase transition occurs at 120 K. Fig. 1b shows the variation of difference spectra (measured at a and b) as photo-illumination is repeated. It is clear that photo-induced spin conversion between S = 0 and S = 2 states (5.1 K) are reproducible and bi-directional.

The solid line, dashed line and dotted line indicate the spectra for high-temperature high-spin (HTHS), photo-induced high-spin (PIHS) phase and low-temperature low-spin (LTLS) phase. **b**, Variation of difference features (a, b) as laser light illumination (532 nm) is repeated at 5.1 K. The last data points are taken after S = 0 → S = 2 spin transformation took place.

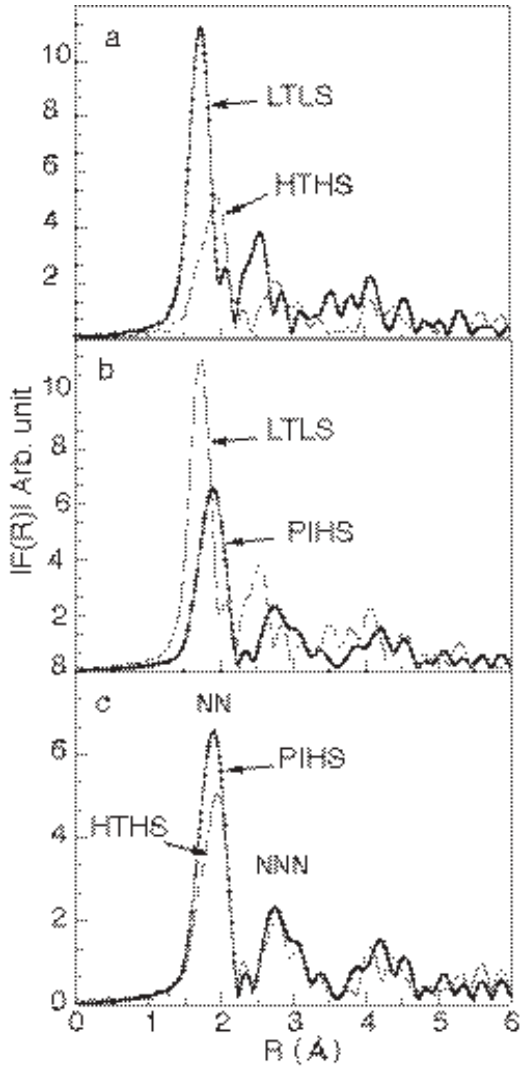

Fig. 2. **a**, Magnitude of Fourier transform (FT) of the Fe K-EXAFS oscillations times k^3 for [Fe(II)(2-pic)$_3$]Cl$_2$EtOH. FT magnitudes for HTHS and LTLS phases. **b**, FT magnitudes for PIHS and LTLS phases. **c**, FT magnitudes for PIHS and HTHS phases.

It is also indicated that the photo-induced high spin (PIHS) phase shows very similar spectral pattern to the high temperature high spin (HTHS) phase. The local structure around Fe ions was studied by Fourier transform (FT) of the Fe K-EXAFS oscillations multiplied by k^3. Figure 2 shows the FT magnitude plots for (a) LTLS and HTHS, (b) PIHS and LTLS, and (c) PIHS and HTHS phases, respectively. Prominent peaks around 1.5–1.7 Å are due to the nearest neighbor (NN) nitrogen atoms. Correcting the phase shift for the Fe-N contributions using FEFF code [15], the $R_{Fe\text{-}N}$ (LTLS) and $R_{Fe\text{-}N}$ (HTHS) values are determined as 2.01 ± 0.01 Å and 2.20 ± 0.01 Å, respectively. $\Delta R_{Fe\text{-}N} \sim 0.20$ Å is in agreement with crystallographic data of Mikami *et al.* [16]. The monoclinic space group $P2_1/c$ is unchanged upon the thermally phase transition [16].

Early studies of photo-induced phase transitions indicated that the photo-excited states are trapped by the metastable HS state at much lower temperatures than 120 K. Recently, dynamics of photo-induced spin transition showed nonlinear characteristics such as the threshold light intensity, incubation period and phase separation [9]. Although nonlinear properties are explained by a simple two-step model with a symmetrical lattice vibration mode with a long-range interaction, the recent Raman experiment raised a puzzling question [11]. Tayagaki *et al.* showed symmetry breaking in the PIHS phase from Raman lines which can not be ascribed to symmetric vibrational modes. The local structure information is needed to quantitatively understand the symmetry of PIHS [17].

As shown in Fig. 2c, the FT magnitudes of PIHS is quite similar to that of HTHS. Difference between the photo- and thermally induced HS phases is only seen in the next-nearest neighbor (NNN) peaks due to Fe-C distances. In contrast, the nearest Fe-N peak is almost the same for the two phases except thermal broadening in the high temperature phase. Change of the radial distribution could be interpreted as accompanied with distortions of FeN_6 octahedron. For instance, in Q_3 mode Jahn-Teller distortion, the in-plane bonds are shortened while the apical bond increases, giving rise to two different bond distances. We note that the split NN peak reported in our earlier works is due to the multidomain, *i.e.*, coexistence of HTHS and LTLS phases. In this work, as temperature of sample was carefully controlled, the single phase PIHS was formed that shows a single FT peak.

Symmetry breaking during photo-induced spin conversion is still an open question. In Fig. 3, the local structure (FeN_6 octahedron and coordinated ligands) of Fe-pic is schematically illustrated. The EXAFS results show that the octahedron expands by *ca.* 0.2 Å, maintaining the nearly octahedral (O_h) geometry. Thus the XANES and EXAFS results indicate that the local structure of PIHS is essentially unchanged from that of thermally

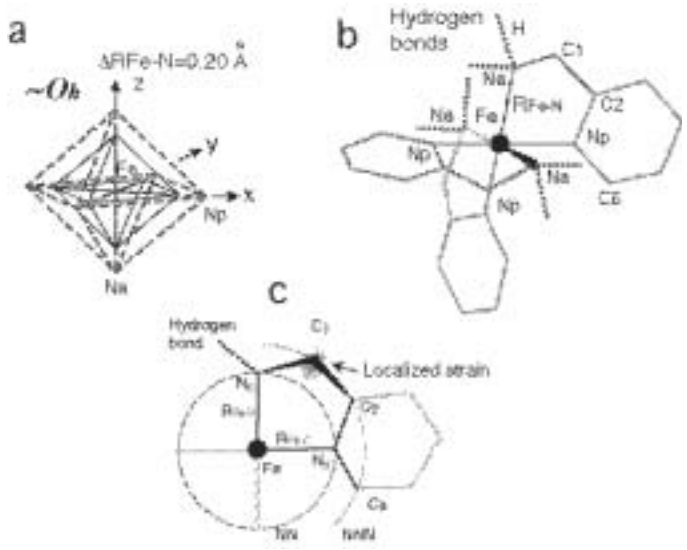

Fig. 3. **a**, Schematic local structure of FeN_6 octahedron in [Fe(II)(2-pic)$_3$]Cl_2EtOH. Upon the photo-induced spin conversion, the Fe-N distance expands by *ca.* 0.2 Å upon illumination while maintaining nearly octahedral geometry. **b**, Schematic crystal structure taken from ref. [16]. **c**, The next-nearest neighbor coordination. In the photo-induced phase, local strains are expected to persist around N_a-C_1 bonds, which can not relax since the photo-induced spin conversion takes place at low temperature where thermal fluctuation and hydrogen bond disorder are absent.

induced HS phase with respect to the NN atoms. Three ligand molecules in a unit cell are linked by hydrogen bonds and compressive strain caused by local expansion propagates *via* a long-range intermolecular interaction. The LS→HS conversion in one molecule is associated with the local expansion of FeN_6 cluster by more than 30% *local* volume change which gives a compressive strain to the nearest neighbor three molecules. As the Fe-C (NNN) distances expand roughly by the same amount, the FeN_6 deformation leads to isotropic expansion of ligand molecules. The PIHS phase is formed at low temperature where thermal relaxations can not take place. As illustrated in Fig. 3c, the local strain may give rise to bond bending distortions observed as inversion symmetry breaking. A subtle change in the next-nearest neighbor Fe-C peak between the PIHS and HTHS phases (Fig. 2c) indicate distortions of ligand molecules. Such local distortions would introduce inhomogeneous character in the strain distribution. The origin of non-linear phase transition could be due to inhomogeneous strain distribution which hampers cooperativity of phase transition [18].

4. Conclusions

Local structures of photo-induced high spin phases of spin-crossover complex [Fe(II)(2-pic)$_3$]Cl_2EtOH were studied by *in-situ* x-ray absorption spectroscopy. Fe K-edge XANES and EXAFS results showed that *the variation of nearest-neighbor local structure upon photo-induced* $S = 0 \rightarrow S = 2$ *spin transition is essentially an expansion of octahedral coordination* (O_h) *without lowering symmetry*. The nearest neighbor Fe-N distance ($R_{\text{Fe-N}}$) increases by *ca.* 0.20 Å on going from LS to HS state, resulting in an increase of *10Dq* by 60%. Symmetry of the nearest neighbor FeN_6 octahedron in the photo-induced phase is unchanged on spin conversion by laser light illumination. Perfect spin conversion and bi-directional transformation were confirmed. Slight distortions of ligand molecules were indicated in the next-nearest neighbor radial functions, which may be interpreted as *inversion symmetry breaking* observed in Raman spectra.

Abstract

Magnetic structure and $L_{2,3}$ edge X-ray magnetic circular dichroism (XMCD) spectra of free spherical iron clusters containing 9–89 atoms are calculated employing the *ab-initio* fully-relativistic spin-polarized multiple-scattering method. The average spin m_{spin} and orbital m_{orb} magnetic moments as well as their ratio m_{orb}/m_{spin} are larger in clusters than in the bulk, with the ratio m_{orb}/m_{spin} approaching the bulk values more rapidly than either m_{spin} or m_{orb}. Theoretical XMCD spectra of free clusters differ from their bulk counterpart mainly through smaller widths and sharper maxima of the main peaks. A small yet distinct feature just above the main L_3 edge peak appears for all the investigated clusters and could thus serve as a marker of clusterization.

1. Introduction

Transition metal clusters ought to have larger magnetic moments than bulk systems because they contain a high portion of surface atoms, which have larger spin magnetic moments m_{spin} and, especially, orbital magnetic moment m_{orb} than bulk atoms. X-ray magnetic circular dichroism (XMCD), defined as a difference of the absorption rate for left- and right-circularly polarized X-rays in magnetic targets, offers the possibility to study angular-momentum selected spin and orbital contributions to the total magnetic moment separately. Several experimental studies were performed on supported iron clusters [1, 2, 3]. These studies suggest an essential enhancement of m_{orb} as well as of the ratio m_{orb}/m_{spin} with respect to the bulk, while m_{spin} remains the same as in the bulk or even decreases. In our study we want to concentrate on *free* iron clusters with the aim to investigate theoretically the effect of clusterization on XMCD, relying on ab-initio calculations.

2. Theory

We investigate free spherical iron clusters with their geometry taken as if they were cut from a bcc Fe crystal. Our theoretical framework is based on the local density approximation. The magnetic structure and $L_{2,3}$ edge XMCD spectra were calculated employing the fully-relativistic spin-polarized multiple-scattering technique in the atomic sphere approximation, as implemented in the SPRKKR code [4]. The scattering potential was obtained from self-consistent multiple scattering calculations for molecular clusters using an amended XASCF code [5, 6]. The Vosko, Wilk and Nusair parametrization of the exchange-correlation potential was used. In order to account for the spilling of the electron charge into the vaccum, each cluster was surrounded by empty spheres. Further technical details can be found in Ref. [7].

The helicity of the incoming photons is assumed to be either parallel or antiparallel with the cluster magnetization, which coincides with the [100] direction in the parental crystal. All theoretical spectra were convoluted by Lorentzian curves of the same widths which account both for core hole lifetimes [8] as well as for (energy-dependent) photoelectron lifetime [9].

3. Results and discussion

We explored clusters ranging from 9 to 89 atoms, i.e., comprising from one to seven coordination shells. The details of their magnetic structure will be published elsewhere [10]. Generally, atoms close to the cluster surface have larger m_{spin} and m_{orb} than inner atoms. The average m_{spin} and m_{orb} per atom and the m_{orb}/m_{spin} ratio are summarized in Tab. I. We present the average number of holes in the 3d band, too, as this quantity is often used in analyzing XMCD spectra via sum rules. It can be seen from Tab. I that neither m_{spin} or m_{orb} approach their bulk values even for the largest of the investigated clusters. This is not surprising as Stern-Gerlach type experiments actually demonstrated that the total magnetic moment converges to the bulk value only for clusters containing several hundreds of atoms [11]. However, Tab. I reveals that the m_{orb}/m_{spin} *ratio* approaches the bulk value much more quickly than m_{spin} or m_{orb} separately. This finding is in contrast with some experimental studies which suggest that the m_{orb}/m_{spin} ratio is about twice as high for supported iron clusters than for the bulk Fe crystal [1, 2, 3]. The resolution of this discrepancy might be that the supported clusters investigated in those studies were in fact more flat than spherical, containing thus a much larger portion of surface and edge atoms with larger m_{orb}.

The theoretical Fe $L_{2,3}$ edge XMCD spectra shown in Fig. 1 were obtained by superposing calculated XMCD signals from

Table I. *Average moments m_{spin} and m_{orb} per atom (in μ_B), the ratio m_{orb}/m_{spin} and the number n_h of holes in the d band of spherical iron clusters of N atoms.*

N	m_{spin}	m_{orb}	m_{orb}/m_{spin}	n_h

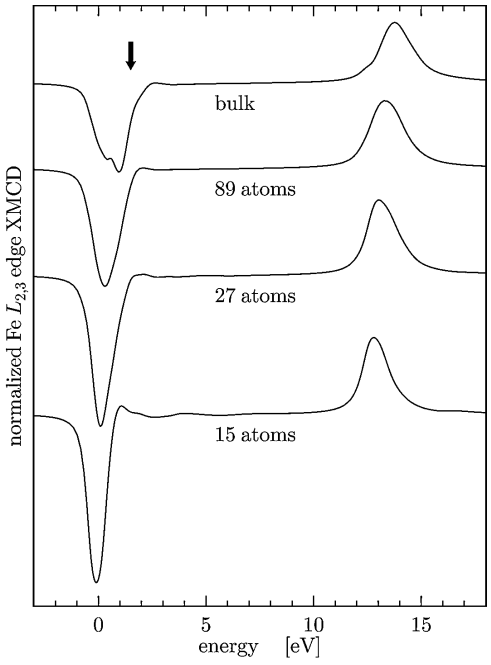

Fig. 1. Fe $L_{2,3}$ edge XMCD spectra of bulk iron crystal and of free clusters containing 15, 27 and 89 atoms.

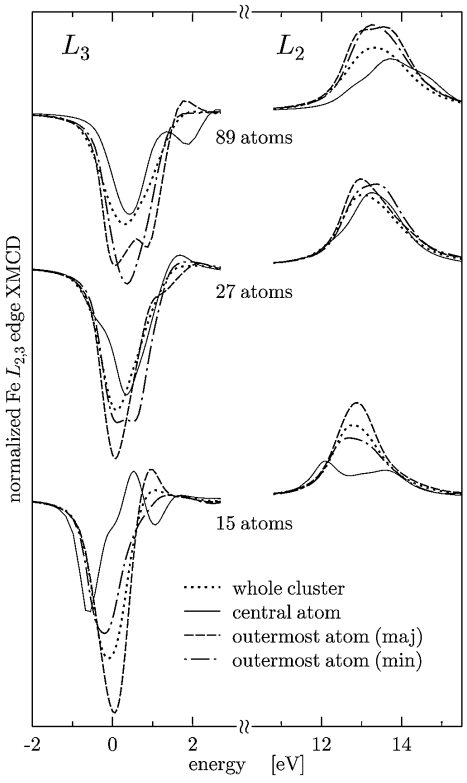

Fig. 2. Fe $L_{2,3}$ edge XMCD spectra of the central atoms, of the outermost atoms and combined spectra of the whole clusters for three cluster sizes. Spectra of inequivalent atoms belonging to the same coordination shell are distinguished by line types (dashed lines for atoms of the majority group, dash-dotted lines for atoms of the minority group).

all atoms in the given cluster and were normalized per one atom. The splitting of the L_3 negative peak at 0.5 eV in the bulk spectrum has not been observed in the experiment [12]. It seems that this discrepancy is of a many-body origin. This splitting, namely, appears even in spectra obtained via full-potential calculations [13, 14] but it disappears if a relaxed core hole is included [13].

Generally, XMCD spectra of clusters are characterized by narrowing and deepening of the main L_3 and L_2 peaks in comparison with the bulk. This systematic trend is more apparent at the L_3 edge than at the L_2 edge. There is also a systematic albeit minor change in the shapes of the main L_3 and L_2 features: in clusters, these peaks appear to be tilted towards the low-energy side.

All cluster spectra exhibit a small positive peak just after the main L_3 minimum (marked by an arrow in Fig. 1). Its intensity increases with decreasing cluster size. This feature actually may have been observed in the $L_{2,3}$ edge XMCD spectrum of supported clusters containing $N \approx 475$ atoms, as presented in Fig. 1(b) of the work [2]; unfortunately the scale of that plot does not allow to see clearly whether this was a real effect or not.

Theoretical XMCD spectra of iron crystal surface [13] or multilayers [15] display a distinct fine structure. Such fine structure cannot be seen in the spectra of clusters due to a mutual cancellation of the oscillatory contributions arising from different sites. To demonstrate this, we present in Fig. 2 spectra of the central atoms, of the outermost atoms and combined spectra of the whole clusters for three cluster sizes. (Note that there are in fact two symmetry inequivalent atomic sites in each outermost shell as indicated by the line types, because the magnetization decreases the symmetry of the cluster.) One can see that spectra of individual atoms indeed may contain quite a lot of fine structure. There is, however, no unique pattern connecting the site-dependence of XMCD spectra for clusters of different sizes. In particular, the distinct splitting of the main XMCD peaks into two components appears at some atoms of some clusters but not as a general rule.

4. Conclusions

The ratio m_{orb}/m_{spin} between orbital and spin magnetic moments of free spherical iron clusters converges towards its bulk value with increasing cluster size more quickly than m_{spin} and m_{orb} separately. The Fe $L_{2,3}$ edge XMCD spectra of free clusters distinguish themselves from the bulk spectrum mainly through smaller widths and sharper maxima of the L_3 and L_2 peaks. Most of the fine structure which is present in spectra of individual atoms is mutually cancelled when the total spectra of the clusters are formed. The notable exception is a small positive peak just above the main L_3 feature which appears for all clusters and increases in intensity when the cluster size is decreased.

Abstract

X-ray magnetic circular dichroism (XMCD) at the rare-earth (RE) $L_{2,3}$ absorption edges of RFe$_2$ (R = RE) in the Laves phase has been investigated based on the tight-binding model with the intra-atomic exchange interaction between 5d and 4f electrons. We find that the magnetic polarization of 5d electrons, being essential for these XMCD, is dominated by the intra-atomic exchange interaction and by the hybridization with spin-polarized Fe 3d states. These contributions as well as the quadrupole one compete, resulting in a variety of XMCD spectra, as observed in experiments.

Intermetallic compounds RFe$_2$ (R = rare-earth (RE)) in the Laves phase have been studied intensively for the purpose of industrial applications as permanent magnets. They exhibit quite interesting magnetic properties, which are the manifestation of subtle interactions between RE 4f moments and Fe 3d moments. In order to understand the physics of these properties based on a microscopic point of view, it is quite important to obtain information on RE 5d electrons, which mediate the exchange process between them.

Recently, with the aid of circular polarized X-rays of good quality generated at the third-generation synchrotron facilities, a lot of data have been accumulated on X-ray absorption spectra (XAS) and their magnetic circular dichroism (XMCD) at the RE $L_{2,3}$ edges, since they must provide information on the 5d electrons separately from other shells. It was, however, not so straightforward to obtain the information [1]: even the sign of XMCD intensities could not be predicted by a naive theory. After many challenges, we have come to the conclusion that a novel role of the intra-atomic exchange interaction between the RE 5d and 4f states should solve the main discrepancy in XMCD [2, 3]. For a quantitative comparison, we need also to consider the effect of the Fe spin [4].

It is the purpose of this paper to reveal theoretically how we can get the detailed information on the RE 5d electrons in RFe$_2$ by reproducing quantitatively XMCD spectra at the $L_{2,3}$ edges. To this end, we simulate XMCD spectra based on a more elaborate model, in which the band nature of the RE 5d states and the Fe 3d states is treated by the tight-binding model and the intra-atomic exchange interaction between the 4f and 5d states is described by the mean-field coming from the atomic 4f electrons in the Hund's-rule ground state [2]. It will be shown that the XMCD spectra consist of the two contributions, one is from the RE 4f moments and the other is from the Fe 3d moments. As a typical example, we choose XMCD at the Sm L_3 edge since it shows the interesting spectra [5].

The tight-binding method [6] takes into account naturally the characteristics of the lattice structure and the hybridization effect. The parameters in tight-binding model are determined as follows: Firstly the integrals for LuFe$_2$ are determined according to the table in Ref. [7] and then those for other compounds are scaled by the lattice constant for each material so as to satisfy the Pettifor rule. We assume that the Fe 3d states are in magnetic state, the exchange splitting of which is fixed to 1.1 eV and that the RE 5d states are in the exchange-field of the RE 4f electrons. To distinguish the role of the 4f exchange field, we also consider RAl$_2$, where the Fe 3d states are replaced by the nonmagnetic Al 3p states while, to highlight the role of the spin-polarized Fe 3d states, LuFe$_2$ is discussed as a reference material.

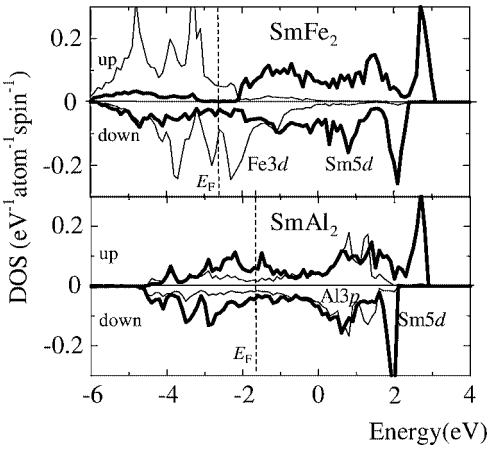

Fig. 1. Density of states for SmFe$_2$ and SmAl$_2$.

The calculated density of states for SmFe$_2$ and for SmAl$_2$ are shown in Fig. 1. We mention the following: 1) DOS of the 5d band shows the characteristic peaks of the Laves phase and 2) in addition to the polarization due to the 4f exchange field over all energy region, DOS in SmFe$_2$ is strongly distorted around the Fermi energy due to the mixing with the spin-polarized Fe 3d states, resulting in an antiferromagnetic 5d moment to the Fe moment. Thus, the tight-binding model manifests a delicate energy dependence of the spin polarization in the RE 5d states, which directly affects XMCD spectra. On the other hand, in SmAl$_2$, the 5d band is polarized only by the 4f exchange field and is not so affected by the Al 3p states, because of the relative energy position and the symmetry of the states.

The calculated XMCD spectra for SmFe$_2$ and SmAl$_2$ are compared with the experimental ones in Fig. 2, where the quadrupole contribution calculated based on the atomic model [9] is added so as to fit the experimental data. In the calculation, we have phenomenologically introduced the enhancement of dipolar matrix elements due to the intra-atomic exchange interaction, in the same manner as in Ref. [2]. Also we have used the Lorentzian with the width of 2 eV HWHM for simulating the lifetime broadening. The XMCD spectrum of SmFe$_2$ has three

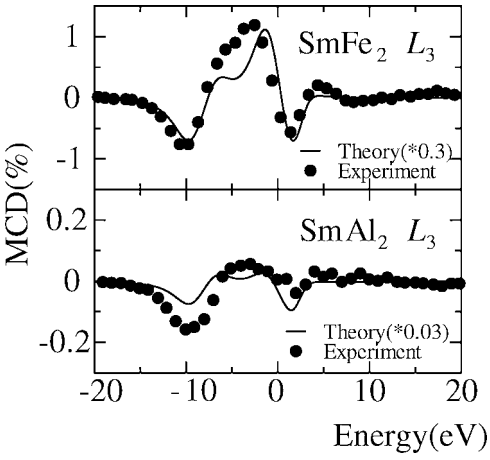

Fig. 2. XMCD spectra of $SmFe_2$ and $SmAl_2$ compared with the experimental results [8].

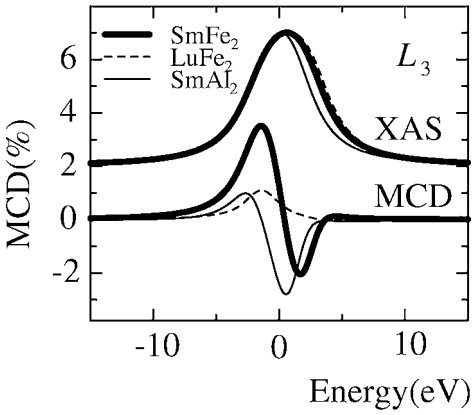

Fig. 3. Comparison of the calculated results for $SmFe_2$, $LuFe_2$ and $SmAl_2$.

distinct peaks, two negative and one positive. Roughly speaking, the lowest negative peak is due to the quadrupole transition, the middle positive peak is dominated by the hybridization effect with the spin-polarized Fe 3d states in addition to the effect from the 4f exchange field, and the highest negative peak comes from the combined effect of the 4f exchange field and the peak in DOS at high energies, which is one of the characteristics of the Laves phase. In the case of $SmAl_2$, we find only a minor positive peak in the middle, which is the consequence of the weak polarization of the 5d band in this energy region. The calculations thus reproduce the experimental XMCD spectra well on the spectral shape and the sign, although its magnitude is scaled down by the reduction factor denoted in Fig. 2 for each case. At the L_2 edge, we can similarly reproduce the XMCD spectra for both compounds based on the same model. Since the different contributions compete with each other in each compound, we have a variety of XMCD spectra at the RE $L_{2,3}$ edges, as observed in experiments [5]. Thus, we can say that, from these spectra, we can draw the detailed information on the energy dependence of the polarization in the 5d band.

To confirm the scenario, we discuss the limiting cases in Fig. 3 only for the dipole contribution. In $LuFe_2$, the XMCD spectra appear near the Fermi energy compared to XAS, while those in $SmAl_2$ spread over the vacant 5d band. These are reasonable since XMCD in the former is the consequence of the hybridization between the Fe 3d and the Lu 5d states and that in the latter is dominated by the exchange field due to the Sm 4f electrons. In $SmFe_2$, both the contributions are effective: the middle positive peak is considerably strong compared with that of $SmAl_2$, pointing out the importance of the hybridization with the Fe 3d states in this energy region.

In conclusion, we have investigated the XMCD spectra at the RE $L_{2,3}$ edges for RFe_2 in the Laves phase and expounded the basic origin of the fine structures in XMCD, which depend on the detailed polarization of the RE 5d states. It is, however, noted that the intensities calculated have been scaled down to match those observed. Furthermore, we need different reduction factors for different compounds. Although we believe that the above explanation should be still valid, we should fix a main reason for the discrepancy in the near future. The following reasons are conceivable: finite-temperature effects, widths coming from experimental resolutions, degrees of the X-ray polarization and of the saturation moment, and details of the energy bands and of the 4f states. Improvements and extensions of the present theory in these directions are now in progress.

Acknowledgments

The authors thank Prof. H. Maruyama, Prof. J. Chaboy, Dr. T. Nakamura and Dr. M. Mizumaki for fruitful discussions and for showing them the data of RAl_2 prior to publication.

Abstract

The analysis of EXAFS and XANES spectra of aqueous solutions and hexane extracts shows the interaction between hydrated (or solvated by $(Oct)_3PO$ molecules) Cu^{2+} cations and the complex anion $[Ru(NO_2)_4(NO)(OH)]^{2-}$. This interaction is accompanied by the increase of the interatomic distances Ru−O from 1.96 to 1.99 Å in the first coordination sphere of Ru atoms. The average interatomic Ru−Cu distances of the resulting heterometallic complexes have been estimated as 3.4 Å. The bond between Ru- and Cu- fragments of heterometallic complexes in their extracts with $(Oct)_3PO$ in hexane is most probably carried out *via* oxygen atoms of OH and NO fragments of NO_2 group of complex anion.

1. Introduction

The recovery of platinum group metals (Pd, Rh, Ru) from high level radioactive solutions is operable to eliminate the destabilizing action of these metals in the vitrification of wastes and proposes a new source of platinum metal. Nevertheless, technological processes of extraction and separation of platinum metals from high-level radioactive wastes (HLW) have not been developed up to now.

An effective extraction of nitro-nitrozo-hydroxo Ru anions by trialkylphosphine oxide to hexane has been revealed recently in the presence of transition metal cations with the participation of this report authors. This phenomenon can be explained by a formation of heterometallic complexes in organic solvent. A similar hypothesis for the formation of bimetallic complexes with Ru and Cu atoms in an aqua solvent was proposed earlier [1]. The goal of the present work is to study the local environment geometry of Ru in nitro-nitrozo-hydroxo Ru anions and a structure of Cu atoms environment in cations both existing in aqua solutions and hexane extracts.

EXAFS (extended X-ray absorption fine structure) and XANES (X-ray absorption near-edge structure) spectroscopy which are capable of studying the local environment of atoms and characterizing noncrystalline objects without long-range order provide a unique possibility to solve such problems [2]. In recent years, these methods were successfully employed, in particular by the authors of this paper, to determine the structure of different coordination compounds in solutions [3, 4].

2. Experimental

2.1. *Experimental and processing procedure*

EXAFS and XANES spectra were measured using synchrotron radiation of the VEPP-3 storage ring at the Budker Institute of Nuclear Physics in Novosibirsk. The electron-beam energy was 2 GeV, with a stored current of between 50 and 100 mA. The RuK and CuK absorption spectra were measured in the transmission mode using Ar/He and Xe ionization chambers as monitoring and final detectors, respectively. A channel-cut Si(111) single crystal was used as a monochromator.

The obtained data were processed with the EXCURV-92 package [5]. The phase and amplitude characteristics were calculated in the X_α approximation. To analyze the local surroundings of Ru and Cu atoms, Fourier-filtered data were fitted with k^2 weighing in the range of photoelectron wave vectors from 3 to 12 $Å^{-1}$. In the fitting procedure, the error of the determined interatomic distances was 0.01 Å in all cases. Structural models have been proposed to heterometallic complexes of several types that have been supposed in extracts of Ru containing anions and Cu containing cations. Various models of the local surroundings of Ru and Cu atoms are checked during the fitting procedure to examine the possibly formation of heterometallic complexes of several types in aqua solution and hexane extracts.

2.2. *Samples under study*

Sample 1 – the individual complex $Na_2[RuNO(NO_2)_4OH]\cdot 2H_2O$. Sample 2 – 0.5 Mol/l aqueous solution of Sample 1. Sample 3 – 0.5 Mol/l aqueous solutions of $Cu(NO_3)_2$. Samples 4, 5 – aqueous solutions containing: 0.5 Mol/l of the complex $Na_2[RuNO(NO_2)_4OH]\cdot 2H_2O$ and M (Mol/l) of $Cu(NO_3)_2$ (M = 0.5: Sample 4; M = 2.5: Sample 5), Samples 6, 7 – the extracts in hexane: extract of composition 0.12 Mol/l $Cu(NO_3)_2$ and 0.25 Mol/l extractant L (Sample 6), extract of composition 0.068 Mol/l of copper and 0.068 Mol/l of ruthenium complexes and 0.25 Mol/l extractant L (Sample 7). The extractant L = $(Oct)_3PO$ = TOPO.

2.3. *Experimental results*

Figs. 1 and 2 show CuK XANES spectra and their first derivatives for Samples 3, 4, 7 and 6, 7, respectively. The spectrum of copper nitrate solution in water (Sample 3) does practically not differ from the spectrum of the aqueous solution of copper nitrate in the presence of the complex of ruthenium (Sample 4). The coincidence of all features in the spectra of these compounds indicates the closeness of the electronic states of copper atoms and their local atomic environments (of the bond lengths and symmetries) [2]. The spectrum of the extracted species in the organic phase (Sample 7) shows substantial differences from the spectra in the aqueous phase (Samples 3 and 4): the main maximum decreases in intensity and broadens. Comparison of the derivatives of the absorption coefficients indicates that there are also differences in the fine structure both in the pre-edge region and below the edge. Such changes in the spectra indicate that there are distortions of the local symmetry of the copper atom

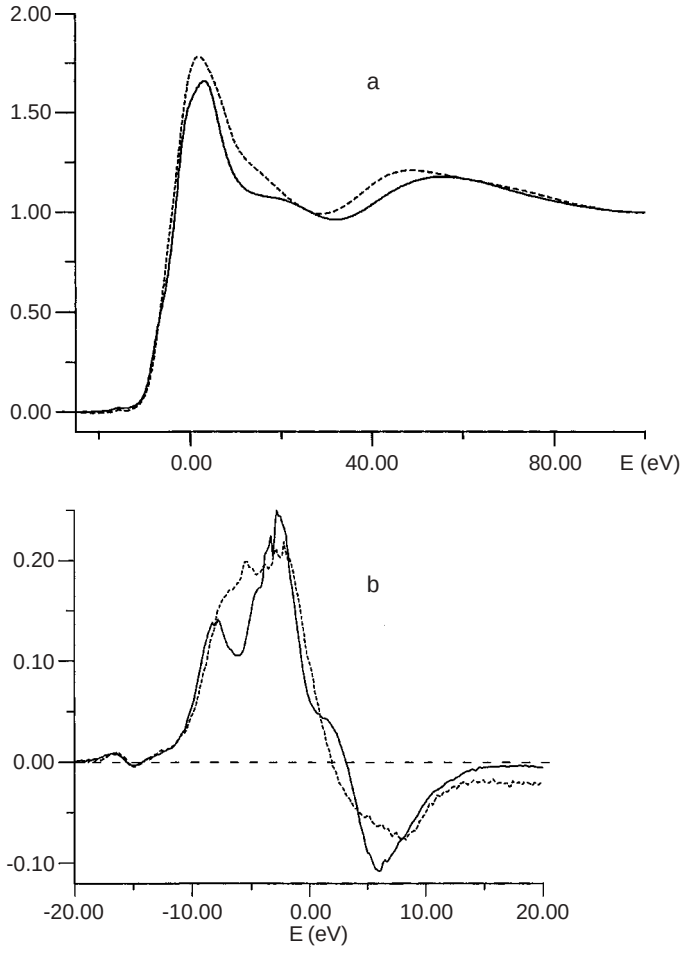

Fig. 2. CuK XANES spectra (a) and their first derivatives (b): solid lines – solutions of $Cu(NO_3)_2$ with $(Oct)_3PO$ in hexane (Sample 6); dashed lines – extract containing copper, ruthenium and $(Oct)_3PO$ (Sample 7).

environment in the organic phase. The shape of the CuK XANES spectrum of the solution of copper nitrate with trioctylphosphine oxide in hexane (Sample 6) is substantially different from that of the heterometallic complex in hexane (Sample 7) (Fig. 2) suggesting substantial differences in geometry and symmetry between the local environments of copper atoms in these samples.

3. Model calculations and discussion

First, a fitting of the RuK EXAFS data for the solid complex (Sample 1) with the known structure [6] was made. The fitting model was made to include atoms of four NO_2 groups and also atoms of the NO group and the oxygen of the OH group taking into account multiple scattering effects and photoelectron focussing. The accuracy of the interatomic distances did not exceed 0.01 Å in any of the fitting procedures.

3.1. *Environment of Ru in "mixed" Ru/Cu^{2+} complexes*

The results of the fitting of the RuK EXAFS data are shown in Table I with fixed Debye-Waller factors determined for the solid compound since their variation in the procedure did not lead to any changes in interatomic distances. Thus, the first coordination sphere of Ru in solutions also includes 4 equatorial NO_2 groups and axial nitrosyl N=O and OH groups. The Ru−O distances to the OH group oxygen in the aqueous solution of the complex with added copper nitrate (Samples 4, 5) and in the extract (Sample 7) increase equally by 0.03 Å relative to the aqueous solution of the ruthenium complex while the Ru−N distances are unchanged within the determination error. The obtained data indicate that there are coordination of copper ions to the ruthenium complex via the oxygen of the hydroxyl group linked to the ruthenium atom.

Table I. *Fitting results of the $k^2\chi(k)$ RuK EXAFS data. R(Ru−N_1), R(Ru−N_2) and R(Ru−O) – interatomic distances between Ru atoms and nitrogen atoms of NO_2, NO groups and oxygen atoms of OH groups, respectively.*

Compound	Solvent	R_1(Å) (Ru−N_1)	R_2(Å) (Ru−N_2)	R_3(Å) (Ru−O)	F_{EXAFS}
1 - (Ru)	Solid comp.	2.09	1.76	1.96	2.1
2 - (Ru)	H_2O	2.11	1.79	1.96	3.1
4 - (Ru + $Cu(NO_3)_2$	H_2O	2.11	1.79	1.99	2.6
7 - (Ru + Cu + TOPO)	C_6H_{14}	2.10	1.77	1.99	2.2

3.2. *Environment of Cu in "mixed" Ru/Cu^{2+} complexes*

Coordination numbers, interatomic distances and Debye-Waller factors presented in Table II have been determined by the computation of the CuK EXAFS data using structural models of various environments of the metal atoms.

It has been found that in $Cu(NO_3)_2$ aqueous solutions the metal atoms are only four-fold coordinated by the oxygen atoms. It has been established that in hexane extract of Cu nitrate with TOPO obtained with and without Ru the metals atoms are four-fold coordinated by oxygen atoms. In this case two additional oxygen atoms can be introduced into the fitting model that

Table II. *Fitting results obtained by $k^2\chi(k)$ CuK EXAFS data computation. Interatomic distances R(Å), Debye-Waller factors σ^2(Å^2) and goodnes of fit index F_{EXAFS} were extracted using EXURV92 package procedure [5].*

Compound	Solvent	Model	R_1(Å) (Cu−O$_1$)	R_2(Å) (Cu−O$_2$)	σ^2(Å^2) (Cu−O$_1$)	σ^2(Å^2) (Cu−O$_2$)	F_{EXAFS}
3 - $Cu(NO_3)_2$	H_2O	4O	1.94		0.005		1.2
4, 5 - Ru + $Cu(NO_3)_2$	H_2O	4O	1.94		0.005		2.4
6 - Cu + TOPO	C_6H_{14}	4O	1.94		0.005		2.0
6 - Cu + TOPO	C_6H_{14}	$4O_1 + 2O_2$	1.94	1.98	0.005	0.049	0.8
7 - Ru + Cu + TOPO	C_6H_{14}	4O	1.92		0.006		1.7
7 - Ru + Cu + TOPO	C_6H_{14}	$4O_1 + 2O_2$	1.92	2.05	0.006	0.045	1.5

results in sufficiently better fit indices. According to the fitting results greater Cu−O interatomic distances and substantially larger Debye-Waller factors for two additional oxygen atoms are found (Table II), which can indicate dynamical instability of them or even cast doubt on their existence.

In the present case it is possible to determine only average interatomic distances Cu−O for four oxygen atoms and two oxygen atoms as far as the fitting procedure gives quite large correlation coefficients of independent parameters when the model with four or six separate shells is used. The CuK XANES data analysis allows us to characterize qualitatively the variations in the local environment around metal atoms in solutions. Unfortunately, for the reason mentioned above EXAFS data computations did not add quantitative information about the Cu first coordination sphere except average interatomic distances Cu−O and coordination numbers of oxygen atoms. It is believed that the Cu first coordination sphere for Sample 3 contains four oxygen atoms of OH groups of aqua solution, for Samples 4, 5 – three atoms of water OH groups and 1 oxygen atom of OH group of the ruthenium complex (formation of Ru/Cu complex). It is suggested that Cu nearest environment for Sample 6 consist of four (or four + two) oxygen atoms from NO_3 and TOPO groups. Early in analysis it was supposed that the Cu nearest environment for Sample 7 consist of oxygen atoms from bridging OH group in addition to three (or three + two) oxygen atoms from TOPO and water OH groups. This supposition was thereafter changed. As can be seen from Fig. 3 a pronounced maximum located around 3 Å appears on the Fourier transform magnitude of the CuK EXAFS data for a heterometallic Ru/Cu complex in extract in comparison with organic Cu containing an extract without Ru. Clearly defined experimental maxima in the curves of Cu radial distribution functions give an indication of Ru atom existence at the rigidly fixed distance. This fact is direct evidence of rigid chemical binding in these binuclear complexes. The interatomic Cu−Ru distance is estimated by the value 3.4 ± 0.05 Å. The measured intensive Ru−Cu signal which corresponds to the Ru occurrence at the fixed interatomic distances in extracts allows us to propose the existence of a sufficiently rigid chemical bond between Ru- and Cu- fragments of the heterometallic complex. Such rigid binding can be provided only by double chemical bonding by two ligands of Ru fragment, especially as the Ru−Cu interatomic distance is shorter (3.4 Å) that the sum of the Ru−O and Cu−O distances (>3.9 Å) for the reason of Ru−O−Cu line bend in this case.

This means that most probably Cu is linked with Ru *via* two bridging groups, OH and NO_2. So, it is chemical bonding Ru−Cu *via* oxygen atom of OH (look above) and NO fragment of an NO_2 group. This assumption is consistent with conclusions of [7] concerning structure of "mixed" Ru/Cu^{2+} complexes in extracts obtained by IR and electron spectroscopy.

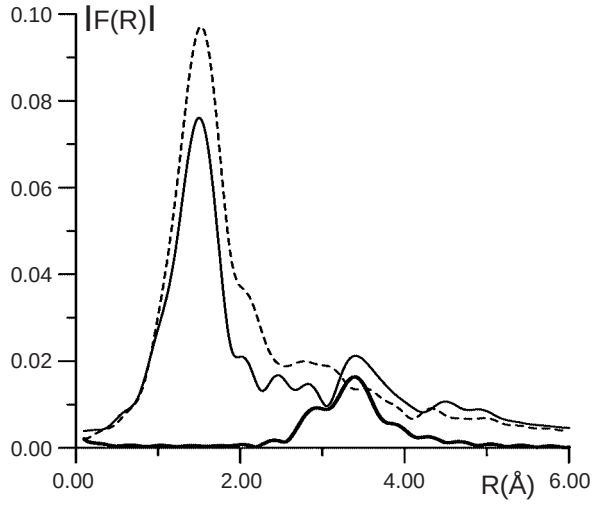

Fig. 3. Fourier transform magnitudes of $k^2\chi(k)$ CuK EXAFS data: solid line – solution of $Ru(NO_2)_4(NO)(OH)]^{2-} + CuL_n^{2+}$ in hexane (Sample 7); dashed – solution of $Cu(NO_3)_2 + 2L$ in hexane (sample 6); thick solid – model function of Cu−Ru atomic pair separated by 3.4 Å.

4. Conclusion

Structural models have been proposed to heterometallic complexes of several types that have been supposed in aqua solution and extracts of Ru containing anions and Cu containing cations. Formation of these complexes are accompanied by Ru−O distance increase while the Ru−N distances are unchanged within the determination error. Clearly defined experimental maxima in the curves of Cu radial distribution functions give an indication of Ru atom existence at the rigidly fixed distance and are direct evidence of rigid chemical bond between Ru- and Cu-fragments of heterometallic complex. The obtained data indicate that double coordination of solvated Cu^{2+} cation to the ruthenium complex could take place through the oxygens of a hydroxyl group and a nitro group both linked to the ruthenium atom.

Abstract

Many-electron (correlation) effects play a dominant role in inner-shell ionization processes in free alkaline earth metal atoms. In this work calcium 2p, strontium 3d and barium 4d photoionization processes have been investigated with emphasis on the correlation effects. Inorder to understand the details of the spectra, a series of *ab initio* calculations based on multiconfiguration Dirac–Fock method have been performed. Theoretical predictions are comapred with high-resolution synchrotron radiation induced electron spectra and the capability of the multiconfigurational computations in reproducing the experiment is discussed.

1. Introduction

Inner-shell photoionization studies of Ca, Sr and Ba atoms have proven fruitful in studying electron correlation [1–6]. In ground states they behave like closed-shell atoms and can be quite accurately described within the single configuration approximation. According to this approximation, the (Ca $2p^{-1}$, Sr $3d^{-1}$, and Ba $4d^{-1}$) photoelectron spectra (PES) should consist of just two peaks due to the spin-orbit splitting. However, strong correlation effects influence the core ionized states as a consequence of the collapse of the empty d (Ca 3d, Sr 4d, Ba 5d) and f (Ba 4f) orbitals. Large changes in the corresponding effective potentials contribute to drastic differences in the shapes and the locations between the ground and the excited states' radial wave functions. This leads to the near energy degeneracy of several electron configurations and mixing of configurations has to be included for a more accurate description of the photoionization processes. The Ba 4d photoionization was already studied in Ref. [6] and by combining the PES and Auger electron studies it was possible to deduct how the numerical simulations should be done to correclty reproduce the experiment.

In the present work the photoionization processes are described within the multiconfiguration Dirac–Fock (MCDF) calculations. The high-resolution synchrotron radiation induced gas phase Ca 2p and Sr 3d PES have been recorded in addition to the Ba 4d PES presented recently in [6]. This has enabled us to resolve the fine structure created by correlated core hole states. Our starting point is the previous study of Ba [6] which is used as a reference for Ca and Sr.

2. Experiment

The measurements of Ca, Sr and Ba vapours were carried out at three different synchrotron radiation laboratories; The Ca 2p PES was recorded at beamline U49-1/SGA at BESSY II storage ring in Berlin, Germany [7], the Sr 3d PES at beamline 10.0.1 at ALS in Berkely, USA [8], and the Ba 4d PES at beamline I411 at MAX II storage ring in Lund, Sweden [9]. The measurements were carried out using resistively heated ovens producing atomic beams of the sample, intersecting the photon beam in the interaction region. The spectra were induced using the photon energies of 400 eV (Ca), 255 eV (Sr) and 138 eV (Ba). The ejected photoelectrons were recorded with rotatable SES-100 (Ca, Ba) and SES-200 (Sr) hemispherical electron analyzers at the emission angle of 54.7° (Sr, Ba) and 0° (Ca) relative to the polarization axis of the linearly polarized light. To check the photoionization angular distribution effects for Ca, this measurement was repeated at beamline I411 at the MAX II storage ring, at an emission angle of 54.7°. No differences in relative intensities were obtained. The main parts of the resulting PES are shown in Figs. 1 (Ca), 2 (Sr), and 3 (Ba), where the binding energies have been calibrated using the well

*Electronic address: juha.nikkinen@oulu.fi

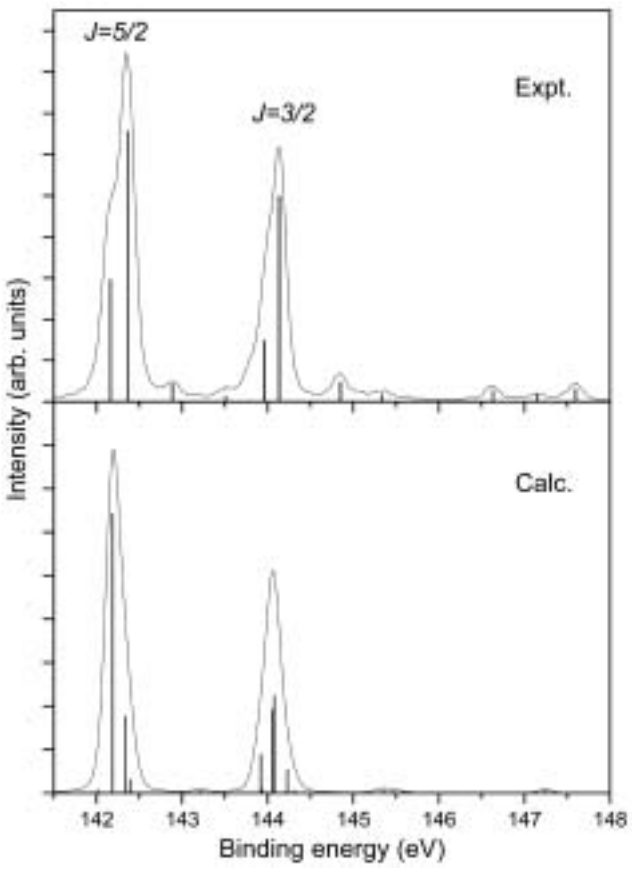

Fig. 2. Experimental (Expt.) and calculated (Calc.) Sr 3d PES.

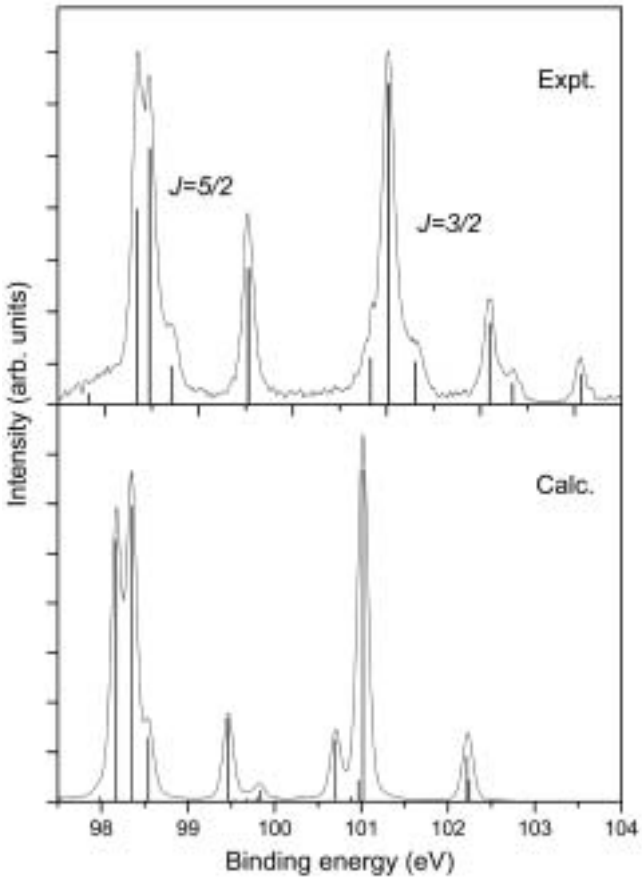

Fig. 3. Experimental (Expt.) and calculated (Calc.) Ba 4d PES.

known rare-gas photoelectron lines. The higher binding energy side of the spectra is shown in Ref. [2] for Ca and in Ref. [5] for Ba.

3. Theory

In MCDF method the atomic state functions (ASFs) are represented by the expansion

$$\Psi_\gamma(PJM) = \sum_r c_{\gamma r} \Phi_r(PJM), \tag{1}$$

where the configuration state functions (CSFs) $\Phi_r(PJM)$ are jj coupled antisymmetrized products of single-electron orbitals classified by the total angular momentum (JM) and parity (P).

In photoionization from an inner-filled subshell, induced by linearly polarized light of randomly oriented atoms, the number of emitted photoelectrons at the so-called magic angle of 54.7° is proportional to the total relative photoionization cross section. If both the ground and core hole state CSFs are constructed using the same set of orthogonal orbitals, the total relative photoionization cross section from the subshell $(n_\alpha l_\alpha j_\alpha)$, integrated over all directions of the photoelectrons, can be expressed as [3]

$$Q_\beta(J_\beta) = \frac{1}{3} Q'_\beta(J_\beta) \sum_{l,j} \int |\langle n_\alpha l_\alpha j_\alpha || r^{(1)} || \epsilon l j \rangle|^2 \, \mathrm{d}\epsilon, \tag{2}$$

where β labels the core hole states. In Eq. (2) the dipole approximation has been applied and the continuum orbitals have been evaluated in an average jj potential of the core hole states by keeping the bound orbitals fixed. The first term is the relative partial photoionization cross section,

$$Q'_\beta(J_\beta) = (2j_\alpha + 1) \left| \sum_\nu \sum_\alpha c_{\beta\nu} c_{i\alpha} \delta_{X_\nu Y_\alpha} \right|^2 \tag{3}$$

with X_ν referring to the configuration associated with $\Phi_\nu(J_\beta)$ and Y_α referring to the same parent configuration after coupling the $n_\alpha j_\alpha$ orbital from $\Phi_\alpha(J_i)$.

4. Results and Discussion

In the present work, the correlation effects were included by generating the ASFs using the GRASP92 package [10] based on the MCDF method. Calculations were performed for the ground and core hole states and the relative PES intensities were obtrained from Eq. (3). The atomic orbitals were constructed from variational calculation of the average energy of all ASFs included.

The effect of correlation in the ground states was found to be negligible in all cases. The core hole state calculations were based on results obtained for Ba in [6]. The strong dependence of calculations on the average energy of all ASFs involved was reduced by performing the calculations in two steps. First, smaller configuration sets were used to find good approximations for inner-shell orbitals,

Ca $2p^{-1}$: $1s^2 2s^2 2p^{-1} 3s^2 3p^6 (3d, 4s)^2$,
Sr $3d^{-1}$: $[Ar] 3d^{-1} 4s^2 4p^6 (4d, 5s, 5p)^2$,
Ba $4d^{-1}$: $[Kr] 4d^{-1} 5s^2 5p^6 (4f, 5d, 6s, 6p)^2$.

In the second step the core orbitals and the s-orbitals, Ca 4s, Sr 5s, and Ba 6s were frozen from the first calculations. To redistribute the intensity among the larger set of states the configuration sets were expanded to

Ca $2p^{-1}$: $1s^2 2s^2 2p^{-1} 3s^2 3p^6 (3d, 4s, 4p, 4d, 5s, 5p)^2$,
Sr $3d^{-1}$: $[Ar] 3d^{-1} 4s^2 4p^6 (4d, 5s, 5p, 5d, 6s, 6p)^2$,
Ba $4d^{-1}$: $[Kr] 4d^{-1} 5s^2 5p^6 (4f, 5d, 6s, 6p, 6d, 7s, 7p)^2$.

The results of these second step calculations are shown in Figs. 1 (Ca), 2 (Sr), and 3 (Ba). For visual comparison with the experiment the spectra are plotted using the line widths obtained from experimental results with calculated relative line intensities which are shown as vertical bars. This kind of calculation procedure seems to work very well for elements involving strong orbital relaxation as was pointed out already for Ba [6]. If we compare the results for Ba (Fig. 3) with those of Ca (Fig. 1) we can conclude that also the Ca spectrum is fairly well reproduced. There are slight deviations in the relative intensities when compared to experiment, but the main $J = 3/2$ and $J = 1/2$ structures and even the minor components of the spectra are predicted quite well. Also the energy splitting between the main structures agrees well with experiment, only the minor structures are slightly too close to the main structures. Inspection of Fig. 2 shows, however, that this type of calculation reproduces the Sr spectrum somewhat worse. There are significant deviations in the relative intensities within the $J = 5/2$ main structure but the $J = 3/2$ structure and the energy splitting is well reproduced. In total the effect of correlation is not as strong in Sr as in Ca and Ba.

Configuration set used for Ca in the first calculation differs a bit from the set used for Ba; the first correlation orbitals of p and f type (4p and 4f) were not included for Ca. This was because the CSFs produced via inclusion of these orbitals were not so strongly involved into the main structure components; they mainly affected to the average energy of the system by drawing it apart from the main structure. The effect of the 4p orbital was tested by including it to the configuration set used in the first step and repeating the similar second step calculation as discussed above. The comparison of this calculation with the experiment was worse than the one presented in Fig. 1. The 4f orbital was also neglected for Sr from the first configuration set. Instead, the first p type correlation orbital (5p) was included. The effect of neglecting the 5p orbital from the first step was tested and no significant changes were noticed. No notable improvements were obtained by further expanding or reducing the configuration sets in both steps of the procedures.

5. Conclusions

In conclusion, high-resolution experimental photoionization studies combined with extensive MCDF calculations have allowed us to resolve and to understand the fine structure in Ca 2p, Sr 3d and Ba 4d PES. Those effects arise as a consequence of strong electron correlation induced by a collapse of the empty d and f orbitals in the photoionization process; the collapsing orbitals make several configurations nearly degenerate in energy, and to describe this, the electron correlation has to be taken correctly into account in the calculations. Multiconfigurational Dirac–Fock calculations presented here reproduced the experimental results quite well, but due to the sensitivity of the calculations to the configuration sets used and to the average energy of the states, some uncertainties still remain. Note, however, that in the MCDF method the orbitals remain automatically orthogonal, which is not the case in the configuration interaction (CI) method used e.g. in the Cowan's code [11]. The correlation will also affect the partial Auger rates as shown for Ba [6] and similar studies of Ca and Sr Auger electron spectra are in progress to further test the computational methods.

Acknowledgments

We are grateful to the staff of the MAX, BESSY and ALS synchrotron laboratories for help during the measurements. Financial support from the National Graduate School in Materials Physics, the European Commuity – Access to Research Infrastructure Action of the Improving Human Potential Programme and the Research Council for the Natural Sciences of the Finnish Academy and the Department of Energy, office of Science, BES are acknowledged.

Abstract

We report a theoretical study of core-level X-ray photoemission (XPS), X-ray absorption (XAS) and resonant X-ray emission spectra (RXES) at Mn $L_{2,3}$ edge in Mn thin films on Ag(001). By combining band structure, atomic multiplet and impurity Anderson model calculation, we construct a realistic impurity model that includes full intra-atomic multiplet interaction and inter-atomic coupling to the Mn 3d and Ag-4d bands. The model is applied to various Mn/Ag thin films and related structures. The different systems were modeled by varying only one parameter, the hybridization strength. Good agreement with experiment is obtained. The main conclusion from the impurity model calculations is that the satellite structure observed in the thin films is due to final state charge transfer process, mainly from the Mn-3d states of the neighboring atom. Moreover we predict that the RXES spectra have a satellite structure which is highly sensitive to the local atomic structure around the Mn atoms through its strong dependence on the hybridization of the Mn 3d orbitals.

1. Introduction

Ultrathin transition metal films have attracted much experimental and theoretical interest over the past decade because of their importance for the understanding of interfacial and low dimensional magnetism. For instance, 3d transition metal monolayers (ML) adsorbed on nonmagnetic substrates might be considered as ideal systems for the study of spontaneous two dimensional itinerant magnetism. Low-index noble metal surfaces, such as Cu(100), Ag(100) and Au(100), have often been used as substrate. In the ML range, various artificial structures could be stabilized on these surfaces: adsorbed and embedded MLs [e.g., Mn/Ag(100) and Ag/Mn/Ag(100) (Ref. [1])].

In search of the correlation between structure and magnetism, the Mn/Ag(001) system has been a particular focus [2, 3, 4, 5, 6]. Various new thin film structures of Mn on Ag(001), such as "ideal" adsorbed ML (Mn/Ag) and "buried" ML (Ag/Mn/Ag), were grown and extensively studied by P. Schieffer *et al.* [1, 7, 8, 9]. The Mn 2p XPS of the 0–2 ML films show a pronounced satellite structure. The satellites are located at about 4 and 5 eV higher binding energy than the $2p_{3/2}$ and $2p_{1/2}$ main lines, respectively. Upon decreasing the film coverage their intensity increases continuously and even exceeds that of the "main" lines in the sub-ML regime.

In this context it is also instructive to recall some older experiments on Mn impurities in Ag host. In 1980, Höchst *et al.* [10] measured the Mn 2p XPS in $Mn_x\,Ag_{1-x}$ alloys as a function of x. In the dilute limit $x \to 0$, the spectrum shows a two-peak structure with very broad, but simple $2p_{3/2}$ and $2p_{1/2}$ lines. For a critical concentration range ($0.1 < x < 0.2$) a four-peak satellite structure develops, which is similar to the one in Mn/Ag thin film. Höchst *et al.* attributed the satellites to a chemical shift between Mn atoms with different local environments in the alloy. Whether this interpretation is correct can only be answered on the basis of a microscopic model which would require precise knowledge of the local structure around the Mn atoms. Such information is unfortunately not available. In the theoretical analysis in this paper, we will therefore consider only the dilute limit ($x \to 0$). In this case it is quite certain that all the Mn atoms are surrounded only by Ag atoms which occupy perfect fcc lattice sites.

The situation is more favorable in the case of the thin film systems where precise structural data have been available. For instance, in an adsorbed Mn ML system on Ag(001), which can be grown with high structural quality, all Mn atoms are structurally equivalent. Consequently, chemical shifts cannot occur [8] and the satellite structures must be an intrinsic effect, due to electron correlation [11, 8]. Pursuing this idea, we present here a theoretical study of the core-level XPS, XAS, RXES spectra of Mn thin films on Ag(001) by combining band structure, atomic multiplet and impurity model calculations. In the present work, three possible Mn/Ag(001) thin films and four related systems are considered: (a) an adsorbed Mn ML on Ag(001), (b) a "buried" one (i.e. Ag/Mn/Ag(001)), (c) an adsorbed bilayer Mn/Mn/Ag(001), (d) a free standing Mn ML, (e) bulk body-centered-tetragonal (bct) Mn, (f) Mn impurity in Ag, and (g) a single Mn atom on Ag(001).

The paper is organized as follows: The model and the formalism used in this analysis are given in Sec. 2. The results are summarized and discussed in Sec. 3.

2. Method of calculation

Here we shall give a brief description of the model. We take into account the Mn 3d orbitals of a central Mn atom (core hole site) together with appropriate linear combinations of Mn 3d orbitals on neighboring sites and Ag 4d orbitals of the Ag substrate. We make the following approximations: (*i*) We assume, mainly for simplicity, always an antiferromagnetic (AFM) order where the spins of all neighboring Mn atoms are antiparallel to that of the central Mn atom. The real magnetic structure might be more complex, since several different AFM orders are competing for the ground state. The details of the AFM order have, however, only a small effect on the core level spectra treated here. (*ii*) From the results of *ab initio* calculations [12], we infer the ground state electronic structure in the atomic limit: The central Mn atom has a $3d^5$ configuration and, on the neighboring sites, the Ag 4d band is filled (both spins), while the Mn 3d band is filled for

locally majority spin (denote ↑) and empty for locally minority spin (denote ↓). The spin of the central Mn atom is aligned antiferromagnetically to the Mn bands. (*iii*) For simplicity, we assume a cubic point symmetry throughout. While this is the exact symmetry only for system (f) (Mn impurity in Ag), we believe that it is a good approximation for all systems and that the effect of lower symmetry is small for the spectra considered here.

The ground state is represented as a linear combination of basis states from the manifold of the following eight configurations: $3d^5$, $3d^{5+n}\ \underline{(\mathrm{Ag})}^n$, $3d^{5+n}\underline{(\mathrm{Mn}\uparrow)}^n$, $3d^4(\mathrm{Mn}\downarrow)$, $3d^6\underline{(\mathrm{Mn}\uparrow)}$, $3d^7\underline{(\mathrm{Mn}\uparrow)}(\mathrm{Ag})$, $(n = 1, 2)$. $\underline{\mathrm{Ag}}$ and $\underline{\mathrm{Mn}\uparrow}$ denote holes in the Ag band and in the Mn band with (locally) majority spin, respectively. Mn↓ represents an electron in the Mn band with (locally) minority spin.

The Hamiltonian is given by

$$
\begin{aligned}
H = &\sum_{\Gamma,\sigma} \varepsilon_{3d}(\Gamma) d^\dagger_{\Gamma\sigma} d_{\Gamma\sigma} + \sum_{m,\sigma} \varepsilon_{2p} p^\dagger_{m\sigma} p_{m\sigma} \\
&+ U_{dd} \sum_{(\Gamma,\sigma)\neq(\Gamma',\sigma')} d^\dagger_{\Gamma\sigma} d_{\Gamma\sigma} d^\dagger_{\Gamma'\sigma'} d_{\Gamma'\sigma'} \\
&- U_{dc} \sum_{\Gamma,m,\sigma,\sigma'} d^\dagger_{\Gamma\sigma} d_{\Gamma\sigma} (1 - p^\dagger_{m\sigma'} p_{m\sigma'}) + H_{\mathrm{multiplet}} \\
&+ \sum_{X,k,\sigma} \varepsilon_X(k) a^\dagger_{Xk\sigma} a_{Xk\sigma} \\
&+ \sum_{X,k,\Gamma,\sigma} \frac{V_X(\Gamma)}{\sqrt{N}} (d^\dagger_{\Gamma\sigma} a_{Xk\sigma} + a^\dagger_{Xk\sigma} d_{\Gamma\sigma}). \qquad (1)
\end{aligned}
$$

The first five terms of the total Hamiltonian H are the atomic part describing the central Mn atom. The sixth term represents the X band (X = Mn↑, Mn↓ and Ag) and the last term describes the hybridization between the atomic Mn 3d state and the X band. The $\varepsilon_{3d}(\Gamma)$, ε_{2p}, and $\varepsilon_X(k)$ represent the energies of Mn 3d, Mn 2p, and X band states, respectively, with the irreducible representation Γ ($= e_g, t_{2g}$) of the O_h symmetry. The indices m and σ are the orbital and spin states. $V_X(\Gamma)$, U_{dd}, and U_{dc} are the hybridization between the central Mn 3d and X band states, the Coulomb interaction between Mn 3d states, that between Mn 3d and 2p core-hole states, respectively. The term $H_{\mathrm{multiplet}}$ describes the intra-atomic multiplet coupling between Mn 3d states and that between Mn 3d and 2p states. The spin-orbit interactions for Mn 3d and 2p states are also included. The Slater integrals and the spin-orbit coupling constant are calculated by Cowan's Hartree-Fock program [13] and then the Slater integrals are rescaled by 80%, as usual. We assume rectangular bands X of width $W(X)$, and we approximate them by N discrete levels $\varepsilon_X(k) = \varepsilon_X + \frac{W(X)}{N}(k - \frac{N+1}{2})$, $(k = 1, \ldots, N)$. For the hybridization, we use the empirical relation: $V_X(e_g) = -2V_X(t_{2g})$. The charge transfer energy Δ is defined as $\Delta \equiv \varepsilon_{3d} + 5U_{dd}$.

3. Results

Here we calculated the Mn 2p XPS, 2p XAS and 2p → 3d → 2p RXES with excitation at L_3 and L_2 for various Mn/Ag thin films and related structures. The model parameters are summarized in Table I. Most of those values are estimated from the previous *ab initio* calculations [12]. Among them, the important parameters are Δ, V_{Mn}, U_{dc} and U_{dd}. Δ and V_{Mn} control mainly the ground state properties. The relative intensity between the main line and the satellite of XPS is sensitive to V_{Mn}, while their energy separation is affected by Δ and U_{dc}. The XPS spectra are rather insensitive to U_{dd}, but the analysis of XAS is crucial in determining whether the value of U_{dd} is around 1.0 eV or 3.0 eV.

Table I. *Parameter values (in eV) used in the calculations.*

System independent impurity model parameters

Δ	U_{dd}	U_{dc}	$\varepsilon_{Mn\uparrow}$	$\varepsilon_{Mn\downarrow}$	ε_{Ag}	N	$10Dq$
−3.012	3.0	4.123	−2.5	0.5	−5.0	4	0.5

system	W(Ag)	$V_{Ag}(e_g)$	W(Mn)	$V_{Mn}(e_g)$
impurity in Ag	3	0.866	0	0
1 Mn atom/Ag	3	0.5	0	0
free Mn ML	0	0	1	0.8
Mn/Ag	3	0.5	1	0.8
Ag/Mn/Ag	3	0.707	1	0.8
Mn/Mn/Ag(S)	0	0	2	1.25
Mn/Mn/Ag(I)	3	0.707	2	1.25
Mn bct	0	0	3	2.0

The calculated Mn 2p XPS is shown in Fig. 1(a). The dashed line represents the back ground contribution which is given with an adjustable constant C, by $B(E_B) = C\int_{-\infty}^{E_B} F(E'_B)\mathrm{d}E'_B$, where $F(E_B)$ represents the 2p XPS spectrum. The core hole lifetime broadening Γ is taken to be 0.5 eV, and the Gaussian broadening to be $\sigma = 0.5$ eV. The calculated 2p XPS spectra reproduce well the experiments in the whole range of structures from Mn impurities in Ag and to Mn/Ag [8, 10]. For comparison, we also calculated the spectra of a free ML and that of a single Mn atom on Ag. The satellite intensity decreases slightly from Mn/Ag to Ag/Mn/Ag and more strongly from Mn/Ag to Mn/Mn/Ag.

Since the Ag 4d-band lies 2.5 eV below the Mn 3d↑ band, the $3d^6\underline{\mathrm{Ag}}$ configurations contribute much less to the ground state than $3d^6\ \underline{\mathrm{Mn}\uparrow}$. As for the final states, the $2p^53d^6\underline{\mathrm{Ag}}$ states have energies around the $2p^53d^5$ ones, whereas the $2p^53d^6\ \underline{\mathrm{Mn}\uparrow}$ states lie clearly below them. As a consequence, the satellites are due to poorly screened $2p^53d^5$ final states with some Ag-screened $2p^53d^6\ \underline{\mathrm{Ag}}$ contribution, whereas the main lines are due to Mn-screened $2p^53d^6\ \underline{\mathrm{Mn}\uparrow}$ states.

Figure 1(b) shows calculated Mn 2p XAS spectra where we use the same parameter values as those of 2p XPS. The experiment is also shown by closed symbol only for Mn/Ag system. The calculation for Mn/Ag is in good agreement with the experiment. All systems have very similar spectrum shape. This is because the charge transfer effect is suppressed due to the screening of the core hole potential by the 3d electron photoexcited from the core level. Unfortunately, to the author's knowledge, there is only one experiment of Mn 2p XAS for Mn/Ag(001) systems [14] so that the comparison with experiment is only limited to this system.

We also calculate the 2p → 3d → 2p RXES. For simplicity we neglect the polarization of the incident photon. The calculations at L_3 and L_2 excitations are shown in the left and right panel in Fig. 1(c), respectively. At L_3 excitation, the elastic peak have a strong intensity and the spectrum have similar shape for all systems. For L_2 excitation, the intensity of the inelastic peak increases and is larger than that of the elastic peak for all systems. Moreover, while the XAS spectra at L_2 region does not change very much, the RXES spectra with the L_2 excitation strongly depend on the systems.

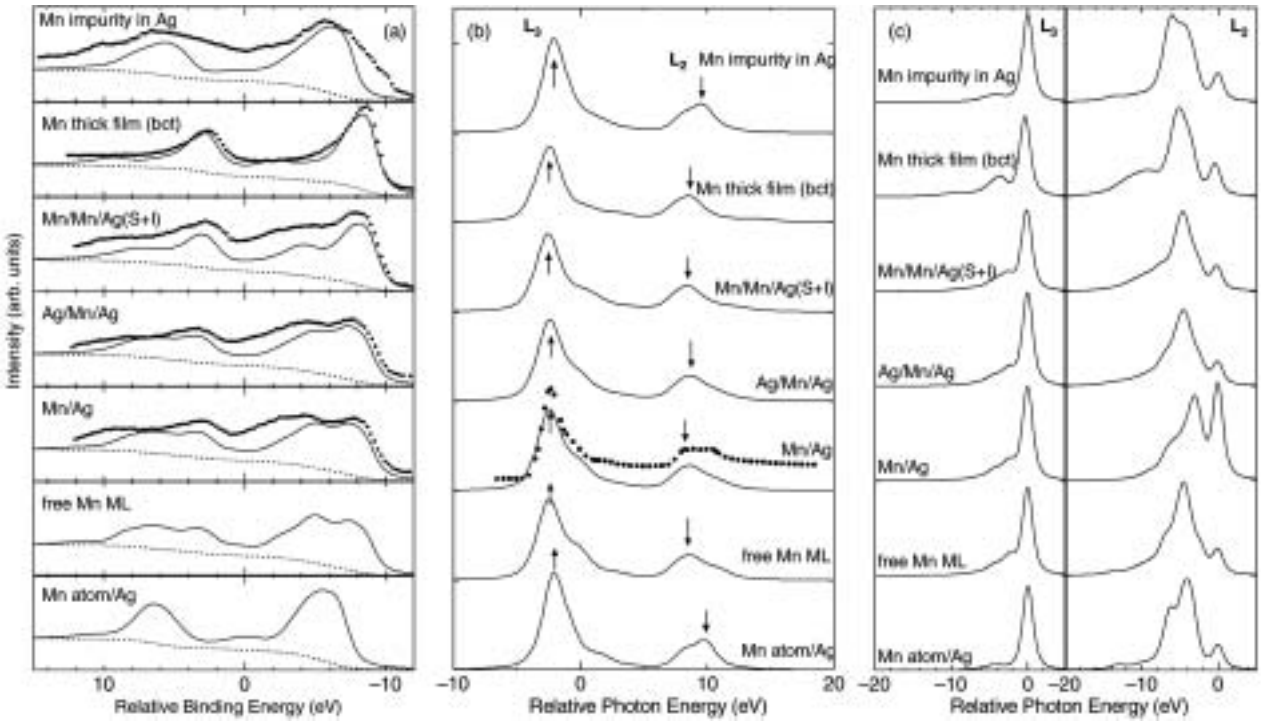

Fig. 1. Calculated XPS, XAS, and RXES spectra at Mn $L_{2,3}$ edge for various Mn-Ag structures with experimental spectra (closed symbol). (a): Mn 2p XPS spectra. The dashed line represents the calculated background spectra. (b): Mn 2p XAS. (c): 2p → 3d → 2p RXES at the photon energies marked by the vertical arrows in the $L_{2,3}$ XAS in (b).

In summary, we have presented 2p XPS, XAS and RXES spectra of various Mn/Ag thin film and related structures. The results are interpreted using the realistic impurity model that includes full atomic multiplet interaction and coupling to the Mn 3d and Ag 4d bands. Good agreement between the experimental results and the model calculations is achieved in 2p XPS. Using the same parameter values, we could also reproduce the experimental 2p XAS spectrum of the Mn/Ag(001) system. Moreover, we predict theoretically that the RXES lineshape is very sensitive to the hybridization of the Mn 3d orbitals and thus to the local atomic structure.

Abstract

The probabilities of non-monopole processes of additional electron excitation/ejection (conjugate shake up/off processes) upon 2p-photoionization of atomic sulphur are calculated in the frame of first-order perturbation theory for the wavefunctions. Both conjugate shake up and conjugate shake off processes are important on a comparatively wide energy scale, and they may cause noticeable discontinuities in atomic photoabsorption.

1. Introduction

It is known that additional excitations/ionizations above inner-shell thresholds cause discontinuities in atomic photoabsorption which may cause difficulties in obtaining the normalized EXAFS (see [1] and references therein). The appearance of a more or less pronounced step at the threshold of additional excitation or ionization and the change of the slope of the atomic photabsortion spectrum above this threshold lead to appearance of non-structural low-frequency oscillations in normalized EXAFS if one approximates the atomic photoabsorption with a smooth function of the photoelectron energy. These non-structural oscillations lead to the appearance of the meddling low-R peaks in the Fourier transforms of EXAFS. This situation may become embarrassing when the structural signal is weak as, say, in amorphous samples [2] or when an absorbing atom is surrounded by light ligands with low back-scattering amplitudes.

The effect of additional monopole excitations on EXAFS treatment was studied theoretically in [3–5]. Monopole (shake) excitations are those additional excitations where an electron is either shaken up into a bound excited state or shaken off into continuum without change of its orbital momentum quantum number.

There exists another mechanism of additional non-monopole electron excitation due to dipole excitations of electrons in the final state of photoabsorption [6-10]. Those processes were called conjugate shake (CS) processes. Close-coupling calculations for sodium [7] and R-matrix calculations for boron [8], magnesium [9] and aluminum [10] showed that the conjugate shake up (CSU) processes for valence electrons may be important during photoionization having probabilities of up to about 20%. No theoretical study on conjugate shake off (CSO) processes has not yet been performed.

In this work we calculate the relative probabilities of both CSU and CSO processes upon 2p-photoionization of atomic sulphur in the frame of the first order perturbation theory for the wavefunctions.

Table I. *Conjugate shake processes and respective correlations in the 2p-photo-absorption final state.*

Process	Correlation*
CSU3p → 3d	$2p^5 3s^2 3p^4 \varepsilon_1 d - 2p^5 3s^2 3p^3 d\varepsilon_2 p^{**}$
	$\varepsilon_2 f$
CSU 3p → 4s	$2p^5 3s^2 3p^4 \varepsilon_1 d - 2p^5 3s^2 3p^3 4s\varepsilon_2 f^{**}$
	$\varepsilon_2 p$
CSO 3p	$2p^5 3s^2 3p^4 \varepsilon_1 d - 2p^5 3s^2 3p^3 \varepsilon_2 p\varepsilon_3 d^{**}$
	$\varepsilon_2 s\varepsilon_3 f$
	$\varepsilon_2 d\varepsilon_3 f$
	$\varepsilon_2 s\varepsilon_3 p$
CSU 3s → 3p	$2p^5 3s^2 3p^4 \varepsilon_1 d - 2p^5 3s^1 3p^5 \varepsilon_2 p^{**}$
	$\varepsilon_2 f$
CSO 3s	$2p^5 3s^2 3p^4 \varepsilon_1 d - 2p^5 3s^1 3p^4 \varepsilon_2 s\varepsilon_3 d^{**}$
	$\varepsilon_2 f\varepsilon_3 f$
	$\varepsilon_2 d\varepsilon_3 d$
	$\varepsilon_2 p\varepsilon_3 f$
	$\varepsilon_2 p\varepsilon_3 p$

* $1s^2 2s^2$ are omitted in the configuration notations.
** Correlation giving the principal contribution to CS probability.

2. Method of Calculation

We calculate the probabilities of additional conjugate shake up and shake off excitations due to the dipole correlations in the final state of the 2p-photoabsorption. The conjugate shake processes and respective final-state correlations are listed in Table I.

Let us denote by $|1\rangle = |2p^5 3s^2 3p^4 \varepsilon_1 d\rangle$ the wavefunction of the 2p single photoabsorption final state. Here $\varepsilon_1 d$ is the photoelectron continuous spectrum wavefunction with the energy

$$\varepsilon_1 = \varepsilon_{\rm ph} - IP_{\rm 2p}$$

where $\varepsilon_{\rm ph}$ is the exciting photon energy and $IP_{\rm 2p}$ is the ionization potential of the 2p subshell. $|2\rangle$ will stand for the wavefunction of an excited state interacting with $|1\rangle$, for example, $|2\rangle = |2p^5 3s^2 3p^3 3d\varepsilon_2 p\rangle$, see Table I. Then the corrected wavefunction of the 2p photoabsorption final state is

$$|\Psi(\varepsilon_1)\rangle = C_1|1\rangle + \int C_2|2\rangle d\varepsilon_2. \quad (1)$$

If the continuous spectrum orbitals $\varepsilon_1 d$ and $\varepsilon_2 p$ are normalized in the energy scale and for the determination of C_2 the first order perturbation theory is used, then for comparatively small interaction between $|1\rangle$ and $|2\rangle$ one has the following integral contribution from correlation states $|2\rangle$ to $|\Psi(\varepsilon_1)\rangle$ [11]:

$$P(\rm CS) = 1 - C_1^2 = \pi^2 \langle 1|V|2\rangle^2. \quad (2)$$

Here $\langle 1|V|2\rangle$ is the electrostatic interaction integral calculated upon the condition that the energies of the continua $|1\rangle$ and $|2\rangle$

[1] E-mail: agk@jeo.ru
[2] Permanent address: Observatoire de la Côte d'Azur, CNRS Laboratoire Cassini, BP 4229, 06304 Nice Cedex 4, France; e-mail: petrini@obs-nice.fr

are equal. The expression (2) gives the probability to discover the system in a state with additionally excited electron, i.e. the probability of the conjugate shake process, in the above example the conjugate 3p → 3d shake up process (CSU3p → 3d).

When $|2\rangle$ contains two continuous spectrum electrons as in the CSO processes, for example $|2p^5 3s^2 3p^3 \varepsilon_2 p \varepsilon_3 d\rangle$, then to obtain the CSO probabilities an additional integration of (2) over ε_3 is needed.

To construct the many-electron wavefunctions $|1\rangle$ and $|2\rangle$ we use the Hartree-Fock-Pauli orbitals of the configuration $|1\rangle$, whereas in $|2\rangle$ the excited electron functions are obtained in the field of respective two-hole cores. Excited channels with the orbital momenta up to 3 were included in the calculation.

3. Results and Discussion

Calculated probabilities of conjugate shake up and shake off excitations from 3p and 3s subshells of the sulphur atom upon 2p-photoionization are presented in Figure 1 and Figure 2. Each CSU or CSO excitation for the same additionally excited electron have either two or several contributing types of correlation states, see Table I.

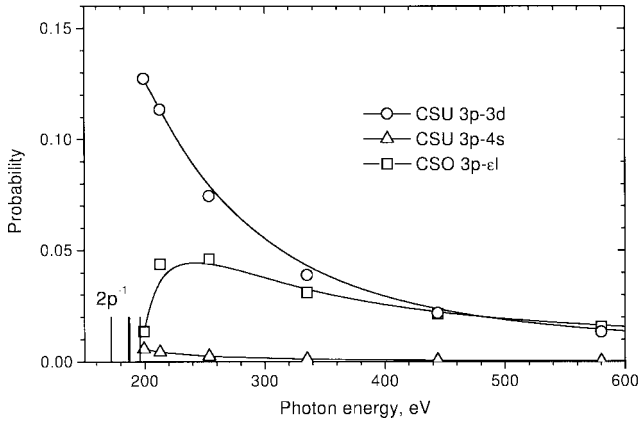

Fig. 1. Probabilities of the conjugate shake up and shake off excitations from the 3p subshell upon 2p-photoionization of atomic sulphur. Calculated values are shown with symbols, lines are the results of B-spline approximations of the calculated data. Circles, CSU3p → 3d; triangles, CSU3p → 4s; squares, CSO3p. Vertical bars show the positions of the 2p-threshold and the CS thresholds.

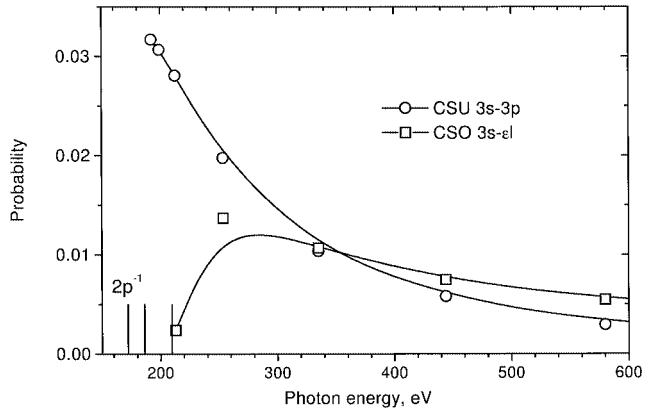

Fig. 2. Probabilities of the conjugate shake up and shake off excitations from the 3s subshell upon 2p-photoionization of atomic sulphur. Calculated values are shown with symbols, lines are the results of B-spline approximations of the calculated data. Circles, CSU3s → 3p; squares, CSO3s. Vertical bars show the positions of the 2p-threshold and the CS thresholds.

Consider first the CSU processes. Of these, the most probable is the CSU 3p → 3d process having at its threshold the probability of about 15% (Figure 1, circles). This value compares well with the CSU probabilities for Mg and A1 obtained in [9, 10] in the *R*-matrix approach. The CSU 3s → 3p process (circles in Figure 2) has lower probability of about 3% near its threshold. This is what one would have expected considering the number of 3p and 3s electrons in $|1\rangle$ and the number of accessible free bound states. The maximum value of the CSU3p → 4s probability (Figure 1, triangles) is less than 1%. We did not discover any other noticeable CSU processes.

The probabilities of all the three CSU processes discussed above behave in the same way with respect to the exciting photon energy. They have maximal values near thresholds and then decrease rapidly with the growth of energy. This behavior is in line with earlier theoretical predictions [7–10].

The probabilities of the CSO 3p → εl and 3s → εl processes are shown in Figures 1 and 2 with squares. One can see that the probabilities of these processes are significant, too. The integral relative contribution of CSO to total CS probability on the energy interval of 190 to 850 eV is 42% for 3p excitations and 48% for 3s excitations. The energy dependence of the CSO probabilities is notably different from that of the CSU processes. One can see from Figures 1 and 2 that the CSO probabilities are very small at their thresholds, then they grow rapidly reaching maximal values and then descend. The slope of the descent of the CSO probabilities is lower than that for the CSU. Resultantly, the relative importance of the CSU and CSO processes changes with the exciting photon energy. While the CSU processes dominate at small photon energies, at higher energies the CSO processes become more probable than the CSU ones. For the CSO from the 3p subshell it happens above 480eV (310 eV above the 2p-threshold), and for the CSO from the 3s subshell – above 356 eV (184 eV above the 2p-threshold).

The calculations showed that both for the CSU and CSO processes there always exists a correlation state that gives the principal contribution to the CS process probability. Those correlation states are marked in Table I. In the case of the CSU processes the principal correlation gives about 75% of the total probability. As for the CSO processes, the dominant correlations here are more pronounced giving up to 98% of the total CSO probability.

It should be noted that both "diagram" final state $|1\rangle$ and correlation states $|2\rangle$ are reached by the dipole transitions from the ground state, and the calculations of the shape of the photoabsorption cross section must deal with this fact. Although the cross sections were not calculated in this work, one can still suppose that since the probabilities of the CS processes are great and they are sharply dependent on the photon energies this may cause significant additional features in atomic XANES.

4. Conclusions

The probabilities of conjugate shake up and conjugate shake off processes upon 2p photoionization of atomic sulphur in the first-order perturbation theory for the wavefunctions. The most prominent are the CSU3p → 3d and CSU3s → 3p. The CSO processes are comparable with CSU comprising on a wide energy interval 42% (3p-excitations) and 48% (3s-excitations) of the total CS probability. In the near edge region the CSU processes dominate while due to rapid decrease of the CSU probabilities with energy the CSO processes become more probable at photon energies 200 to 300 eV above threshold. Great probabilities of

the CS processes and their sharp dependences on exciting photon energies may cause additional features in atomic XANES.

Abstract

The (010) surface of vanadium pentoxide, V_2O_5, contains 1-, 2-, and 3-fold coordinated oxygen centers which can participate as active sites in specific surface reactions. In the present work we use *ab initio* density functional theory (DFT) together with cluster models to calculate 1s core excitation spectra of the different oxygen centers. Excitation energies and intensities are characterized by details of local V-O binding where the data depend strongly on coordination. As a result, strong coordination dependence of the angle-resolved NEXAFS spectra of different oxygen centers is found. The differences can also be seen in the total spectrum obtained from a superposition of the atom specific spectra. A comparison of our theoretical spectra with experimental NEXAFS data yields good agreement and allows an assignment of the experimental peaks to the differently coordinated oxygen centers.

1. Introduction

Vanadium pentoxide V_2O_5 is member of a large vanadium oxide family, e.g. VO, VO_2, V_2O_3 [1], where the oxidation state of vanadium runs from +2 to +5. This causes a variety of geometric and electronic properties and makes vanadium oxides interesting for scientific studies as well as industrial applications [2–4]. For example, V_2O_5 is used as a component in catalysts for the reduction of NO_x with ammonia [5, 6] or for the selective oxidation of hydrocarbons [7].

V_2O_5 forms an orthorhombic layer-type crystal [1] where the layers extend perpendicular to the (010) direction with VO_5 pyramids sticking out at both sides of the layers. These layers possess three differently coordinated oxygen centers: singly coordinated vanadyl, O(1), twofold coordinated bridging, O(2), and threefold coordinated oxygen, O(3). The oxygen centers, if placed at the (010) surface, are expected to react differently with respect to adsorption of small molecules [8, 9]. However, it is quite difficult to discriminate between them in the experiment. For example, XPS studies on O 1s ionization of V_2O_5 [10] show only one broad structureless peak.

In the present work we have performed *ab initio* DFT cluster calculations of angle-resolved NEXAFS spectra for different oxygen centers in V_2O_5 which allow us to distinguish between the three oxygen species in the NEXAFS experiment.

2. Computational Methods

Density functional theory (DFT) cluster calculations are performed to evaluate the electronic structure of vanadium pentoxide. The theoretical NEXAFS spectra are calculated by the transition state approach [11, 12] in combination with a double-basis-set technique [13]. A detailed description of the method can be found elsewhere [14]. Here the orbitals of the cluster are determined using a double zeta or better quality basis set with a half-occupied core orbital at the ionization center. The orbitals of the excited electron states are obtained by diagonalizing the Kohn-Sham matrix built from the initial density with an additional diffuse basis set (150–400 functions) centered at the excited atom in order to account for states above ionization threshold. The resulting orbital transition energies and (dipole) oscillator strengths provide a good representation of the theoretical NEXAFS spectrum. In Slater's transition state approach electronic core hole relaxation is not fully accounted for. Therefore, we calculate the relaxation shifts of the ionization potentials at the three oxygen centers and shift all transition energies according to the corrected relaxation (by 1.8 eV). The theoretical spectrum is generated from the discrete transitions by gaussian convolution with varying broadening. For the region below ionization threshold a broadening of 1.0 eV is used, within 10 eV above the broadening is increased linearly to 4.5 eV and kept fixed at this value for higher energies. The angle-resolved spectra are computed from the x, y, and z components of the dipole transition matrix elements (m_x, m_y, m_z) using appropriate angle projection [15]. All DFT calculations are performed using the StoBe cluster program [16, 17] with gradient corrected RPBE exchange and correlation functionals [18, 19].

All angle-resolved NEXAFS spectra are obtained for the $V_{10}O_{31}H_{12}$ cluster used previously [20], see inset of Fig. 1. This cluster represents a section of the orthorhombic V_2O_5 bulk and provides also a good model for the V_2O_5(010) surface [21, 22]. The hydrogen atoms are added to the cluster to saturate dangling bonds of peripheral oxygen atoms.

3. Results and Discussion

NEXAFS spectra are calculated for each of the three differently coordinated oxygen centers. For the sake of briefness we will describe only results of the singly coordinated vanadyl oxygen in greater detail. The corresponding spectrum is shown in Fig. 1, bottom panel, and combined with partial density of states (PDOS) of the 2p orbitals of the excited oxygen O(1), middle panel, and of the 3d orbitals of nearest neighbor vanadium, top panel. Obviously, the shape of the NEXAFS spectrum is almost identical to that of the O 2p PDOS, whereas it is different from that of the V 3d PDOS. Therefore, the former seems to determine the shape of the NEXAFS spectrum although the O 2p PDOS is much smaller in size compared with the V 3d PDOS. This is obvious from the different scales in Fig. 1. The reason for this behavior becomes clear after a closer look at the formula for the calculation of the

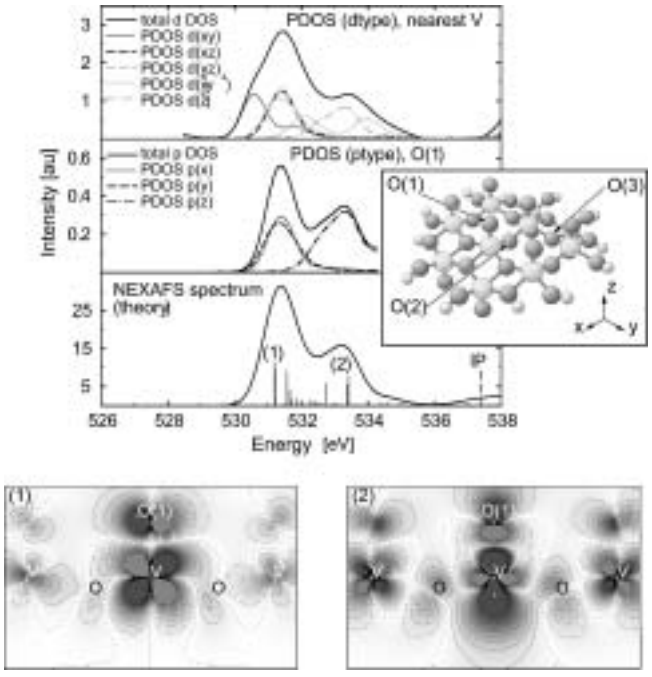

Fig. 1. Theoretical O 1s excitation results for the O(1) center of $V_{10}O_{31}H_{12}$ (the cluster is sketched in the inset). The three panels show the 3d PDOS of vanadium neighbors (top), the 2p PDOS of O(1) (middle), and the computed O(1) 1s NEXAFS spectrum (bottom). The shaded contour plots below the panels refer to final state orbitals of characteristic high intensity transitions in the spectrum. The plotting planes extend along the yz plane through O(1) and its V neighbors.

energy dependent and direction-averaged intensity $I(E)$ in the NEXAFS spectrum

$$I(E) = \text{const.} \cdot \left(\iint \varphi(\text{O 1s}) \cdot \boldsymbol{e} \cdot \boldsymbol{r} \cdot \varphi^*(\text{final})\, \mathrm{d}r^3\, \mathrm{d}\Omega \right)^2 . \qquad (1)$$

The peak intensity in the spectrum scales with the dipole matrix element of the O 1s orbital and the final state orbital. Hence, a transition appears in the spectrum only if the final state orbital has sizeable p contributions at the excited oxygen center.

The double-peak spectrum below ionization threshold, see Fig. 1, can be understood from simple geometric considerations. The bond of the oxygen O(1) with its V neighbor is aligned along the z direction. Thus O $2p_x$ and $2p_y$ orbitals are affected only weakly by nearby V 3d orbitals building weakly antibonding orbital combinations, explaining the low-energy peak. In contrast, the oxygen $2p_z$ orbital points directly towards the V $3d_z{}^2$ orbital and, thus, forms a more strongly antibonding combination, explaining the high-energy peak. The orbital plots corresponding to the two most prominent transitions in the spectra are also included in Fig. 1 and substantiate the different antibonding behavior.

The spectra of the two- and threefold coordinated oxygen centers can be explained as before. Again, the shape of the NEXFAS spectrum is almost identical to that of the O 2p PDOS exhibiting a double-peak structure. However, the assignment of the low and high-energy peaks is different. The doubly coordinated bridging oxygen O(2) $2p_y$ orbital forms weakly antibonding orbital combinations with V 3d orbitals and transitions to these orbitals appear in the low-energy peak of the double-peak spectrum. In contrast, the O(2) $2p_x$ orbital is pointing directly towards corresponding V 3d orbitals and builds strongly antibonding orbital combinations, refering to the high-energy peak. For threefold coordinated oxygen O(3) the low-energy absorption peak does not appear due to the binding geometry and only strongly antibonding orbital combinations contribute to the high-energy peak.

The theoretical NEXAFS spectra for the different oxygen centers are superimposed (using the correct stoichiometry) to yield the total spectrum to be compared with experiment. Further, angle-resolved spectra for given X-ray polarization (polar angle θ, azimuthal angle φ) are evaluated according to:

$$I(E, \boldsymbol{e}) = \text{const.} \cdot (m_x e_x + m_y e_y + m_z e_z)^2 \qquad (2)$$

where

$$\boldsymbol{e} = (e_x, e_y, e_z) = (\sin\theta\cos\varphi, \sin\theta\sin\varphi, \cos\theta). \qquad (3)$$

Fig. 2 shows a series of angle-resolved spectra for xz (Fig. 2a) and yz (Fig. 2b) polarized X-ray beams. In both cases the angular dependence is quite strong. For $\theta = 0^\circ$ the polarization vector is perpendicular to the xy plane. Thus, transitions into orbitals with O $2p_z$ character contribute. These transitions lie for all three oxygen centers in the high-energy part of the spectrum. With increasing angle θ the high-energy part looses intensity whereas the low-energy part gains. For $\theta = 90^\circ$ the polarization vector is parallel to the xy plane and transitions into orbitals with O $2p_x$ ($2p_y$) character are visible for the xz (yz) polarized beam. For xz polarization transitions into orbitals with $2p_x$ character contribute to the low-energy peak in the case of singly coordinated vanadyl oxygen, whereas for two- and threefold coordinated oxygen these transitions refer to the high-energy peak. Thus, excitations at the singly coordinated vanadyl oxygen can be clearly assigned. For yz polarization transitions into orbitals with $2p_y$ character contribute to the low-energy peak for singly and doubly coordinated oxygen,

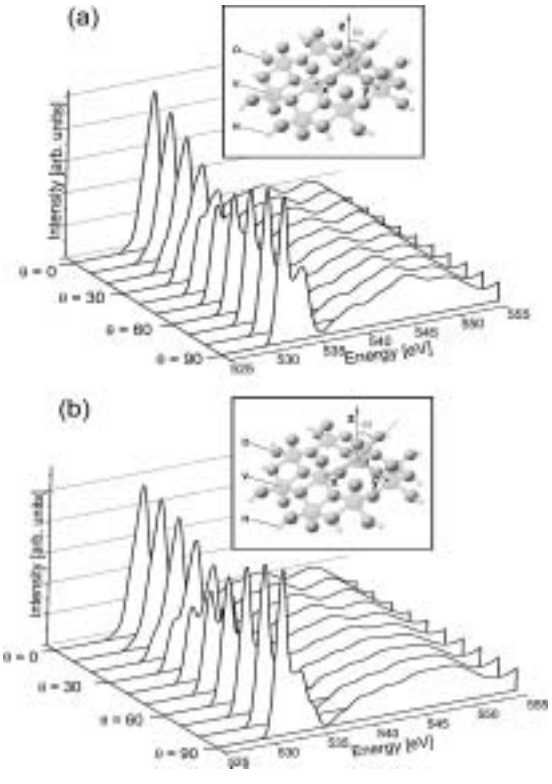

Fig. 2. Theoretical angle resolved O 1s NEXAFS spectra for different X-ray beam polarization of the V_2O_5(010) surface. The spectra refer to a superposition of all oxygen centers and polarization along (a) the xz plane, (b) the yz plane. In both cases the polar angle θ, defined in the inset, varies between 0° and 90° in steps of 10°.

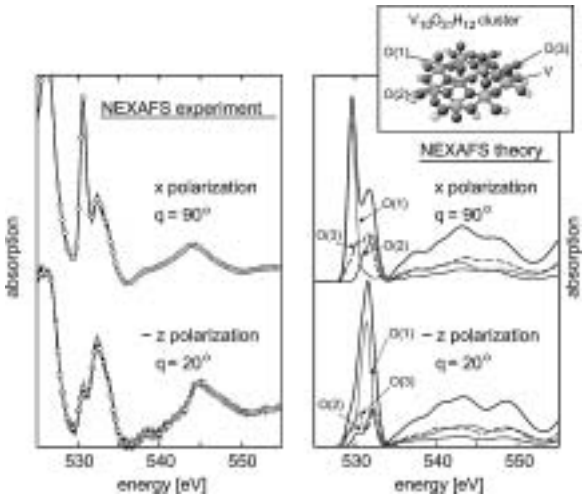

Fig. 3. Comparison of theoretical O 1s core level excitation spectra of the V_2O_5(010) surface with experimental spectra from NEXAFS studies [23] for two different polar angles with *xz* polarization. The contributions of the differently coordinated oxygen centers to the theoretical spectrum are shown in dotted (O(1)), solid (O(2)) and dashed lines (O(3)), respectively. All theoretical spectra are shifted by 1.8 eV to correct for the relaxed ionization potential.

whereas for threefold coordinated oxygen these transitions appear in the high-energy peak. Therefore, excitations at the threefold coordinated oxygen can also be clearly assigned.

A comparison of theoretical spectra with NEXAFS experiments [23] is shown in Fig. 3. The experiments refer to two different angles of incidence of the X-ray beam. For normal incidence (*x* polarization) the agreement between theory and experiment is almost perfect. Both the energetic positions and intensity ratios of the double-peak near 530 eV match extremely well. Further, the broad resonance in the continuum part of the spectrum about 540 eV is reproduced correctly by theory. It may be assigned to transitions into resonances with O 3p character. For grazing incidence ($\sim z$ polarization) the agreement is somewhat worse. While the energetic peak positions match quite well, the measured intensity ratio of the double-peak is reproduced only qualitatively by theory. This may be explained by different adjustment of the polarization angle θ in the experiment. This angle could be influenced by Fresnel diffraction effects such that the effective angle of incidence may be different from that of the primary beam. In fact, a comparison of the experimental spectrum with a theoretical angle-resolved spectrum for $\theta = 35^\circ$ yields much better agreement. Unfortunately, a complete series of angle-resolved NEXAFS spectra, which allows detailed comparison of the angle dependence, does not exist so far.

4. Conclusion

In this work we present angle-resolved NEXAFS spectra for 1s core excitation at the differently coordinated oxygen centers of V_2O_5. In contrast to the angle-integrated spectra published recently [20] a clear assignment of the peaks to specific oxygen centers is possible with the angle-resolved spectra. This may be used in adsorption experiments at the V_2O_5(010) surface where oxygen appears with the three different coordinations discussed above and participates in the adsorption as an active site. Thus, adsorption induced changes in the NEXAFS spectrum may indicate specific oxygen centers where adsorption happens. So far, experiments along these lines have not been published. However, we do hope that the present study can stimulate corresponding measurements.

Abstract

We present a reciprocal-space "non muffin-tin" scheme for calculating X-ray Absorption Near-Edge Structure (XANES). The method uses pseudopotentials and reconstructs *all electron* wave functions within the Projector Augmented Wave framework. The method incorporates a recursive method to compute absorption cross section as a continued fraction. The continued fraction formulation of absorption is advantageous in that it permits the treatment of core-hole-electron interaction through large supercells (hundreds of atoms). This opens new fields of applications like surfaces, molecules, small aggregates or amorphous materials, for which large supercells are required. The method is applied to the natural linear dichroism at the Al K-edge in corundum (α-Al_2O_3). Details about the convergence process of the calculation are given. The influence of the core-hole effects is emphasized and comparison with "muffin-tin" multiple scattering calculation is made.

1. Introduction

As compared to multiple scattering cluster methods, reciprocal space approaches are not commonly used for the calculation of X-ray Near-Edge Absorption Structure (XANES). Indeed the periodicity of the system has limited the treatment of the core-hole effects, as well as the calculation of complicated materials. In order to take into account the core-hole-electron interaction, one has to build a supercell, i.e. a multiple cell where only one of the atoms is excited (with only one 1s electron for the K-edge). This supercell has to be large enough so that the excited potential does not interact with the excited potential of neighboring supercells. This requires a supercell that typically contains around one hundred of atoms. Here we present a method that overtakes this drawback by using a recursive technique. Our scheme uses pseupotentials and plane wave basis sets for the wave function expansion. Such an *ab initio* method has also the crucial advantage to be full potential and self-consistent.

Our method was successfully applied to the C K-edge in diamond and to the Si and O K-edge in α-quartz [1]. We have also calculated the Ti K-pre-edge in rutile, and confirmed the analysis given in Ref. [2]. Here we show an application to the X-ray Natural Linear Dichroism (XNLD) at the Al K-edge in corundum. Two other applications can be found in these proceedings: the case of the Cr K-edge in ruby [3] and the anisotropy of the anomalous atomic factor of Fe in pyrite [4].

2. Theory

2.1. *Derivation of the absorption cross section*

In a single-electron approach, the X-ray absorption cross section $\sigma(\omega)$ is given by the Fermi Golden rule as

$$\sigma(\omega) = 4\pi^2\alpha\hbar\omega \sum_f |\langle\psi_f|\mathcal{O}|\psi_i\rangle|^2 \delta(E_f - E_i - \hbar\omega), \tag{1}$$

where α is the fine structure constant, $\hbar\omega$ is the photon energy, $\mathcal{O}$ is a transition operator coupling the initial state $|\psi_i\rangle$ with energy E_i and the final states $|\psi_f\rangle$ with energy E_f. In the case of K-edges (or L_1-edges), the difficulty of the absorption cross section calculation concerns the determination of the final *all electron* wave function, $|\psi_f\rangle$. Our scheme uses pseudopotentials in a plane wave basis set and the *all electron* $|\psi_f\rangle$ is not directly computed. So let us see how Eq. (1) can be rewritten within the pseudopotential formalism using the Projector Augmented Wave (PAW) method [5].

The PAW formalism permits the reconstruction of the *all electron* wave function from the corresponding pseudo-wave function by using a linear operator $\mathcal{T}$, which differs from unity by a sum of local atom-centered terms:

$$\mathcal{T} = \mathbf{1} + \sum_{\boldsymbol{R},n} [|\phi_{\boldsymbol{R},n}\rangle - |\tilde{\phi}_{\boldsymbol{R},n}\rangle]\langle\tilde{p}_{\boldsymbol{R},n}|. \tag{2}$$

The local atom-centered contributions act only within spherical core regions (called $\Omega_{\boldsymbol{R}}$) centered on each atomic site $\boldsymbol{R}$. $|\phi_{\boldsymbol{R},n}\rangle$ and $|\tilde{\phi}_{\boldsymbol{R},n}\rangle$ are *all electron* and pseudo partial waves, respectively, which coincide outside $\Omega_{\boldsymbol{R}}$. A natural choice for $|\phi_{\boldsymbol{R},n}\rangle$ is the solutions of the radial Schrödinger equation for the isolated atom. The vectors $\langle\tilde{p}_{\boldsymbol{R},n}|$, called projector functions [5], are chosen arbitrarily provided they satisfy the two following conditions: (*i*) they are equal to zero outside $\Omega_{\boldsymbol{R}}$; (*ii*) $\langle\tilde{p}_{\boldsymbol{R},n}|\tilde{\phi}_{\boldsymbol{R}',n'}\rangle = \delta_{\boldsymbol{R}\boldsymbol{R}'}\delta_{nn'}$. The index n refers to the (ℓ, m) quantum numbers and to an additional number j used if there is more than one projector per angular momentum channel. It is important to notice that the $|\phi_{\boldsymbol{R},n}\rangle$ funtions and the $|\tilde{\phi}_{\boldsymbol{R},n}\rangle$ functions form a complete basis for any physical non core *all electron* and pseudo wave functions within $\Omega_{\boldsymbol{R}}$, respectively.

Now we substitute $|\psi_f\rangle = \mathcal{T}|\tilde{\psi}_f\rangle$ in Eq. (1) and replace $\mathcal{T}$ by its definition (Eq. 2). Using the fact that the initial wave function $|\psi_i\rangle$ is localized on $\boldsymbol{R}_0$, i.e. $|\psi_i\rangle$ is zero outside $\Omega_{\boldsymbol{R}_0}$, the sum over $\boldsymbol{R}$ is restricted to only one site: the absorbing atom site, $\boldsymbol{R}_0$. It is then rather easy to show [1] that the absorption cross section can be written as:

$$\sigma(\omega) = 4\pi^2\alpha\hbar\omega \sum_f |\langle\tilde{\psi}_f|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle|^2 \delta(E_f - E_i - \hbar\omega), \tag{3}$$

with $|\tilde{\varphi}_{\boldsymbol{R}0}\rangle = \sum_n |\tilde{p}_{\boldsymbol{R}_0,n}\rangle\langle\phi_{\boldsymbol{R}_0,n}|\mathcal{O}|\psi_i\rangle$. In a reciprocal space approach, the index f refers to two indices: the number of empty bands and the number of $\boldsymbol{k}$-points that mesh the irreducible Brillouin zone (BZ) of the reciprocal space. The calculation of XANES from Eq. (3) requires the computation of many empty states, which is computationally expensive. The size of the supercell is then drastically limited [6].

To avoid this drawback, we use the recursion method of Haydock, Heine and Kelly [7], that contains a powerful algorithm to transform a Hermitian matrix into a tridiagonal form. We rewrite Eq. (3) within the Green function formalism

$$\sigma(\omega) = -4\pi\alpha\hbar\omega\Im[\langle\tilde{\varphi}_{\boldsymbol{R}_0}|(E - \tilde{H} + \mathrm{i}\gamma)^{-1}|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle], \tag{4}$$

where $E = Ei + \hbar\omega$. The pseudo-Hamiltonian $\tilde{H} = \mathcal{T}^{\dagger} H \mathcal{T}$ is Hermitian in the plane wave basis set. The recursion method sets up a new basis (Lanczos basis) in which $\tilde{H}$ has a symmetric tridiagonal representation. The Lanczos basis is built by the repeated action of $\tilde{H}$ onto the normalized vector $|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle / \sqrt{\langle\tilde{\varphi}_{\boldsymbol{R}_0}|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle}$, through a three term recurrence relation [7], that is definitely less expensive than the calculation of empty states as in Eq. (3). The recursion method allows to rewrite the matrix elements $\langle\tilde{\varphi}_{\boldsymbol{R}_0}|(\tilde{H} - E - \mathrm{i}\gamma)^{-1}|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle$ as a continued fraction, leading to the following expression for the cross section:

$$\sigma(\omega) = 4\pi\alpha\hbar\omega \times \Im\mathrm{m} \cfrac{\langle\tilde{\varphi}_{\boldsymbol{R}_0}|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle}{a_0 - E - \mathrm{i}\gamma - \cfrac{b_1^2}{a_1 - E - \mathrm{i}\gamma - \cfrac{b_2^2}{a_2 - E - \mathrm{i}\gamma - \cfrac{b_3^2}{\ddots}}}} \tag{5}$$

$\{a_i\}$ and $\{b_i\}$ correspond to the diagonal and subdiagonal real matrix elements of the Hamiltonian tridiagonal representation, respectively. Further details about our framework can be found in Ref. [1].

2.2. *Computational details*

The formalism presented above has been implemented in an *ab initio* total energy code based on the density functional theory (DFT), called `paratec` [8]. The calculation of the absorption cross section comprises two steps: (*i*) the calculation of the self-consistent charge density of the supercell including a 1s core-hole on the absorbing atom, (*ii*) the calculation of the XANES spectrum (Eq. (5)). All the reciprocal space integrations are performed using a Monkhorst-Pack $\boldsymbol{k}$-point grid [9].

(*i*) The charge density calculation can be done either in the local density approximation (LDA) [10] or in the generalized gradient approximation (GGA) [11], and can include spin polarization. The basic ingredients of the code are the pseudopotentials. The code uses norm-conserving Troullier-Martins [12] pseudopotentials with a single component for each (ℓ, m). The pseudopotential of the excited atom is generated with only one 1s electron. The energy cut-off of the plane wave basis set and the number of $\boldsymbol{k}$-points in the BZ are two *convergence-parameters* of the calculation.

(*ii*) The second step of the calculation comprises the evaluation of the $|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle$ function and the evaluation of the $\{a_i\}$ and $\{b_i\}$ coefficients obtained within the construction of the Lanczos basis. For K-edges, $|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle$ is given by: $|\tilde{\varphi}_{\boldsymbol{R}_0}\rangle = \sum_{m,j} |\tilde{p}_{\boldsymbol{R}_0,\ell,m,j}\rangle\langle\phi_{R_0,\ell,m,j}|\mathcal{O}|\psi^{1s}_{\boldsymbol{R}_0}\rangle$ where $\ell = 1$ and $\mathcal{O} = \hat{\varepsilon}\cdot\boldsymbol{r}$ in the case of electric dipole (E1) transitions. $\ell = 2$ and $\mathcal{O} = \hat{\varepsilon}\cdot\boldsymbol{r}\hat{\boldsymbol{k}}\cdot\boldsymbol{r}$ in the case of electric quadrupole (E2) transitions, $\ell = 2$ and $\mathcal{O} = \frac{1}{2}(\hat{\varepsilon}\cdot\boldsymbol{r})$ and $(\boldsymbol{k}\cdot\boldsymbol{r})$, where $\hat{\varepsilon}$ and k are the direction of the polarisation vector and the wave-vector of the incident photon beam, respectively. The partial wave $|\psi^{1s}_{\boldsymbol{R}_0}\rangle$ is the 1s core wave function, solution of the Schrödinger equation for the isolated absorbing atom (non excited). The partial waves $|\phi_{\boldsymbol{R}_0,\ell,m,j}\rangle$ are ℓ valence wave functions, obtained by solving the Schrödinger equation for the isolated excited atom (with one 1s electron). The corresponding Blöchl's projectors are generated as in Ref. [13]. The dimension of the Lanczos basis and, again, the number of $\boldsymbol{k}$-points contitute two other *convergence-parameters* of the calculation. It should be noted that the number of computed Lanczos vectors strongly depends on the value of the broadening parameter γ (Eq. (5)).

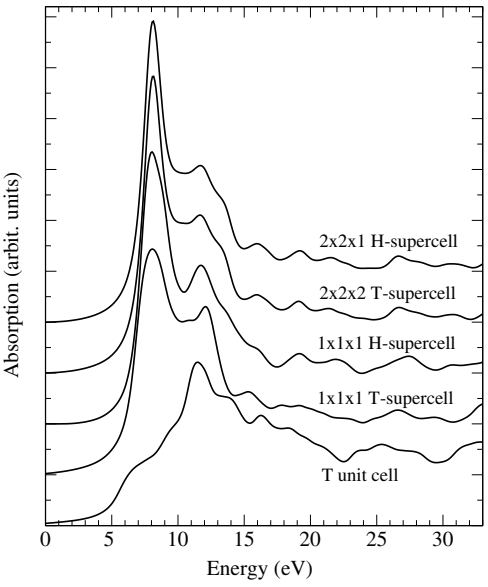

Fig. 1. Al K-XANES calculated spectra for different sizes of cell. From the bottom to the top: 10 atom trigonal (T) unit cell (ground state calculation), 10 atom trigonal $1 \times 1 \times 1$ supercell, 30 atom hexagonal (H) $1 \times 1 \times 1$ supercell, 80 atom trigonal $2 \times 2 \times 2$ supercell and 120 atom hexagonal $2 \times 2 \times 1$ supercell.

To summarize, the XANES calculation converges when increasing the size of the supercell. Increasing the energy cutoff of the plane wave expansion, adding vectors in the Lanczos basis, and adding $\boldsymbol{k}$-points in the irreducible Brillouin zone do not provoke any visible change onto the calculated spectrum.

3. Results and discussion

Corundum crystallizes in the trigonal system (space group $R\bar{3}c$), with two Al_2O_3 entities per unit cell. The structure can also be described by a triple hexagonal cell ($a = 4.759$ Å, $c = 12.991$ Å), where the [001] axis is a three-fold symmetry axis (C_3) [14]. Trigonal and hexagonal supercells were built in order to study the supercell size convergence, so demonstrating the spacial extent of the core-hole relaxation. The corresponding calculated spectra (E1 transitions) are displayed in Fig. 1. The pseudopotentials for Al (excited or in ground state) were built with 1s, 2s, 2p as core states and with 3s, 3p, 3d as valence states (core radius: 1.06 Å). The pseudopotential for O was generated with 1s as core state and with 2s and 2p as valence states (core radius: 0.77 Å). The calculations were performed in the LDA considering an energy cut-off of 64 Ry. One Blöchl's projector ($j = 1$) was used. We indicate in Table I the numbers of $\boldsymbol{k}$-points and of Lanczos vectors that were required to get convergence for each kind of cell.

Table I. *Convergence-parameters for the calculated spectra of Fig. 1. $n^{\rho}_{\boldsymbol{k}}$ (resp. $n^{\sigma}_{\boldsymbol{k}}$) is the number of $\boldsymbol{k}$-points for the charge density, ρ (resp. the cross section, σ). n_{vec} is the number of Lanczos vectors required for $\gamma = 0.3$ eV.*

Cell name	Cell dimension	$n^{\rho}_{\boldsymbol{k}}$	$n^{\sigma}_{\boldsymbol{k}}$	n_{vec}
$2 \times 2 \times 1$ H supercell	$a = 9.518$ Å, $c = 12.991$ Å	1	8	~ 1400
$2 \times 2 \times 2$ T supercell	$a = 10.257$ Å	1	11	~ 1200
$1 \times 1 \times 1$ H supercell	$a = 4.759$ Å, $c = 12.991$ Å	8	32	~ 1300
$1 \times 1 \times 1$ T supercell	$a = 5.128$ Å	6	38	~ 700
T unit cell	$a = 5.128$ Å	6	38	~ 700

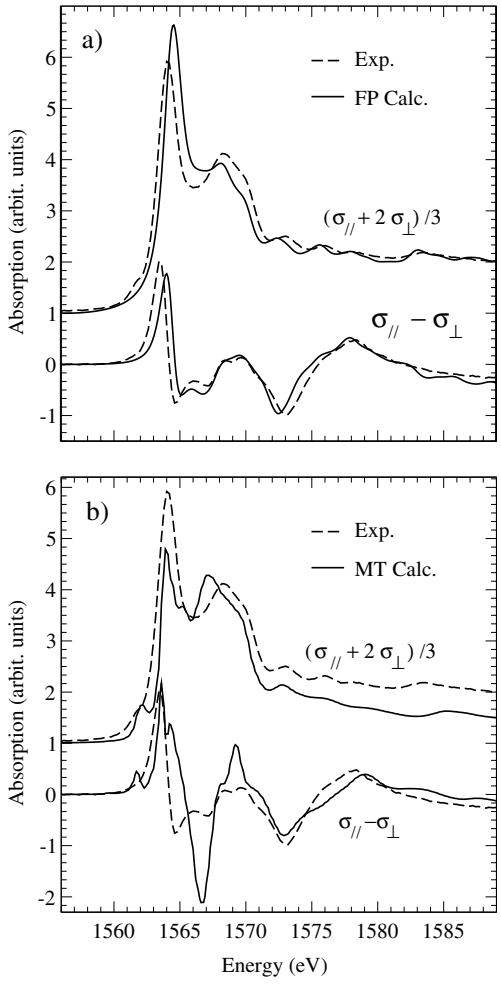

Fig. 2. Experimental Al K-XANES ($\sigma_{\rm iso}$) and corresponding XNLD signal in corundum, compared with full potential (FP) calculation (a) and "muffin-tin" (MT) calculation (b).

The spectra presented in Fig. 1 are calculated with a final broadening parameter $\gamma = 0.7$ eV. One can see that the supercell size convergence was reached for the 80 atom $2 \times 2 \times 2$ trigonal supercell, since the two upper curves are rigorously identical. The lower curve, which is a ground state calculation (no core-hole), differs strongly from the others, showing the importance of the core-hole effects at the Al K-edge in corundum.

Comparison between the converged calculation and polarization dependent experiments is presented in Fig. 2a. Experimental XANES and XNLD spectra were recorded on the SU22 beam line of the Super-ACO storage ring of LURE (Orsay). The beam line was equipped with a double α-quartz $(10\bar{1}0)$ crystal monochromator. The sample was a single crystal disk (3 mm width, 15 mm diameter), cut such as the C_3 axis is in the plane of the face. Absorption was measured in the total electron yield mode for two orientations of the sample: for the C_3 axis parallel and perpendicular to $\hat{\varepsilon}$ ($\sigma_{||}$ and $\sigma_{\perp}$, respectively). Fig. 2a diplays the isotropic spectrum given by $(\sigma_{||} + 2\sigma_{\perp})/3$ and the XNLD spectrum $(\sigma_{||} - \sigma_{\perp})$. Calculations and experiments are in good agreement.

We present in Fig. 2b calculations performed within the full multiple scattering theory, using non self-consistent "muffin-tin" (MT) potential (`continuum` code [15]). The MT calculated spectrum was obtained for a 164 atom cluster (radius 7.85 Å), by using the $Z + 1$ approximation to model the core-hole effects. All the details of this calculation are given in Ref. [16]. The agreement between calculation and experiment is not so bad, although it is definitely less convincing than the full potential (FP) calculation. To obtain such an agreement, we had to play with the MT parameters, like the MT potential level and the overlap between the MT spheres. However these parameters have no real physical meaning. As compared with usual MT multiple scattering approaches, the FP approach is a parameter-free method.

Now let us (focus our attention on the pre-edge feature located at 1561.8 eV. This peak is reproduced by the MT calculation, suggesting that it could be related to medium range order, since it appears only in large cluster calculations [16]. However the FP calculation does not at all reproduce this feature. Its presence in MT calculation is then clearly an artefact. Complementary calculation is needed to clarify the origin of the pre-edge.

4. Conclusion

We have presented an efficient *ab initio* reciprocal space scheme to calculate XANES at the K or L_1 edge. Up to now this framework has been applied to crystalline materials. Thanks to the recursive method incorporated in the method, new fields of application, like biological molecules, surfaces and amorphous systems, are also possible.

Self-Consistent Non-Local Optical Potential for XANES

Keisuke Hatada, Maurizio Benfatto and Calogero R. Natoli

Laboratori Nazionali di Frascati, INFN, CP13,00044 Frascati, Italy

Received June 26, 2003; accepted November 4, 2003

Abstract

We have studied the performance of the non local optical potential as developed by Fujikawa, Hatada and Hedin [Phys. Rev. B **62**, 5387 (2000)] along the lines of the *GW* approximation for the photoelectron self-energy, in the case of the absorption spectrum of nickel hydrate ($Ni(OH_2)_6$). Comparison with the local Hedin-Lundqvist potential [J. Phys. C **4**, 2064 (1971)] shows a substantial improvement especially in the low energy region of the spectrum.

1. Introduction

Recently a method for utilising the near edge part of the absorption spectrum (XANES) for structural analysis has been proposed by Benfatto and Della Longa [3]. In this method hundreds of theoretical signals obtained by fully inverting the multiple scattering matrix are compared with the experimental data, until a best fit is obtained in the parameter space of the atomic positions. Very good results are obtained if in the course of the fitting procedure the optical potential used to generate the theoretical signal is taken as the real part of the local Hedin-Lundqvist (H-L) potential, whereas for the imaginary part, describing the damping of the excited photoelectron, a suitably parametrised functional form is fitted together with the structural parameters. Indeed the use of the imaginary part of the H-L potential usually leads to fits with bad *R*-factors. This is an indication that the fault might lie in the single plasmon pole approximation applied also to core electron densities, as usually done in the H-L potential. Following the theory for the optical potential based on the *GW* approximation for core electrons as developed by Fujikawa, Hatada and Hedin [1], we have studied the performance of this potential in a significant test case, namely a transition metal ions in water solution. The results of this investigation are hereby presented.

2. Theory

For sake of clarity we briefly describe the *GW* approximation to the photoelectron self-energy, referring the reader to the more complete treatment of this problem by Hedin and Lundqvist [4]. In this approximation the electron self-energy $\Sigma(\boldsymbol{r}, \boldsymbol{r}'; \omega)$ is expanded in terms of the screened Coulomb interaction $W = \epsilon^{-1}V$, where V is the bare Coulomb interaction and $\epsilon = 1 - VP$ is the dielectric response function of the system, while P is the polarization propagator. This expansion has a better convergence rate than that based on the bare Coulomb potential, so that one approximates the true $\Sigma(\boldsymbol{r}, \boldsymbol{r}'; \omega)$ by the first term of this expansion, namely $\Sigma_{GW}(\boldsymbol{r}, \boldsymbol{r}'; \omega) = GW$, where G is the electron propagator.

By splitting both the polarization and the electron propagator into a core and a valence part, so that $G = G^c + G^v$ and $P = P^c + P^v$, where the index c runs over the core states while v runs over both occupied and unoccupied valence states, and noting that the core polarization is substantially smaller than the valence one, Hedin and Lundqvist [4] obtained the following expression for Σ_{GW}:

$$\begin{aligned}\Sigma_{GW} &= GW \\ &= G^c W + G^v W^v P^c W^v + G^v W^v + \cdots \\ &= V^c_{ex} + \Sigma^c_{pol} + \Sigma^v + \cdots . \end{aligned} \tag{1}$$

Here the first term V^c_{ex} is the bare Hartree-Fock exchange potential from the core electrons, the second term Σ^c_{pol} is the screened polarization potential from the core and the last term Σ^v is the self-energy of the valence electrons. This latter, when calculated *via* the plasmon pole approximation for the electron wave function [4], can be safely approximated by an H-L local potential referred only to the valence density. This potential is amenable to an analytical form, which can be found for example in ref. [5].

For the second term (screened polarization potential) Fujikawa, Hatada and Hedin developed the method to calculate it. Using the Random Phase Approximation (RPA) to calculate the polarisation propagator they obtained the following expression:

$$[G^v W^v P^c W^v](\boldsymbol{r}, \boldsymbol{r}'; \omega) = \sum_l^{core} \int_{\varepsilon_F}^{\infty} \mathrm{d}\varepsilon_k G^v(\boldsymbol{r}, \boldsymbol{r}'; \omega - \omega_{kl})$$

$$\times \mathrm{Im}\langle c_l | W^v(\boldsymbol{r}; \omega_{kl}) G(\varepsilon_k) W^{v*}(\boldsymbol{r}'; \omega_{kl}) | c_l \rangle . \tag{2}$$

Here $\omega_{kl} = \varepsilon_k - \varepsilon_l$ is the energy gap between an empty valence level ε_k and a core level ε_l, whereas $W^v(\boldsymbol{r}; \omega)$ is the energy-dependent screened Coulomb interaction. Fig. 1 gives a diagrammatic expression for this quantity.

Following the conclusions of the paper by B. Holm and U. von Barth [6] we make a non-self-consistent approximation in the actual calculation of the self-energy, meaning that we calculate the electron propagator G_0 from the solution of the Dyson equation with $\Sigma = V^c_{ex} + \Sigma^v$, the polarization function from $P_0 = -iG_0G_0$ and the screened interaction from $W_0 = VW_0P_0V$, without performing the self-consistent loop. This approach seems to give better results for excitation energies than the complete

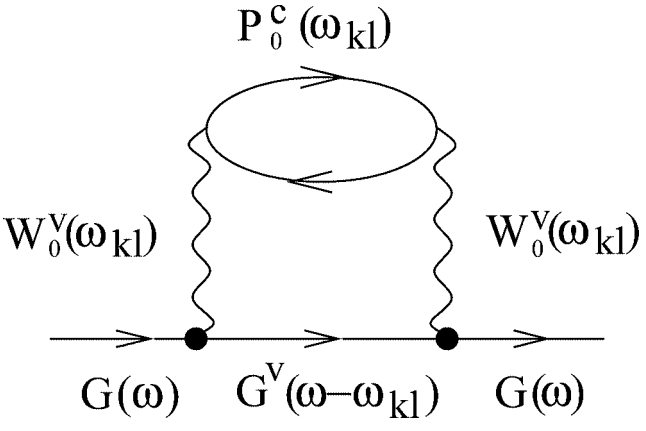

Fig. 1. Diagrammatic representation for Σ^c_{pol} $(\boldsymbol{r}, \boldsymbol{r}'; \omega) = [G^v W^v P^c W^v]$ $(\boldsymbol{r}, \boldsymbol{r}'; \omega)$.

self-consistent approach. For example in this latter the feature in Σ corresponding to the one plasmon excitation is lost. For a recent review on this problem, see also W. G. Aulbur *et al.* [7].

Moreover, following Fujikawa *et al.* [1] one can also neglect the energy dependence of the screening, so that $W^v(\boldsymbol{r};0)$ reduces to the static potential $e^{-q_{\rm TF}r}/r$, where q_{TF} is the Thomas-Fermi screening length. Finally, near the edge region, the core polarisation does not depend strongly on the photoelectron kinetic energy, so that in Eq. (2) we can put $\omega_{kl} = \varepsilon_k - \varepsilon_l = \varepsilon_{\rm F} - \varepsilon_l$, where $\varepsilon_{\rm F}$ is the Fermi energy. In this approximation the second factor in Eq. (2) can be calculated by closure giving:

$$[G^v W^v P^c W^v](\boldsymbol{r},\boldsymbol{r}';\omega) = \sum_l^{core} G^v(\boldsymbol{r},\boldsymbol{r}';\omega-\varepsilon_{\rm F}+\varepsilon_l)A_l(\boldsymbol{r},\boldsymbol{r}') \quad (3)$$

where

$$A_l(\boldsymbol{r},\boldsymbol{r}') = \sum_k^{unocc} W^v_{kl}(\boldsymbol{r};0)W^{v*}_{kl}(\boldsymbol{r}';0)$$

$$= \int W^v(\boldsymbol{r}-\boldsymbol{r}_1;0)W^v(\boldsymbol{r}'-\boldsymbol{r}_2;0)$$

$$\times[\delta(\boldsymbol{r}_1-\boldsymbol{r}_2)-\rho^{tot}(\boldsymbol{r}_1,\boldsymbol{r}_2)]\rho^c_l(\boldsymbol{r}_2,\boldsymbol{r}_1)\,d\boldsymbol{r}_1\,d\boldsymbol{r}_2.$$

Here $\rho^{tot}(\boldsymbol{r}_1,\boldsymbol{r}_2)$ is the density matrix relative the total density of the system, whereas $\rho^c_l(\boldsymbol{r}_2,\boldsymbol{r}_1)$ is the one relative to the density of the l core state. A further approximation is to use only the atomic part of the Green's function in Eq. (3), neglecting for the moment the scattering part, which is left to future developments.

Notice that this valence Green function does not take an imaginary part (therefore producing no damping) for all photoelectron energies ω below the first core excitation (in the case of $Ni(OH_2)_6$ system discussed below, this is the $3p$ core excitation of Ni, around 100 eV from the edge).

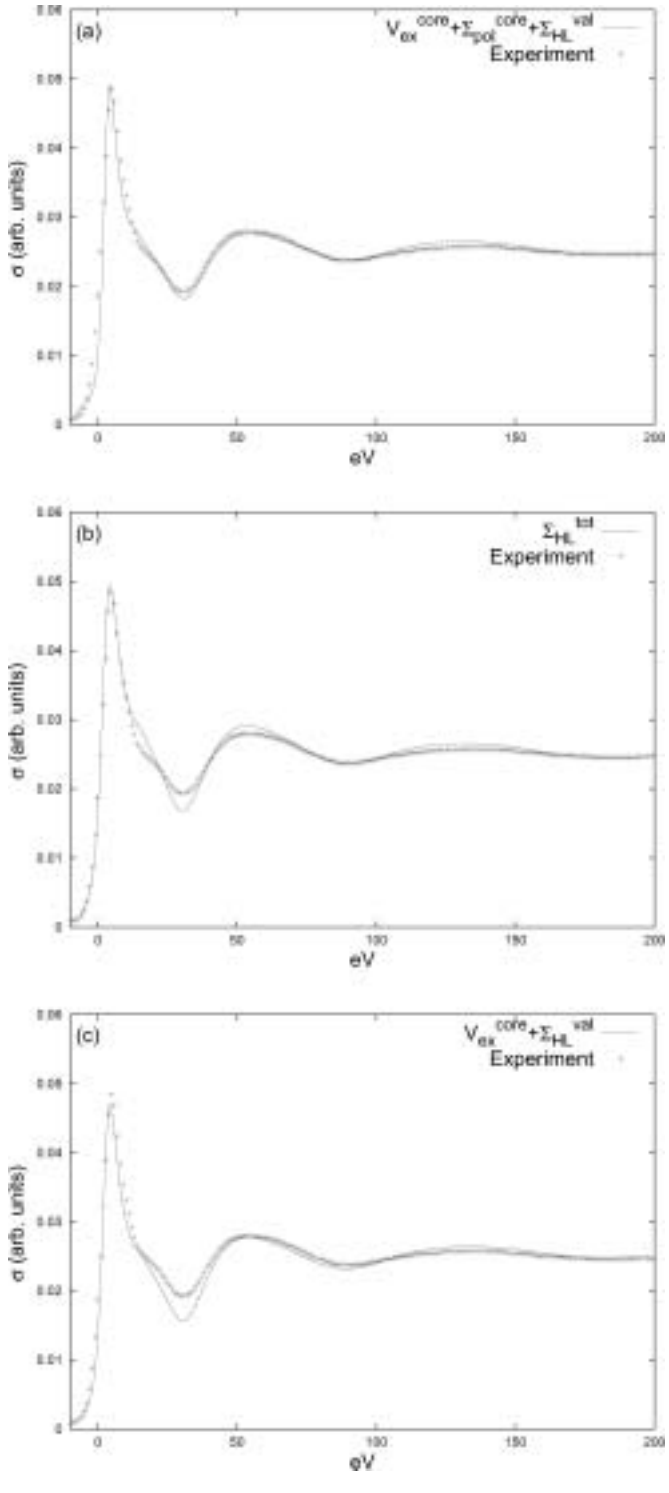

Fig. 2. Absorption cross section for $Ni(OH_2)_6$ at the Ni K-edge calculated for three types of optical potential, compared with the experimental data: the *GW* self-energy discussed in the present paper (panel (a)), the total H-L potential (panel (b)) and the *GW* self-energy less the core polarization potential (panel (c)).

3. Conclusions

We tested our new optical potential by calculating the absorption spectrum in a significant model system, namely the Ni K-edge of $Ni(OH_2)_6$ (Ni in water solution). Hydrogen atoms were included since they affect significantly the near edge structure. The geometrical and muffin-tin parameters were taken from an EXAFS analysis of the compound [8]. Fig. 2 shows the results for three different kinds of optical potential, namely: the *GW* self-energy discussed above (panel (a)), the total H-L potential (panel (b)) and the *GW* self-energy less the core polarization potential, *ie* $V^c_{ex} + \Sigma^v$ in Eq. (1). The calculated spectra were further convoluted with a Lorentzian function with a core hole width of 1.44 eV (full width half maximum of the Ni K-edge [9]).

In the comparison with experimental data the *ab initio* theoretical simulations were normalized to coincide with the experimental absorption spectrum at around 200 eV above the rising edge. This comparison shows that the best agreement is obtained with the *GW* potential, confirming in this particular case the validity of the *GW* model. Further investigation is planned in other model compounds.

Ab Initio R-Matrix/MQDT Method for Near-Edge X-ray Absorption Fine Structure

Abstract

We have investigated the feasibility of an *ab initio* polyatomic R-matrix/MQDT (multichannel quantum defect theory) method using Gaussian type basis functions for bound and continuum states to analyze the near edge feature of molecules. Test molecules here are N_2, C_2H_2, and NO. The R-matrix/MQDT method is revealed to be indispensable for the Rydberg states with higher quantum numbers and continuum states, none of which can be described by using Gaussian type functions in the outer region from an appropriate boundary. The close-coupling calculation augmented with the correlation term, which is carried out for the inner region, is powerful to describe the valence states and the interchannel coupling in several core-ionized states.

1. Introduction

Near-edge X-ray absorption fine structure (NEXAFS or XANES) is characterized in two energy regions: below and above the ionization thresholds or photoabsorption edges ($E_{\rm th}$). Main features in NEXAFS arise from bound-state and continuum resonances. To calculate the NEXAFS feature, there are mainly two theoretical approaches: one is multiple-scattering (MS) [1] and the other is molecular orbital (MO)-like approaches. The latter includes density-functional-theory (DFT) and L^2 static-exchange (STEX) methods [2, 3]. The MO-like approach is based on the method to calculate bound states, and therefore has some deficiencies in description of the continuum. On the other hand, the MS approach flexibly describes the continuum as multiple scattering states of a photoelectron, but needs artificial $E_{\rm th}$ shift to get bound-state resonances as multiple scattering states. Furthermore, the coupled-channel, or multichannel, MS approach is developed to treat several $E_{\rm th}$ cases accompanying shakeup and shakedown excitations [4].

In recent sophisticated experiments, higher-lying Rydberg states near $E_{\rm th}$, vibrational fine structures, and multiple excitations have been resolved in the inner-shell spectroscopy of small molecules (for example, refs. [5, 6]). From a theoretical point of view, we have to treat channel couplings involving not only open channels but also closed channels such as multiply excited states. The previous multichannel MS approach [4] is not appropriate for this kind of multiple excitation problems. More accurate scattering approaches are necessary to explain such highly-resolved NEXAFS features.

The ionized states are regarded as $N-1$ electron correlated bound states Ψ_j^{N-1}, namely, target states in terms of scattering, coupled with a continuum electron η_k. The multiply excited states are N electron correlated bound states Ψ_i^N. In the region far from the ion core, the continuum electron gives only long-range electrostatic and polarization interactions; on the other hand, short-range interactions such as electron correlation and exchange are also important in the coupled Ψ_j^{N-1} with η_k and the correlated bound states Ψ_i^N. In solving molecular ionization and excitation problems, the R-matrix approach is one of the most promising approaches, which is an *ab initio* approach on an equal level with the complex Kohn and Schwinger variational methods [7]. In the R-matrix method [8], electron configuration space is divided into two parts, the inner and outer regions. The inner region is defined by the R-matrix radius R_0, which is large enough that any $N-1$ electron correlated target function Ψ_j^{N-1} is completely enveloped by the sphere $r < R_0$. In the inner region, η_k is determined in the close coupling with Ψ_j^{N-1}, which is augmented with Ψ_i^N. In the outer region ($r > R_0$), the continuum and the higher Rydberg orbitals are described in an appropriate asymptotic form, e.g. Coulomb function in the case of electron-cation scattering or photoionization/photoexcitation.

In the present work, we investigate feasibility of the polyatomic R-matrix/MQDT method (R-matrix method combined with multi channel quantum defect theory) [9] in the inner-shell excitation, where we can use Gaussian type basis functions in the inner region. For the inner part, the R-matrix code including *ab initio* configuration interaction approaches developed by Tennyson's group [12] has been used in the R-matrix/MQDT method. The R-matrix/MQDT has be successful to get diabatic potential energy curves of the Rydberg series converging to some excited ion cores by improvement on the outer part of the R-matrix method [9]. Thus, the polyatomic R-matrix/MQDT method is a promising one in the calculation of NEXAFS of polyatomic systems. In the present work, we show R-matrix/MQDT results for some simple molecules: Rydberg states in N_2, Rydberg and valence states in C_2H_2, and shape resonances of NO radical. One of the purposes of the present work is improvement of *ab initio* CI part in R-matrix/MQDT. The close-coupling calculation code for the inner region is incorporated into the *ab initio* SCF-CI code GSCF3 [10, 11] for the inner-shell excitation and ionization, which has been developed by one of the present authors (NK). In the present stage of GSCF3 implementation the Gaussian integrals including the tail integration over the $r > R_0$ region were taken from the UK molecular R-matrix codes [12]. The outer-region and MQDT codes have been developed by the other author (MH). The R-matrix radius R_0 chosen is 10 a.u.

2. Theoretical background

2.1. *R-matrix method*

In the R-matrix method, the N electron total wavefunction $\Psi^N(E)$ in the inner region is expanded by energy-dependent expansion coefficients $A_P(E)$ and energy-independent basis functions Ψ_P^N,

e-mail: miyabi@ims.ac.jp, kosugi@ims.ac.jp

$$\Psi^N(E) = \sum_P A_P(E)\Psi_P{}^N. \quad (1)$$

In the case of photoionization and photoexcitation, transition dipole matrix elements $D(E)$ from the ground state $\Psi_G{}^N$ are obtained as follows:

$$D(E) = \langle \Psi^N(E)|T|\Psi_G{}^N\rangle = \sum_P A_P(E)\langle \Psi_P{}^N|T|\Psi_G{}^N\rangle. \quad (2)$$

The correlated N electron basis function $\Psi_P{}^N$ is described by the following "close coupling plus correlation (CCPC)" form:

$$^S|\Psi_P{}^N\rangle = \sum_{jk} c_{jk}\,{}^S|\Psi_j{}^{N-1},\ \eta_k\rangle + \sum_{jt} c_{jt}\,{}^S|\Psi_j{}^{N-1},\ \varphi_t\rangle + \sum_i c_i\,{}^S|\Psi_i{}^N\rangle. \quad (3)$$

In the R-matrix method, the CCPC equation is defined only in the inner region. $^S|\Psi_j{}^{N-1}, \eta_k\rangle$ indicates an antisymmetrized spin and symmetry (denoted by S) adapted product of the corresponding $N-1$ electron correlated state function and the one electron continuum function for open channels. $^S|\Psi_j{}^{N-1}, \varphi_t\rangle$ is a similar product for closed channels; φ_t is one of square-integrable (L^2) diffuse functions which are not used in either $\Psi_j{}^{N-1}$ or $\Psi_i{}^N$. The third term $\Psi_i{}^N$ describes the N electron correlation in multiply valence excited states and intruder and dissociative states, which have different electron correlation and orbital relaxation effects from those of the ionized state $\Psi_j{}^{N-1}$. At each scattering energy E, the R-matrix is computed on the boundary ($r = R_0$), and various properties are obtained by using the R-matrix.

In the case of core excitation, the third term $\Psi_i{}^N$ involves core-to-valence excited states. The second term involves core-to-Rydberg excited states with an ion core $\Psi_j{}^{N-1}$. In the R-matrix method, the CCPC equation is solved only in the inner region ($r < R_0$). Therefore, we have to evaluate contributions to the Hamiltonian matrix in solving eq. (3) from outside the R-matrix sphere ($r > R_0$), and subtract them from the all-space Hamiltonian matrix ($r < R_0$ and $r > R_0$) [13, 14]. In the polyatomic R-matrix calculation, Gaussian type basis functions (GTF's) are used [15] to describe both the target orbitals and continuum (Coulomb) functions [16].

2.2. *Quantum chemical approach*

The $N-1$ and N electron eigensolutions $\Psi_j{}^{N-1}$ and $\Psi_i{}^N$ are obtained by standard *ab initio* CI calculations over configuration state functions (CSF's) or Slater determinants, $\Phi_r{}^{N-1}$ and $\Phi_s{}^N$ expanded by the L^2 basis functions:

$$\Psi_j{}^{N-1} = \sum_r d_{jr}\Phi_r{}^{N-1}, \qquad \Psi_i{}^N = \sum_s d_{is}\Phi_s{}^N, \quad (4)$$

where well-balanced treatment of the $N-1$ and N electron systems within the framework of the same one electron basis set (molecular orbital set) is essential to get reliable excitation and ionization energies to avoid underestimation and overestimation ("over correlation" [17]).

Decoupling by eq. (4) gives a compact description for the bound-state contributions in the close coupling eq. (3). The "contracted CI" approach removes the need for redundant re-diagonalization of the large-scale CI Hamiltonian matrix [18]. The contracted CI approach is achieved by the one-to-one correspondence between the Slater determinants expanding the $N-1$ and N electron systems to satisfy the phase matching. Tennyson [18] has resolved all phase ambiguities by using the orbital ordering convention in ALCHEMY [19]. A similar correct treatment of the phase matching has been developed to evaluate the monopole matrix element between the ground and ionized states [20]. Previous methods such as the prototype CI method [19, 21] and the dummy orbital method [22, 23] sometimes cause serious phase mismatch [18], depending on the orbital ordering convention in the CSF generation of the $N-1$ and N electron systems.

The continuum functions η_k are orthogonalized to the orbital functions used in the second and third terms *for convenience*. However, the orthogonality constraint for the continuum functions leads to physically incorrect results, especially when many virtual orbitals are used in CI expansions (4). $\Psi_i{}^N$ and $\Psi_j{}^{N-1}$ in eq. (3) should allow for relaxation of the orthogonalized continuum orbitals as well as polarization of the target states. The orbital relaxation and polarization effects can be incorporated in eq. (3) as long as enough numbers of $\Psi_i{}^N$ and $\Psi_j{}^{N-1}$ are included in eq. (3) or original CI expansions eq. (4) are optimized directly in eq. (3). However, in case it is impractical from a computational point of view, it is better to add some effective electron configurations for orbital relaxation and polarization to $\Psi_i{}^N$ and $\Psi_j{}^{N-1}$ in eq. (3). These additional configurations are not eigensolutions and are unphysical "pseudo" states [24].

In the CCPC equation (3), the second term can generally be incorporated into the third term within the same L^2 manifold. Furthermore, it is also possible to incorporate the second term ($< E_{\rm th}$) into the first term ($> E_{\rm th}$); that is, the static exchange (STEX) method for both the bound and continuum state as follows:

$$|\Psi_P{}^N\rangle = \sum_j \left| \Psi_j{}^{N-1}, \left(\sum_k c_{jk}\eta_k + \sum_t c_{jt}\varphi_t \right) \right\rangle. \quad (5)$$

The widely-used STEX method corresponds to single excitation CI to the virtual orbital space for both continuum and bound-state excitation, keeping a specified Hartree-Fock description of the ion core or fixing a hole in a specified orbital; that is the Hartree-Fock (HF) based STEX approach. It may be called SC-SRSTEX (single-channel single-reference STEX), which is also obtained with the hole or V^{N-1} potential method to improve the virtual molecular orbitals [25]. On the other hand, eq. (5) may be generally called MC-MRSTEX (muliti-channel multi-reference STEX); however, it is not so easy to take into account the orthogonality relaxing through mixing with the virtual orbitals used in the correlated CI description for the target state $\Psi_j{}^{N-1}$ [26].

2.3. *MQDT method*

The STEX approach based on the GTF expansion is ill-behaved for Rydberg states with higher principal quantum numbers due to linear dependence of diffuse basis functions. Furthermore, in the R-matrix method, the higher-lying Rydberg states are not defined within the inner region ($r < R_0$), but only the lowest s, p, and d states (and sometimes the second lowest s state as well) are defined. For the higher-lying Rydberg states we need another approach. In the present work we use the R-matrix/MQDT approach to evaluate quantum defects. The asymptotic formula of the wave function $\Psi^N(E)$ in eq. (1) is represented by the linear combination with Coulomb functions. At the R matrix radius, $\Psi^N(E)$ is written by

$$\Psi^N(E) = f - g\,K, \quad (6)$$

where f and g are the regular and irregular Coulomb functions, respectively. The K matrix in eq. (6) is related to the R matrix as follows:

$$K = (g - R\mathrm{d}g/\mathrm{d}r)^{-1}(f - R\mathrm{d}f/\mathrm{d}r). \quad (7)$$

In the R-matrix/MQDT method, the K matrix can be obtained at any energy, because both positive and negative Coulomb functions [27] are used in f and g in eq. (7). The MQDT method is based on a single target state [28]; on the other hand, the R-matrix/MQDT method can take into account interaction among multiple target states through the R matrix.

3. Results and Discussion

3.1. *Rydberg states in the 1s ionization of N_2 and C_2H_2*

Relatively large core-valence exchange interaction between the adjacent atoms results in observable $1s\sigma_g$-σ_u splittings in N_2 and C_2H_2 [29]. Rydberg transitions from the Σ_g ground state have two symmetries, Σ_u and Π_u. Thus, there are four channels; $1s\sigma_g \rightarrow n\sigma_u(\Sigma_u)$, $n\pi_u(\Pi_u)$ and $1s\sigma_u \rightarrow n\sigma_g(\Sigma_u)$, $n\pi_g(\Pi_u)$. N_2 has $\pi^*(1\pi_g{}^*)$ and $\sigma^*(3\sigma_u{}^*)$ valance orbitals. C_2H_2 has $\pi^*(1\pi_g{}^*)$ and $\sigma^*(3\sigma_u{}^*, 4\sigma_g{}^*, 4\sigma_u{}^*)$ valance orbitals. The lowest 1s excited states are the $1s\sigma_u \rightarrow 1\pi_g{}^*$ excitations, which are observed below the Rydberg states. It is generally known that the term value of the lowest Rydberg state with s character is around 4 eV. In N_2 and C_2H_2 the term values of the $1s \rightarrow \pi^*$ excitations are 8.9 eV and 5.4 eV. On the other hand, in C_2H_2, the term values of the lowest $3\sigma_u$ excited state is predicted to be 3.2 eV [30].

Diffuse functions used for the STEX calculation of the Rydberg states are taken from ref. [31] (n_s and n_d = 2.0, 2.5, 3.0, 3.5, 4.0; n_p = 2.0, 2.5, 3.0, 3.5, 4.0, 4.5) and augmented with one s and two d functions (ζ_s = 0.06, ζ_d = 1.335, 0.288). The core and valence basis functions (721/52/1*) for C and N and (42) for H are taken from the (73/7/1*) and (6) contracted Gaussian-type functions of Huzinaga *et al.* [32]. In the R-matrix calculation the continuum functions were taken from ref. [16]. The valence CI in the close-coupling calculation was based on the CAS (complete active space)-type description in the $3\sigma_g$, 2-$3\sigma_u$, $1\pi_u$, and $1\pi_g$ orbital manifold for N_2 and in the 3-4σ_g, 2-4σ_u, $1\pi_u$, and $1\pi_g$ orbital manifold for C_2H_2.

In the case of N_2, some orthogonalization procedures are compared. First of all, the unoccupied valence orbitals $3\sigma_u{}^*$ and $1\pi_g{}^*$ are optimized within the SRSTEX method using the relaxed Hartree-Fock occupied orbitals with no diffuse function. The other unoccupied orbitals are called virtual orbitals. The diffuse functions to describe Rydberg states should be orthogonal to the occupied and unoccupied orbitals (and virtual orbitals if they are used in the CCPC calculation). Some orthogonalization methods are compared in table I, which shows the term value for the Rydberg state. In STEX (1), the $n\mathrm{d}\pi_g$ Rydberg states are unphysical ones, and the $1\pi_g{}^*$ state was not obtained within the orbital manifold orthogonalized to all the diffuse functions. The $n\mathrm{d}\pi_g$ Rydberg states are correctly obtained after orthogonalization to the $1\pi_g{}^*$ orbital in STEX (2) and (3). On the other hand, the $np\sigma_u{}^*$ Rydberg states are correctly obtained in STEX (1) and (2), but are unphysical for orthogonalization to the $3\sigma_u{}^*$ orbital in STEX (3). The present results indicate that diffuse functions describing the Rydberg state should be orthogonalized to unoccupied valence orbitals corresponding to bound state resonances below the Rydberg region, but should not be orthogonalized to either unoccupied valence orbitals corresponding to continuum resonances or virtual orbitals.

Table I shows that the R-matrix/MQDT method is applicable to higher-lying Rydberg states than 5s, 5p and 4d. The STEX method is not applicable because of linear dependence in diffuse Gaussian-type functions. The CCPC calculation (eq. (3)) in the inner region ($r < R_0$) was found not to be applicable to higher-lying Rydberg states than 5s, 4p and 3d. The same behavior was found in C_2H_2 (Table II). As discussed in ref. [30], the lowest 1s-$3\sigma_u{}^*$ excited state is observed near the 1s-3s Rydberg state. The STEX calculation fails in its prediction, but the CCPC calculation predicts correctly the $3\sigma_u{}^*$ excited state and the $np\sigma_u$ Rydberg series.

(3) The STEX calculation using only the diffuse functions orthogonalized to all the occupied orbitals and the unoccupied valence orbitals $3\sigma_u$ and $1\pi_g$.
(4) The fully-relaxed STEX calculation using the core, valence, and virtual orbitals and additional diffuse orbitals.

3.2. *Exchange splitting in $N1s \rightarrow \sigma^*$ shape resonances of NO*

NO has the $X^2\Pi$ ground state with one more electron than N_2 and CO, but has similar π^* and σ^* valence orbitals. The $1s \rightarrow \pi^*$ excitation results in two π^* electrons and three different electronic states coupled with the 1s electron [35]. On the other hand, the $1s \rightarrow \sigma^*$ excitation results in one σ^* and one π^* electron and two dipole-allowed $^2\Pi$ states coupled with the 1s electron. The $^2\Pi$ $1s \rightarrow \sigma^*$ excited states are characterized by the singlet and triplet couplings between two of the three open-shell electrons and the doublet coupling with the remaining electron. In the N 1s excitation, the σ^* and π^* electrons have a possibility of strong coupling with the triplet and singlet spins as discussed in [36]. The N $1s \rightarrow \sigma^*$ excited states of NO are the continuum, shape resonances located above the two ionization thresholds, which correspond to triplet (T) and singlet (S) target states through coupling of the 1s and π^* electrons. Therefore, the σ^* electron in each continuum resonance is auto-ionized to both the T- and

Table II. *Term values in eV obtained with the STEX and R-matrix/MQDT methods for the C 1s-Rydberg and valence (V) excitation in C_2H_2.*

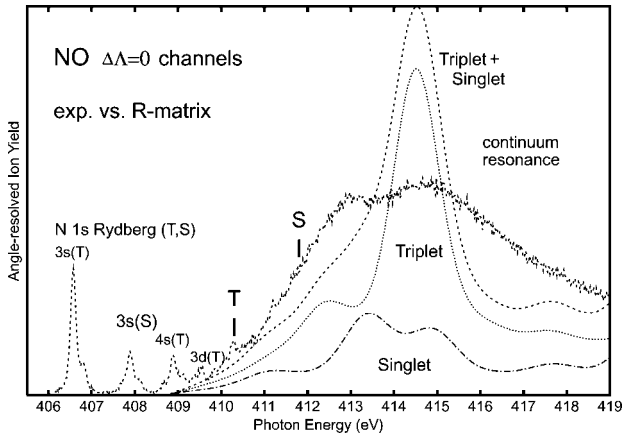

Fig. 1. R-matrix results for the $^2\Pi \leftarrow X\ ^2\Pi$ excitation (parallel transition, $\Delta\Lambda = 0$) in the NO N 1s region in comparison with 0° ion yield spectra (parallel to the linear polarization plane of the incident photon) [37] . Ionization channels to the triplet and singlet target states are decomposed.

S-target states. In terms of the R-matrix method, the σ^* continuum electron has exchange interaction with the π^* and 1s electrons in the inner region, but does not have exchange interaction with either π^* or 1s electron in the outer region. Figure 1 shows that the R-matrix results for the $^2\Pi \leftarrow X\ ^2\Pi$ excitation in the NO N 1s continuum region. The CI space and basis set were the same as in N_2. Ionization channels to the triplet and singlet target states are decomposed. This shows that the lower-energy continuum resonance (σ^* shape resonance) has more singlet target contribution and the higher-energy continuum resonance has more triplet target contribution. Thus, the R-matrix/MQDT approach is proved to be applicable to coupled-channel continuum resonances in the mutiple-target system such as singlet and triplet ionizations in NO.

Acknowledgements

The authors would like to thank Prof. J. Tennyson for fruitful discussion of the molecular R-matrix algorithm. M.H. is also grateful to Prof. M. S. Child for encouraging her to establish the R-matrix/MQDT approach during a stay in his group. Abstract

The local structure of dilute Ge impurity in Si thin film has been studied by grazing incidence fluorescence XAFS in the temperature region of 20 ∼ 300 K. Multiple-scattering XAFS (MS-XAFS) data analysis is used to fit the local structures around Ge atoms from the first to third coordination shells for the $Ge_{0.006}Si_{0.994}$ thin film. The results indicate that the bond length $R_{Ge\text{-}Si}$ of the first, secong and third Ge-Si shell is 2.38, 3.83 and 4.49 Å for the $Ge_{0.006}Si_{0.994}$ thin film, respectively. The $R_{Ge\text{-}Si}$ of the first Ge-Si shell in the $Ge_{0.006}Si_{0.994}$ thin film is 0.03 Å larger than that of the first Si-Si shell in Si crystal, and the $R_{Ge\text{-}Si}$ of the second and third Ge-Si shells in the $Ge_{0.006}Si_{0.994}$ thin film are almost equal to those of the corresponding Si-Si shells in Si crystal. These results imply that the local lattice deformation exists in the first nearest neighbor around Ge atoms and the lattice distortion relieves in the second and third Ge-Si shells for the $Ge_{0.006}Si_{0.994}$ thin film. Furthermore, the results show that the Debye-Waller factor ${\sigma_1}^2$ of the first Ge-Si shell of the $Ge_{0.006}Si_{0.994}$ thin film increases slightly from 0.0018 to 0.0020 Å^2 in the temperature region between 20 and 100 K, and rises strongly to 0.0040 Å^2 at 300 K. The bond angles $\theta_{Ge\text{-}Si\text{-}Si}$ at all temperatures are about 108.1°, which is close to the value of tetragonal network of 109.47°. The bond angle variation $\Delta\theta_{Ge\text{-}Si\text{-}Si}$ is about ±3.4°, ±3.5° and ±5.0° at the temperatures of 20, 100 and 300 K, respectively, indicating a weak tetragonal distortion around the Ge atoms in the $Ge_{0.006}$ $Si_{0.994}$ thin film.

1. Introduction

For the last decade, the crystalline Ge-Si alloys and hetero-structural Ge-Si superlattices have attracted increasing attention, due to their significantly improved electronic properties with relatively simple incorporation into existing Si technology [1]. The 4.2% mismatch for the lattice constants between Ge and Si crystals leads to significant strain during the epitaxial growth of Ge-Si thin films. This changes the band structures and electronic properties relative to that of pure Ge and Si [2], creating the potential for band gap engineering in Ge-Si device technology.

Understanding the structural parameters of Ge-Si thin films is favorable to calculate the band structures of these Ge-Si quantum systems [3]. So far, a lot of XAFS studies have been done to determine the local structures in Ge-Si system [4–6], however, they have paid attention to only the local structure of the first shell around the Ge atoms, but not the local structures of their higher shells. In order to well determine the tetragonal distortion of the unit cell in a Si thin film doped by Ge atoms, the local structures for the first three shells of Ge atoms can be expected to provide an opportunity to investigate the lattice distortion around Ge atoms in the Si host matrix [7]. Moreover, the structural information of high shells is useful to determine both bond length and bond angle accommodation of strain [8]. More recently, Pascarrelli *et al.* [9], Tormen *et al.* [10], and we [11] have used the multiple-scattering (MS) XAFS to study the local structures of the high shells for III-V semiconductors with the zinc-blende structure.

In this paper, MS-XAFS analysis is performed to study the local structures of the first three shells around Ge atoms for the $Ge_{0.006}Si_{0.0994}$ thin film in the temperature range of 20 and 300 K. We aim to investigate the tetragonal distortion and the strained distribution in the Si thin film induced by the dilute Ge impurity. The temperature dependence for the local structure of Ge impurity in Si(001) thin film is also presented.

2. Experiment

The $Ge_{0.006}Si_{0.0994}$ thin film sample was prepared by molecular beam epitaxy (MBE), which was described elsewhere [12]. Boron-doped Si (001) substrate (10 Ωcm) was chemically cleaned by the Shiraki method prior to the insertion to the vacuum. The 2 μm-thick heteroepitaxial $Si_{1-x}Ge_x(x = 0.006)$ thin film was deposited on the substrate of Si (001) at 673 K in a MBE growth chamber with a base pressure 1×10^{-10} Torr.

XAFS measurements were performed at BL-13B of the Photon Factory of National Laboratory for High Energy Physics (PF, KEK). The electron beam energy was 2.5 GeV and the maximum stored current was 400 mA. The Ge K-edge XAFS spectra of the $Ge_{0.006}Si_{0.0994}$ thin film were recorded at the temperatures of 20, 100 and 300 K in a fluorescence mode with a grazing incidence geometry. The detailed experiment procedure can be found elsewhere [4]. XAFS data were analyzed by USTC-XAFS2.0 software package compiled by Zhong and Wei according to the standard procedures [13].

3. Results and Discussions

Figure 1 shows the normalized Ge K-edge EXAFS function $\chi(k)$ of the $Ge_{0.006}Si_{0.0994}$ thin film measured in the temperatures of 20, 100 and 300 K. It can be observed that the oscillation intensity of $Ge_{0.006}Si_{0.0994}$ thin film is higher at the low k region with the maximum at about $k = 4$ Å^{-1}, then it damps very fast with the k increase. This characteristic indicates that the Ge atoms in the $Ge_{0.006}Si_{0.0994}$ thin film are predominantly surrounded by the light element Si, which has been confirmed by our previous work [4].

The solid lines in Figure 2 show the radial structural functions (RSF) of the $Ge_{0.006}Si_{0.0994}$ thin film obtained from Fourier transforming their $k^2\chi(k)$ spectra. Three peaks located at about 2.0, 3.4 and 4.1 Å are related to the first, second and third coordination shells of Ge atoms, respectively. For the $Ge_{0.006}Si_{0.0994}$ thin film measured at 300 K, the peak intensity of the first shell of Ge atoms decreases to about 80% of that measured at 20 K while the peak magnitudes of the higher shells decrease to about 50% of those measured at 20 K.

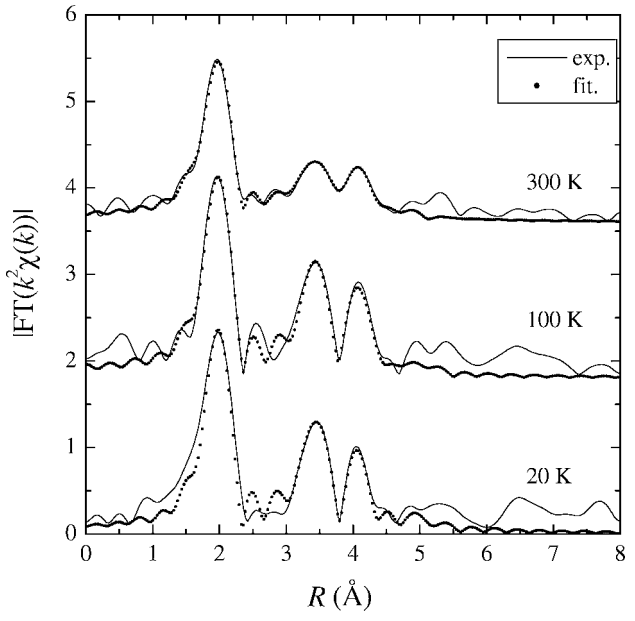

Fig. 2. The radial structural function by fourier transforming $k^2\chi(k)$ for $Ge_{0.006}Si_{0.994}$ thin film recorded at 20, 100 and 300 K: experimental (solid line) and fitting (dotted line).

For quantitative analysis, the least-squares curve fit including the multiple-scattering contributions was performed in *R*-range of [1.0, 4.8] Å using the FEFFIT code [14]. The theoretical magnitudes and phase-shifts of all the single-scattering (SS) and MS paths in the first three shells were calculated by FEFF7 [15]. In the fitting procedure, the coordination numbers were fixed to 4, 12 and 12 for the first, second and third shells, respectively. The most important MS path is the triangular double-scattering path Ge → Si_1 → Si_2 → Ge(DS2), which interferes destructively with the SS2 path of the second coordination shell [11]. The fitting results are shown in Figure 2 as dotted lines, and the structural parameters are summatized in Table I.

Seen from table I, the bond length $R_{Ge\text{-}Si}$ of the first shell in the $Ge_{0.006}Si_{0.0994}$ thin film is larger than that (2.35 Å) in c-Si by 0.03 Å, indicating the compressive strain in the first nearest neighbor around Ge atoms. However, its bond lengths $R_{Ge\text{-}Si}$ of

	3	4.503		

the second and third shells are almost equal to the corresponding interatomic distances in c-Si within the uncertainties. This shows that the shift of the nearest Si atoms toward the [111] direction can hardly affect their positions of the more distant Si atoms, despite of the second shell bonds bend. Therefore, the tetragonal distortion in the $Ge_{0.006}Si_{0.0994}$ thin film is limited to the first nearest neighbor atoms and the strain caused by the doping of Ge atoms is completely relieved in more distant atoms.

The temperature dependence of the Debye-Waller factors is plotted in Figure 3. It can be observed that in the temperature range from 20 to 100 K, the Debye-Waller factors in the first three Ge-Si shells show a slight increase with temperatures, *i.e.,* from 0.0018, 0.0037 and 0.0040 Å^2 at 20 K to 0.0020, 0.0040 and 0.0049 Å^2 at 100 K for σ_1^2, σ_2^2 and σ_3^2, respectively. However, when the temperature rises to 300 K, σ_1^2 (or σ_2^2 and σ_3^2) sharply increases to 0.0040 Å^2 (or 0.0096 and 0.0108 Å^2). These results indicate that at temperature lower than 100 K, the Debye-Waller factors in the first three Ge-Si shells are very weakly dependent on

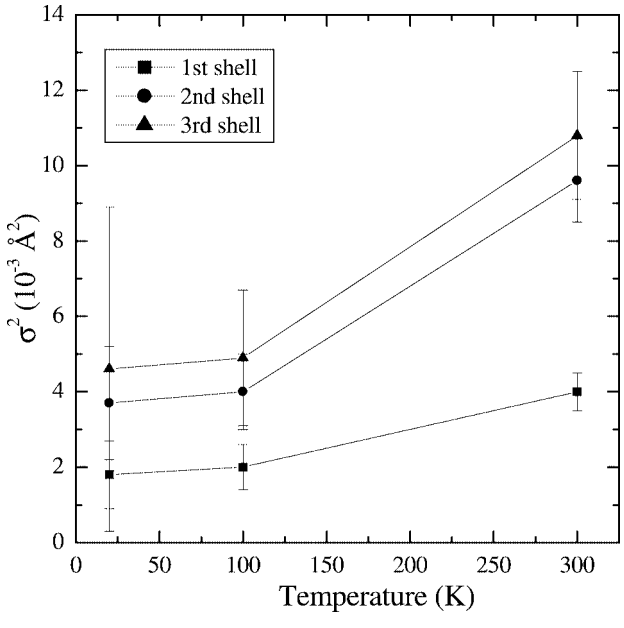

Fig. 3. The temperatures dependence of the Debye-Waller factors of the first three shells for $Ge_{0.006}Si_{0.994}$ thin film.

temperature. This means that even at temperature as high as 100 K, the zero-point contributions [16] to the Debye-Waller factors of the $Ge_{0.006}Si_{0.0994}$ thin film play the dominant role, implying that the characteristic temperature such as Debye temperature and Einstain temperature of the Ge-Si covalent bond is higher than 100 K. As the temperature increases to 300 K, the contributions of thermal motion to the Debye-Waller factors are much larger, which results in the rapid increase of the Debye-Waller factors with temperature.

An important parameter for characterizing the tetragonal distortion is the bond angle. Knowledge of the Ge-Si bond lengths of the first and second shells in the $Ge_{0.006}Si_{0.0994}$ thin film allows to determine the bond angle $\theta_{\text{Ge-Si-Si}}$ from a simple trigonometric consideration. Due to the identical bond lengths at different temperatures of 20, 100 and 300 K, their bond angles $\theta_{\text{Ge-Si-Si}}$ are all about 108.1°, close to the value expected for a tetragonal network of 109.47°. This small deviation shows a weak tetragonal distortion around Ge atoms in the unit cell of the $Ge_{0.006}Si_{0.0994}$ thin film. Moreover, the bond angle distribution is also important to understand the distortion of the tetrahedron. Following Baker *et al.*'s consideration [17], the standard variation $\Delta\theta_{\text{Ge-Si-Si}}$ can be calculated by using the Debye-Waller factors of the first, second shell Ge-Si bonds and the nearest Si-Si bond. The Debye-Waller factors of the nearest Si-Si bond in crystalline Si were theoretically calculated by Benfatto *et al.* [18] to be 0.0026 and 0.0034 $Å^2$ at 80 K and 300 K, respectively. We can determine the values of $\Delta\theta_{\text{Ge-Si-Si}}$ to be $\pm 3.4°, \pm 3.5°$ and $\pm 5.0°$ at the temperatures of 20, 100 and 300 K, respectively. The values of bond angle variation agree with that ($\pm 5°$) in crystalline GaAs at 300 K [17], indicating the weak bond angle disorder in the $Ge_{0.006}Si_{0.0994}$ thin film. Combining the bond angle variation with the result of the bond lengths, we can further confirm that the strain accumulated by the doping of Ge atoms to the Si matrix is limited to the nearest neighbors of Ge, and is easily relieved for the more distant neighbors.

Abstract

EXAFS measures the thermal variation of average interatomic distances, while Bragg diffraction and dilatometric techniques measure the variation of distances between average atomic positions. The difference not only gives information on vibrational motion perpendicular to the bond direction, but can be exploited to study the local behaviour in systems affected by negative thermal expansion. Recent results on copper, germanium and Ag_2O are presented and critically compared.

1. Introduction

The expression *thermal expansion* literally refers to the increase of geometrical dimension which is observed in most substances when their temperature is raised. Many solids however exhibit anomalous behaviours [1]. A weak *negative* thermal expansion (NTE) is observed in some tetrahedrally coordinated crystals, like silicon, in a limited temperature range. Framework structures can exhibit NTE over large temperature intervals (the lattice parameter of ZrW_2O_3 regularly contracts from 0.3 to 1050 K [2]).

Well established techniques are available for accurate macroscopic measurements and a rigorous thermodynamic description of thermal expansion is possible [3, 4]. On the contrary, the microscopic interpretation is in many cases uncertain, owing to the lack of suitable experimental techniques and the limitations of theoretical approaches. For a two-atomic system, the interaction potential is typically characterised by a steep repulsive part and a smoother attractive part; the positive thermal expansion is easily explained in terms of the potential asymmetry. This simple picture cannot be trivially extended to many-atomic systems like crystals, where the potential is defined in a many-dimensional configurational space. From the microscopic point of view, interesting clues on the vibrational origin of thermal expansion and its anomalies have been proposed on the basis of simple central force mechanisms [4]. The anharmonicity of the effective pair potential induces positive thermal expansion, via a *bond-strecting* effect like in two-atomic systems. Geometrical *tension effects*, connected to vibrational motion perpendicular to the bond direction, induce a negative contribution to the thermal expansion (variation of the *distance between average atomic positions*). Further complications can be introduced by non-central forces. In framework structures, different behaviours can be expected depending on the length scale considered, from the nearest-neighbours distance variations up to the macroscopic thermal expansion.

EXAFS, by measuring the interatomic distance between selected atomic species and their first few neighbours shells, is an appealing tool for studying the microscopic mechanisms of thermal expansion. Actually, EXAFS measures the *average path-lengths between instantaneous atomic positions*, giving complementary information with respect to macroscopic dilatometry or Bragg-diffraction. Moreover, the widespread approach to EXAFS analysis based on the single scattering approximation leads to a description of thermal disorder in terms of distance distributions and corresponding effective pair potentials, which is specular to the approach to thermal expansion based on central force mechanisms. The possibility of getting from EXAFS information on atomic vibrations perpendicular to the bond direction can also help in understanding the effects of non-central forces.

Obtaining accurate information on thermal expansion from EXAFS requires a good understanding of the connection of one-dimensional distance distributions and corresponding effective pair potentials with the structural and dynamical properties of three-dimensional systems. To this purpose, a thorough study of reference systems with known structure is important.

In this paper, after a short updated account on some aspects of the cumulant analysis method relevant for thermal expansion studies, strengths and limitations of EXAFS as a probe of local thermal expansion will be illustrated by the results recently obtained on reference systems copper and germanium and on a framework structure affected by negative thermal expansion, Ag_2O.

2. Theory

Thermal disorder spreads atomic positions into three-dimensional probability distributions. In many cases, in particular when only the first coordination shell is considered within the single scattering approximation, the EXAFS analysis can be based on a one-dimensional distribution of interatomic distances, and, for moderate disorder, can be further simplified by a parametrisation in terms of cumulants [5, 6].

Let C_i^* be the cumulants of the one-dimensional distribution of distances $\rho(r, T)$ and R_0 the inter-atomic distance for an ideal classical state of absolute rest. The instantaneous relative displacement $\Delta\vec{u}$ due to thermal motion can be decomposed into its projections $\Delta u_\parallel$ and $\Delta u_\perp$ along the average bond direction and in the perpendicular plane, respectively. The instantaneous bond distance is, to first approximation [6],

$$r \simeq R_0 + \Delta u_\parallel + \Delta u_\perp^2/2R_0. \tag{1}$$

In quasi-harmonic approximation, the parallel relative displacement in Eq. (1) can be decomposed as

$$\Delta u_\parallel = b + (\Delta u_\parallel)_\mathrm{h}, \tag{2}$$

where b is the thermal expansion due to anharmonicity, while $(\Delta u_\parallel)_\mathrm{h}$ is a harmonic contribution.

Let us now consider canonical averages. To clarify the relation between the first EXAFS cumulant $C_1^* = \langle r \rangle$ and the crystallographic distance R_c measured by Bragg diffraction, we will focus the attention on two limiting cases. For a purely

translational relative motion, the three-dimensional harmonic distribution of relative distances is an ellipsoid, so that $\langle \Delta u_{\parallel} \rangle_h = 0$, and

$$C_1^* \simeq R_0 + b + \langle \Delta u_{\perp}^2 \rangle / 2R_0; \qquad R_c = R_0 + b. \tag{3}$$

For a purely *librational* relative motion, the ellipsoid is curved along a spherical surface, so that $\langle \Delta u_{\parallel} \rangle_h \simeq -\langle \Delta u_{\perp}^2 \rangle / 2R_0$, and

$$C_1^* = R_0 + b; \qquad R_c \simeq R_0 + b - \langle \Delta u_{\perp}^2 \rangle / 2R_0. \tag{4}$$

Both b and $\langle \Delta u_{\perp}^2 \rangle$ have finite values at zero kelvin, due to the zero point motion. Relative translational motion describes the behaviour of crystals with simple, highly symmetrical structures. Relative librational motion characterizes the dynamics of rigid units in molecular crystals and framework structures [7]. In any case, the average distance measured by EXAFS is larger than the crystallographic distance:

$$C_1^* \simeq R_c + \langle \Delta u_{\perp}^2 \rangle / 2R_0. \tag{5}$$

The third cumulant measures the asymmetry of $\rho(r, T)$. Frenkel and Rehr [8] have shown, through a perturbative quantum approach, that the contribution to thermal expansion due to the asymmetry of the EXAFS effective pair potential is

$$a = -3k_3 C_2^* / k_0, \tag{6}$$

where the force constants k_0 and k_3 can be obtained by fitting suitable models to the temperature dependence of the 2nd and 3rd EXAFS cumulants. If the EXAFS effective pair potential were temperature independent, then the quantity a, defined in Eq. (6), would correspond to the quantity b of Eq. (2). From the third cumulant one could then obtain the crystallographic thermal expansion via Eq. (3) in the case of a purely translational motion; for a purely librational motion, according to Eq. (4), the 1st and 3rd cumulant would carry the same information.

EXAFS is directly sensitive to an *effective* distribution of distances. The difference between cumulants C_i^* and C_i of the real and effective distributions, respectively, is relevant for the first one,

$$C_1^* \simeq C_1 + (2C_2/C_1)(1 + C_1/\lambda) \tag{7}$$

where λ is the photoelectron mean free path [6]. In the following we will always quote the first cumulants of the *real* distributions.

3. Local thermal expansion in Cu and Ge

Figures 1 and 2 refer to the first coordination shells in copper [9] and germanium [10], respectively. In both figures, the continuous line represents the crystallographic expansion δR_c, calculated from the macroscopic thermal expansion coefficient [11]. The full circles show the temperature dependence δC_1^* of the first cumulant, obtained from an EXAFS analysis based on the ratio method, taking as reference the spectra at the lowest temperature. The difference between δC_1^* and δR_c, according to Eq. (5), depends on the increases with temperature of $\langle \Delta u_{\perp}^2 \rangle$. By a suitable procedure [10] it was possible to recover the absolute values of the perpendicular Mean Square Relative Displacement and calculate the ratio $\gamma = \langle \Delta u_{\perp}^2 \rangle / \langle \Delta u_{\parallel}^2 \rangle$, which at high temperature was about 2.7 and 6 for copper and germanium, respectively.

The diamonds in Figs. 1 and 2 represent the thermal variation δa of the quantity defined in Eq. (6) and calculated from the experimental values of the 2nd and 3rd cumulants. Relative δa values have been plotted instead of absolute values a to get rid of the zero-point thermal expansion [10]. The good correspondence

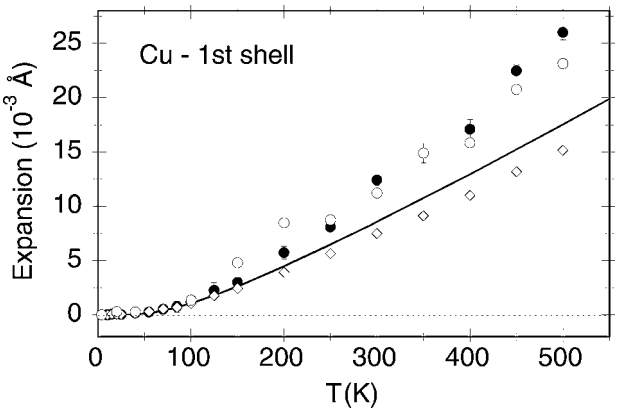

Fig. 1. Thermal expansion for the 1st shell of copper: crystallographic distance (continuous line), 1st EXAFS cumulant for $\lambda = 9$ Å (full circles), contribution of effective potential asymmetry calculated from the 3rd cumulant according to [8] (diamonds), and results from Path Integral Monte Carlo simulations [9] (open circles).

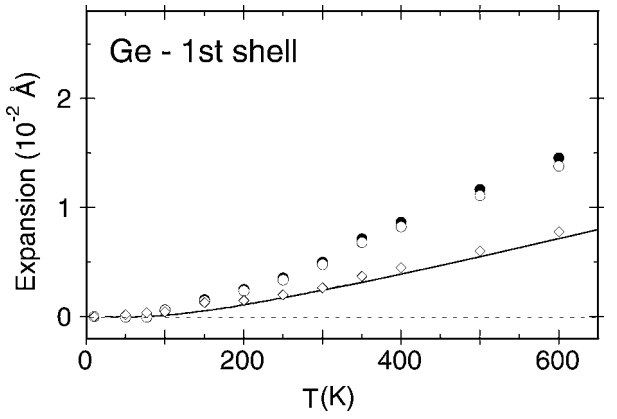

Fig. 2. Thermal expansion for the 1st shell of Germanium: crystallographic distance (continuous line), 1st EXAFS cumulants for $\lambda = 6$ Å (full circles) and $\lambda = 12$ Å (open circles), and contribution of effective potential asymmetry calculated from the 3rd cumulant according to [8] (diamonds).

between δR_c and δa found for germanium suggested that $\delta a \simeq \delta b$, so that the third cumulant could be utilised for measuring the crystallographic thermal expansion, at least for the first shell of simple crystals [10]. The non negligible disagreement found for copper shows instead that the quantity a, depending on the asymmetry of the EXAFS effective pair potential, cannot be identified with the quantity b of Eqs. (3) and (4) even for very simple crystals. The discrepancy between a and b can be explained by a temperature dependence of the effective pair potential; in view of the regular T^2 dependence of the 3rd cumulant, it is reasonable to assume that the shape of the effective potential is constant, and the temperature variation consists in a rigid shift.

The soundness of the correspondence between the coefficients C_i^* obtained from EXAFS analysis and the cumulants of the distribution of distances has been checked by a comparison with independent calculations, in order to exclude relevant artifacts of the data analysis. For germanium, the values $\langle \Delta u_{\parallel}^2 \rangle$, $\langle \Delta u_{\perp}^2 \rangle$ and the 3rd cumulant have been well reproduced by D. Strauch and coworkers through *ab initio* dynamical calculations [12]. For copper, a Path Integral Monte Carlo (PIMC) simulation was done [9], based on a many-body potential of the tight-binding family, previously used for Molecular Dynamics simulations [13]. The results of PIMC calculations are in good agreement with EXAFS results: first and third cumulants are shown in Figs. 1 and 3, respectively.

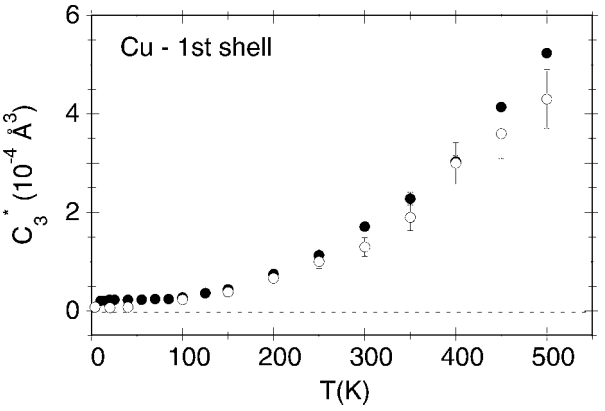

Fig. 3. 3rd cumulant for the Cu 1st shell from EXAFS (full circles) and Path Integral Monte Carlo simulations [9] (open circles).

4. Ag_2O and negative thermal expansion

The potential of EXAFS for studying systems affected by negative thermal expansion has been evidenced by a recent work on silver oxide Ag_2O [14].

Ag_2O shares with Cu_2O the *cuprite* structure. Each Ag atom is linearly coordinated to two O atoms, and each O atom is tetrahedrally coordinated to four Ag atoms. The structure can be alternatively described as a framework of two interpenetrating networks of corner-sharing Ag_4O tetrahedra. A contraction of the lattice parameter has been measured in Ag_2O in the temperature interval from 10 to 470 K by Artioli and coworkers by means of X-ray diffraction [15, 16]. EXAFS measurements were done from 7 to 500 K: the main results concerning thermal expansion are summarized in Fig. 4. The EXAFS sensitivity to local structure allows to distinguish a positive thermal expansion for the 1st-shell Ag-O distance from a negative thermal expansion of the 2nd-shell Ag-Ag distance.

The 1st-shell behaviour is consistent with the rather rigid nearest-neighbour bond with oxygen found in other framework structures affected by lattice parameter NTE [17]. The twelve Ag atoms of the 2nd-shell can be grouped into two sets: six atoms are connected to the central atom via the 1st-shell oxygen atoms and belong to the same network, the remaining six atoms belong to the other network. It is reasonable to assume that the most relevant contribution to the 2nd-shell NTE comes from the average approaching of atoms belonging to different networks, consistently with the presence of empty sites in the intermediate space.

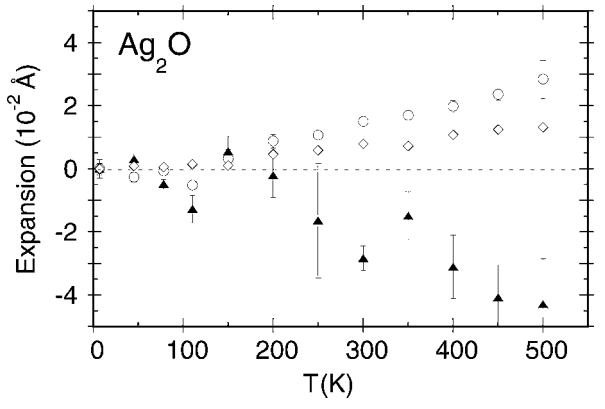

Fig. 4. Thermal expansion measured by EXAFS in Ag_2O: 1st-shell Ag–O (open circles) and 2nd-shell Ag–Ag (triangles). The diamonds are the contribution of effective potential asymmetry calculated from the 3rd cumulant according to [8].

A direct comparison of the 1st-shell EXAFS expansion δC_1^* with the crystallographic expansion δR_c was not be done in this case due to the presence of two very different atomic species and the rather complex framework structure.

An alternative procedure was attempted in Ref. [14] starting from the δa values (diamonds in Fig. 4). Assuming $\delta a \simeq \delta b$, say neglecting possible shifts of the effective pair potential, the discrepancy between δC_1^* and δa was attributed to a deviation of the motion of Ag_4O tetrahedra from a pure libration (Eq. (4)). The difference $\delta C_1^* - \delta a$ was then used to calculate the values $\langle \Delta u_\perp^2 \rangle_{\rm tr}$, where "tr" indicates a purely translational contribution. The ratio $\gamma = \langle \Delta u_\perp^2 \rangle_{\rm tr} / \langle \Delta u_\parallel^2 \rangle$ was about 9 at high temperatures.

This γ value, suggesting that the Ag-O bond is much looser with respect to bending than to strecthing, was quantitatively consistent with the high value found for the ratio between the parallel MSRD $\langle \Delta u_\parallel^2 \rangle$ of 2nd and 1st shell. The assumption $\delta a \simeq \delta b$ seem thus in this case reasonable. The main physical consequence of the difference between δC_1^* and δa is, according to Eq. (4), that the Ag_4O tetrahedra cannot be considered undistorted, as assumed by the "Rigid Unit Mode" (RUM) models which are often used to explain NTE in framework structures [18].

5. Conclusions

EXAFS measurements on Copper and Germanium have shown that the comparison between 1st cumulant and crystallographic thermal expansion gives original information on the atomic vibrations perpendicular to the bond. No general direct connection seems instead possible betwen 3rd cumulant and thermal expansion. The correctness of EXAFS cumulants obtained by the ratio mehtod was supported by independent calculations.

Measurements on Ag_2O have evidenced the peculiar ability of EXAFS to give original information on the local behaviour of systems affected by negative thermal expansion.

Abstract

We present a multi-channel extension of the multiple scattering method for X-ray absorption fine structure (XAFS) spectroscopy that allows to take account of atomic multiplet-like electron correlation effects in condensed systems, on the basis of *ab initio* electron structure calculations. The formalism is outlined and an application to near-edge XAFS at the $L_{2,3}$ edges of Ca metal is presented. In this system, the experimentally observed branching ratio deviates strongly from that obtained from the standard (one-electron) approach to XAFS. This is due to that fact that one-electron theory neglects the multiplet coupling between the photo-electron and the 2p core-hole. Within the multi-channel method, this correlation effect can easily be taken into account and the calculated spectrum agrees well with experiment.

1. Introduction

Multiple scattering (MS) theory provides an accurate and flexible scheme for the calculation of unoccupied electronic states which are probed by various synchrotron experiments such as X-ray absorption spectroscopy and resonant X-ray scattering. The standard theory relies on the single-particle picture, that is, it neglects electron correlation effects. This is a great shortcoming, since core-level X-ray spectra are often strongly modified by electron correlation, in particular by the Coulomb and exchange interaction of the valence electrons with the core hole. In transition metal and rare earth systems, this interaction can give rise to pronounced atomic multiplet and satellite structures in the spectra, which can only be accounted for in a many-electron calculation. A generalisation of MS theory to many-electron wave functions was developed by Natoli *et al*. [1] and is known as "multi-channel" MS theory. Using this approach together with the eigen-channel R-matrix method [2, 3], we have developed a new computational scheme that allows to take into account certain atomic multiplet effects, namely those that are due to the interaction between the photo-electron and electrons/holes in sufficiently localised orbitals. Sufficiently localised means that the wave function is negligible small beyond the atomic radius. This applies exactly to inner-core shells and well to the 4f-shell in rare earths. In this paper, we apply the method to $L_{2,3}$ near-edge XAFS of metallic Ca. A detailed description of the theory will be published elsewhere [4]. The $L_{2,3}$-edge spectrum of Ca is an interesting test case for the new method, because the L_2 and L_3 absorption channels are strongly coupled through the photo-electron–core-hole Coulomb interaction. This leads to a branching ratio of about 1 : 1, far from the statistical ratio (2 : 1) which is obtained in single-particle theory [5, 6].

2. Formalism

In the X-ray absorption process at the $L_{2,3}$ edges, an electron is excited from the 2p core-level to a continuum state above the Fermi level. We consider the six electron wave function made of the 2p core electrons, one of which becomes the photo-electron in the final state. All other electrons are not considered explicitly; they are assumed to contribute only to the mean-field potential. The initial state Ψ_g with energy E_g is simply given by the closed shell configuration $(2p^6, {}^1S_0)$. Final states have energy $E = E_g + \hbar\omega$ and a $(2p^5\epsilon^1)$ configuration, where ϵ denotes a (one-electron) state in the continuum above the Fermi energy. The crucial point is that we take into account multiplet effects through a configuration interaction ansatz for the final state wave function, which is developed as

$$\Psi = \mathcal{A} \sum_{\alpha} \tilde{\Phi}_{\alpha}(X)\phi_{\alpha}(x). \tag{1}$$

Here $\tilde{\Phi}_{\alpha}$ is one of the six $(2p^5)$ states, labelled by $\alpha = (j_c, \mu_c)$ $(j_c = 1/2, 3/2, \mu_c = -j_c \ldots j_c)$; X collects all core-electron coordinates. The $(2p^5)$ multiplet energies are $E_{\alpha} = E_g - \epsilon_c(j_c)$, where $\epsilon_c(j_c)$ are the spin-orbit split $2p(j_c)$ levels. For each $\tilde{\Phi}_{\alpha}$, there is a component ϕ_{α} of the photo-electron wave function. The (radial, angular, and spin) coordinate of the photo-electron is denoted $x = (r, \hat{x}, \sigma)$. Finally, $\mathcal{A}$ denotes the antisymmetrization operator.

For correlated N-electron wavefunctions such as Ψ, where all electrons but one occupy localized orbitals, we have derived a multi-channel multiple scattering method for XAFS in close formal analogy to the standard single-electron method [4]. The total photoabsorption cross section is given by [1, 4]

$$\sigma(\omega) \propto \omega \mathrm{Im} \left\{ \sum_{\Gamma\Gamma'} M^*_{\Gamma} \tau^{00}_{\Gamma\Gamma'} M_{\Gamma'} \right\}. \tag{2}$$

Here $\Gamma = \alpha lms$ is the set of all quantum numbers of Ψ, with lm being the orbital and s the spin quantum numbers of the photo-electron. $M_{\Gamma} = \langle \Psi^{\mathrm{in}}_{\Gamma} | D | g \rangle$ are the transition matrix elements; we consider only dipolar transition and use the length approximation. $\Psi^{\mathrm{in}}_{\Gamma}$ is the inside solution that matches smoothly onto the outside solution

$$\Psi^{\mathrm{out}}_{\Gamma} = \sum_{\Gamma'} \Phi_{\Gamma'}(X\hat{x}\sigma) Z_{\Gamma'\Gamma}(r)/r. \tag{3}$$

Here, "inside" and "outside" refer to the atomic sphere of the absorber, i.e. $r < r_0$ and $r > r_0$, respectively, r_0 being the muffin-tin radius. We have introduced $\Phi_{\Gamma} \equiv \tilde{\Phi}_{\alpha}(X) Y_{lm}(\hat{x}) \delta(s, \sigma)$. The amplitude of the radial photoelectron wave function is given by

$$Z_{\Gamma\Gamma'}(r)/r = j_l(k_{\alpha} r)[t^{-1}]_{\Gamma\Gamma'} - \mathrm{i} k_{\alpha} h^+_l(k_{\alpha} r) \delta_{\Gamma\Gamma'}. \tag{4}$$

*Present address: LRRS, UMR 5613 Université de Bourgogne-CNRS, B.P. 47870 F-21078 Dijon, France.

Here, $h_l^+ = j_l + \mathrm{i}n_l$ and j_l, n_l are the usual spherical Bessel and Neumann functions. k_α is the wave number of the photo-electron, given by $k_\alpha^2 + V_0 = \epsilon_\alpha = E - E_\alpha$, where V_0 is the interstitial potential. $t_{\Gamma\Gamma'}$ is the multi-channel atomic T-matrix of the absorber (at site $i = 0$). In Eq. (2), $\tau^{ij}_{\Gamma\Gamma'}$ is the multi-channel scattering path operator connecting sites i and j. It is calculated for a finite cluster by inversion of the τ^{-1} matrix, whose elements are given by

$$[\tau^{-1}]^{ij}_{\Gamma\Gamma'} = \delta_{ij}[t^{-1}]^i_{\Gamma\Gamma'} - \delta_{\alpha\alpha'}k_\alpha H^{ij}_{lm,l'm'}(k_\alpha)\delta_{ss'}. \quad (5)$$

Here, t^i is the atomic scattering matrix of atom i, and $H^{ij}_{lm,l'm'}$ are the real space KKR structure factors (for a definition, see Ref. [1] appendix A). Apart from the absorber, we treat all atoms in the standard one-electron muffin-tin approximation, which implies $t^i_{\Gamma\Gamma'} = t^i_l(k_\alpha)\delta_{\Gamma\Gamma'}$, for all $i \neq 0$. These T-matrices, as well as the structure factors $H^{ij}_{lm,l'm'}$, are single channel quantities and can thus be calculated using standard multiple scattering techniques [7]. For the spectra shown below we have used a symmetric fcc cluster up to the tenth neighbor shell (177 atoms) and selfconsistent linear-muffin-tin-orbital (LMTO) potentials [8] with (space-filling) Wigner-Seitz spheres for the computation of the t^i_l's. We have developed a partitioning technique for an efficient inversion of the multichannel scattering path operator in real space (for details see Ref. [4]).

The remaining problem is the calculation of the multichannel T-matrix of the absorber and the inner solutions $\Psi^{\mathrm{in}}_\Gamma$. This is done using the eigenchannel R-matrix method [2, 3]. As reaction volume, we use the (absorber's) muffin-tin sphere with radius r_0. As Hamiltonian we take $H = H_0 + V$, where H_0 is the (LMTO-LDA) mean-field hamiltonian and V is the photo-electron–core-hole Coulomb interaction. As a basis of N-electron trial wave functions we use the functions

$$\Psi_{\Gamma v} \equiv \mathcal{A}\{\Phi_\Gamma(X\hat{x}\sigma)P_v(r)/r\}. \quad (6)$$

Here, P_v are solutions of the radial Schrödinger equation for angular momentum l with the self-consistent LMTO potential. Note that this is the same differential equation as the one used for the calculation of the single-channel T-matrices t^i_l, but now we fix the boundary conditions at the muffin-tin radius instead of the single-particle energy ϵ. Since $2\mathrm{p} \rightarrow \epsilon\mathrm{s}$ transitions have negligeable intensity in the near-edge region, we here include only $l = 2$, i.e. d-waves in the basis. We use closed-type orbitals with boundary conditions $P_v\ (r_0) = 0$, and open-type orbitals with boundary conditions $\mathrm{d}P_v/\mathrm{d}r(r_0) = 0$. Convergence of the spectra was achieved with five closed-type orbitals (with zero to four nodes in $0 < r < r_0$) and one open-type orbital (with zero nodes). The Coulomb interaction V can be expressed in terms of (generalized) Slater-integrals $F^k_{vv'} \equiv (2\mathrm{p}, v\mathrm{d}|r^k/r^{k+1}|2\mathrm{p}, v'\mathrm{d})$ and $G^k_{vv'} \equiv (2\mathrm{p}, v\mathrm{d}|r^k/r^{k+1}|v'\mathrm{d}, 2\mathrm{p})$ [9]. The detailed calculation of matrix elements will be presented elsewhere [4]. The monopole part of the photo-electron–core-hole interaction (related to integrals $F^0_{vv'}$) is drastically reduced by metallic screening [5]. Solid state screening is a many-body effect that is not included in the (local) correlation effects we are dealing with in the present approach. Therefore have treated solid state screening in an empirical way.

3. Results

In Fig. 1 we show the absorption spectra as obtained in standard multiple scattering theory and using the ground state LMTO potential. As a check of the new method, we also show

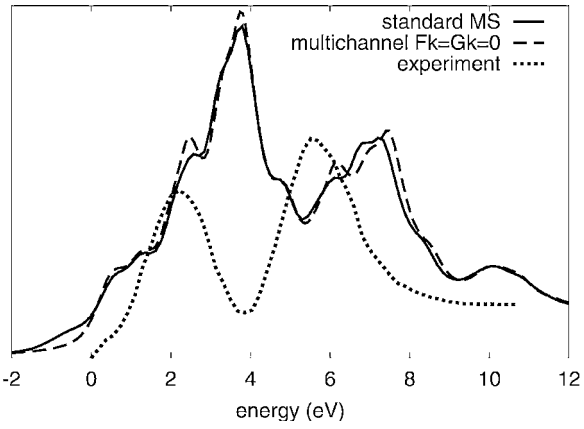

Fig. 1. Ca $L_{2,3}$-edge absorption spectra calculated using standard multiple scattering method (standard MS) and using multichannel method in non-interacting limit (multi-channel $Fk = Gk = 0$).

the spectrum calculated with the multichannel method in the non-interacting limit (i.e. putting the photo-electron–core-hole interaction to zero.) The agreement is perfect within numerical error due to broadening (we use a Lorentzian broadening of 0.5 eV FWHM), which shows that the R-matrix method with the present choice of basis functions gives the same results as direct integration. The $L_3 : L_2$ branching ratio is about 3 : 2 rather than 2 : 1 (statistical value), and thus slightly better than the density of states approximation for $L_{2,3}$-XAFS [5]. Nonetheless, the spectrum is (still) in strong disagreement with the experimental one (taken from Ref. [5]) both as far as branching ratio and line shape is concerned.

The spectra in Fig. 2 have been obtained using the multichannel method and including the photo-electron–core-hole interaction. Spectra (a) and (b) differ with respect to the mean-field potential used for the calculation of the P_v and the treatment of the monopole terms $F^0_{vv'}$. For spectrum (a), we have used the LMTO ground state potential and considered the limit $F^0_{vv'} = 0$, i.e. we simply disregarded the monopole terms. The branching ratio is about 1 : 1 in good agreement with experiment. This shows that it is mainly the multiplet coupling described by F^2, G^1 and G^3, that is responsible for the deviation of the branching ratio from statistical, as already found by Zaanen *et al.* [5] who used model calculations. As far as peak positions and fine structure are concerned, however, spectrum (a) does not improve over the one-electron spectra in Fig. 1. Let us also note that spectrum (a) is almost identical to the

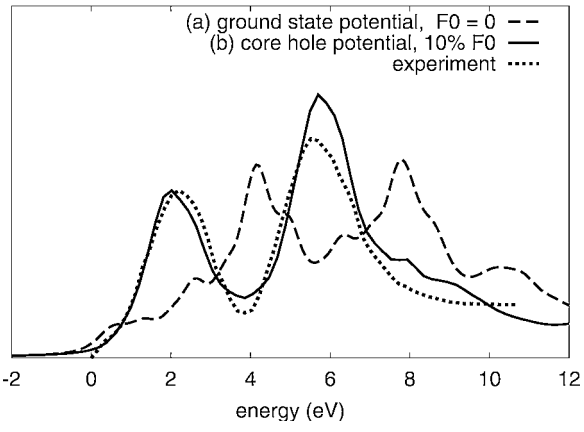

Fig. 2. Ca $L_{2,3}$-edge absorption spectra calculated using multichannel method including electron-hole interaction (see text for details).

one obtained by Schwitalla/Ebert within time-dependent density functional theory [6].

In order to treat the monopole term of the Coulomb interaction including screening, we used a statically screened potential instead of the ground state potential for the calculation of the trial orbitals $P_v(r)$ and levels ϵ_v. This potential was obtained from self-consistent supercell LMTO calculations with a 2p-core hole on the absorber atom. However, the use of the screened potential alone (with $F^0 = 0$) did not improve the spectra. In order to get agreement with experiment, we had to use screened potentials together with non-zero, but strongly rescaled F^0 terms. Specifically, we used $\alpha F^0_{vv'}$, where $F^0_{vv'}$ are the calculated integrals and α is an empirical scaling factor, which we set to 0.1. The corresponding spectrum (b) agrees well with experiment with the small remaining problem that the branching ratio is now slightly "over-corrected". The present treatment of the monopole part of the Coulomb interaction is somewhat unsatisfactory, because it involves an ajustable parameter (α). We are currently seeking for a better solution to this problem.

The main conclusions from the present work are the following. We have presented a multi-channel extention of the multiple scattering method for XAFS that allows the inclusion of multiplet effects between the photo-electron and sufficiently localized orbitals, in particular the core-hole. We have applied the new method successfully to the branching ratio problem in the $L_{2,3}$ near-edge spectrum of metallic Ca. In our method, the multiplet coupling described by Slater integrals F^k, G^k, $k > 0$ can be taken into account without ajustable parameters. In order to account for the strongly screened monopole part of the Coulomb interaction we used statically screened potentials and rescaled the F^0 integrals by an empirical factor α.

Abstract

The sensitivity of X-ray absorption spectroscopy (XAS) to the local structure around a selected atomic species (symmetry, distances and angles) is commonly exploited to quantitatively describe systems where all the configurations around the absorbing atoms may be approximated by the mean one. However, in many cases of disordered systems a simple description of the local structure with single-configuration models cannot be reconciled with experimental spectra.

In this paper the necessity to analyse the XAS spectra by considering a multiplicity of atomic structural configurations is demonstrated in the case of silver borate glasses.

The local coordination around Ag cations in ($Ag_2O.nB_2O_3$) glasses has been studied by comparing the XAS experimental spectra at the Ag K edge with theoretical XANES and EXAFS spectra obtained by a configurational average of model structures.

In order to provide a reasonable agreement with experiment, these models have to take into account that there are many geometrically distinct Ag neighbourhoods present in the system, and that the measured XANES and EXAFS signals are in fact averages over spectra originated at all the non-equivalent photoabsorbing sites (multi-configuration approach).

1. Introduction

The sensitivity of X-ray absorption spectroscopy (XAS) to the local structure of the absorbing site (symmetry, distances and angles) is generally exploited to quantitatively describe systems characterised by single or few atomic configurations.

However, the use of routine best-fitting procedures to fit experimental spectra can give rise to unreliable results, when applied to systems where several atomic configurations around the absorbing species are present, as in the case of some glasses.

In this paper we present a study about the structural configurations of the Ag cation in borate glasses $Ag_2O{\cdot}nB_2O_3$. Silver borate glasses constitute a widely studied class of materials, especially when mixed with AgI to form fast ion conducting glasses, which can be used as solid electrolytes [1].

The local coordination of silver cations has been studied by various spectroscopic and structural techniques both in binary $Ag_2O{\cdot}nB_2O_3$ and ternary (i.e., with AgI) glasses [2–4]. The first X-ray absorption spectroscopy (XAS) experiments on binary glasses identified a mean Ag-O distance of about 2.3 Å, and suggested a structural model where silver is bridging between two oxygen atoms in a quasi linear configuration, like in c-Ag_2O [5, 6]. However most recent calculations, based on reverse Monte Carlo (RMC) analysis of neutron scattering data, show evidence of a broader distribution, with the presence of different local sites around Ag cations, having a higher average coordination number [7].

In particular, the pair correlation functions $G_{ij}(r)$ for $Ag_2O{\cdot}nB_2O_3$ simulated by Swenson *et al.* [8] by RMC show that the first peak of the partial $G_{AgO}(r)$ is relatively sharp and symmetrical around 2.4 Å. The corresponding coordination number is estimated to be about 3.3, in good agreement with the experimental value of 3.7 ± 0.5 previously determined by neutron diffraction [8]. On the contrary, both $G_{AgB}(r)$ and $G_{AgAg}(r)$ show a very broad peak, extending from about 2.5 Å and reaching its maximum value at about 3.1 Å [7].

Since the presence of static disorder reduces the XANES and EXAFS signals in a different way, we undertook in a previous work [9] a comparative analysis of XAS spectra calculated for the near edge region. As a first step, all the known crystalline sites for Ag in borate crystals were simulated and compared with experimental XANES spectra by increasing the number of nearest neighbours and the static disorder. Both XANES and EXAFS signals could not be reproduced by any of these sites [10]. As a second step, some simple geometrical structures were built, in order to evaluate the number and kind of nearest neighbours necessary to reproduce at least the general shape of XANES. The best agreement was reached with a configuration of 8 atoms, distributed within a radial distance of about ∼3 Å, that were displaced angularly and/or radially starting from a cubic model. From the previous [9] XANES simulations, we concluded that the most plausible model for the local coordination of Ag in borate glasses is characterised by a first shell Ag-O_4 at a distance $R = 2.2$–2.3 Å, the remaining atoms being distributed randomly at longer distances. We also verified that the substitution of some next nearest neighbours oxygen atoms with boron slightly improves the agreement with experimental spectra. In any case, the agreement was only qualitative but it gave a clear indication that a single-configuration model is not able to reproduce the experimental spectra.

In the followings, we will present some examples about the use of a multi-configuration approach.

2. Experimental and Theoretical Details

X-ray absorption spectra were measured at the Ag K-edge using the synchrotron radiation from the ESRF storage ring (Grenoble, France) at the GILDA BM08 beamline. A transmission scheme with a Si(311) crystal monochromator and two ion chambers filled with argon gas was used. Three sets of measurements were performed: (*i*) crystalline c-Ag_2O at 77 K; (*ii*) glasses g-$Ag_2O{\cdot}4B_2O_3$ and g-$Ag_2O{\cdot}2B_2O_3$ in a range of temperatures

from 77 to 450 K; (*iii*) a set of glasses g-$Ag_2O{\cdot}nB_2O_3$ with $n = 2,3,4,6,8$ at $T = 77$ K.

The obtained X-ray absorption spectra were analysed using two methods.

1) The XANES part was simulated by real-space full-multiple-scattering calculations [11] for a set of trial structures. We used the *rsms* code, which is an amended descendant of the *icxanes* code [12] and is maintained by O. Sipr [13]. In order to put into evidence the net effect of structural changes, the same scattering potential was chosen for all the trial structures. We resorted to a non-self consistent potential constructed along the Mattheiss prescription for a silver orthoborate crystal. We checked that the particular choice of the potential is not crucial for the aim of our study. Since no significant core-hole effect has been observed, we used a potential which neglects the core-hole.

2) The EXAFS signals were extracted in a conventional way using the EDA software package [14] and analysed as described below. To determine structural parameters from the EXAFS spectra of glasses, one needs to know the amplitude and phase shift functions for required atom pairs. In this work we have used theoretical *ab initio* model within FEFF8 formalism [15], which was tested using reference c-Ag_2O compound with well known structure. The calculated c-Ag_2O EXAFS signal was in excellent agreement with the experimental, confirming the good accuracy of the theoretical amplitude and phase shift functions for Ag-O and Ag-Ag atom pairs.

The EXAFS signals of glasses were extracted on the same energy scale as for the reference c-Ag_2O compound. Their Fourier transforms consist of a broad asymmetric single-peak and do not show any evidence of the contribution from outer coordination shells. This allows to perform the analysis of the first peak using the original EXAFS spectra without employing the Fourier filtering procedure.

The EXAFS signals were best fitted using two techniques, which allow to reproduce the atomic structure up to ~3.2 Å. The first one is a model-independent approach, implemented by the EDARDF code [16]. It allows to reconstruct the total radial distribution function (RDF) without any assumption on its shape. As an example, the RDFs obtained for the glasses at 77 K are shown in Fig. 1.

The second one is a conventional Gaussian multi-shell best-fit, starting from results obtained by using the EDARDF code. In particular, up to three shells were used to reproduce the EXAFS signal, with a maximum number of nine fitting parameters, three (N, R, σ^2) for each shell.

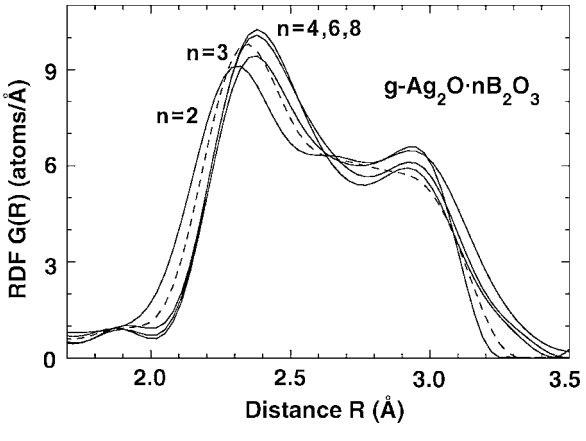

Fig. 1. RDFs in g-$Ag_2O{\cdot}nB_2O_3$ glasses at 77 K, as obtained by EDARDF code.

3. Results and discussion

3.1. *General conclusions from EXAFS analysis*

The RDF around silver ions in silver borate glasses has complex asymmetric shape. As a first approximation, based on the chemical composition of these glasses and general rules of glass network formation, the RDF can be decomposed into two parts: (*i*) the nearest oxygen atoms, which form the first coordination shell of silver ions, and (*ii*) the outer neighbours, presumably oxygens and borons which form the glass network. The oxygen atoms in the first shell show a broad but well defined distribution peaked at ~2.3 Å. At the same time, the group of more distant neighbours has a wide distribution, extending from 2.4 to 3.2 Å. Such a shape of the RDF significantly complicates the analysis, since it cannot be easily approximated by a simple analytical function. Another problem is related to the composition of the outer neighbours. The expected intermixture of oxygen and boron atoms and the similarity of their scattering amplitude and phase shift functions do not allow to separate unambiguously these two contributions. In fact, we have analysed two extreme models: in the first one, all atoms in the outer group were assumed to be oxygens and, in the second one, all atoms were assumed to be borons. The obtained results show that an exchange of oxygen atoms with borons slightly affects the values of structural parameters (N, R, σ^2), but does not substantially change the asymmetric shape of the RDF.

The approximation of the total RDF with three Gaussian functions allows to conclude that there are about 4 oxygen atoms in the first coordination shell of silver and about 4–5 oxygen/boron atoms in the next outer shells.

3.2. *Multi-configuration analysis*

On the basis of the EXAFS results, we have studied the evolution of the simulated XANES spectra, by varying in a systematic way the "1 + 8 atoms cubic cluster" previously identified: atoms were grouped into two shells, allowing different parameters (radial distances and angles, coordination numbers, type of atoms) to be independently varied. Finally, for each set of variable parameters, a mean XANES spectrum was generated by averaging over many configurations obtained from a particular distribution of possible clusters. The choice of shape of the distribution of allowed parameters is one of the crucial points of the procedure. As an illustration of our procedure, we investigate in Fig. 2 the effect of a gradually introduced randomization of the test models geometry. The top curve corresponds to a semi-ordered model with Ag at the cube centre and eight neighbouring atoms located along the cube diagonals: four oxygens form the first shell at $R = 2.3$ Å, four borons form the second shell with R covering equidistantly the 2.5–3.0 Å interval and a partial disorder is introduced via distributing these neighbouring atoms among the cube corners in all possible ways. Then we introduced angular randomization of the second-shell atoms (i.e. their angular coordinates are uniformly distributed over the full space angle) and on top of that also a radial randomization (radial distances of second-shell atoms are uniformly distributed in the interval 2.5–3.0 Å). The remaining theoretical curves describe models with additionally imposed randomization of the first-shell atoms: either only in angular coordinates (fourth curve from the top in Fig. 2) or both in angular and radial coordinates (fifth curve from the top). In the last case, the radial distances of the first shell atoms uniformly deviate from their middle value of 2.3 Å by at most 0.2 Å. A complete description of our constructing the structural models is under publication [10].

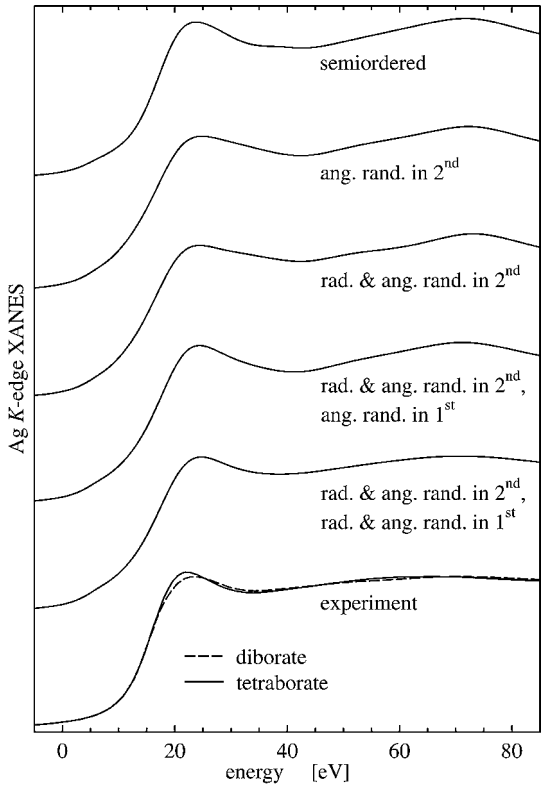

Fig. 2. Configurationally averaged XANES spectra obtained by gradually introducing the randomization in the structure of test models, as described in the text.

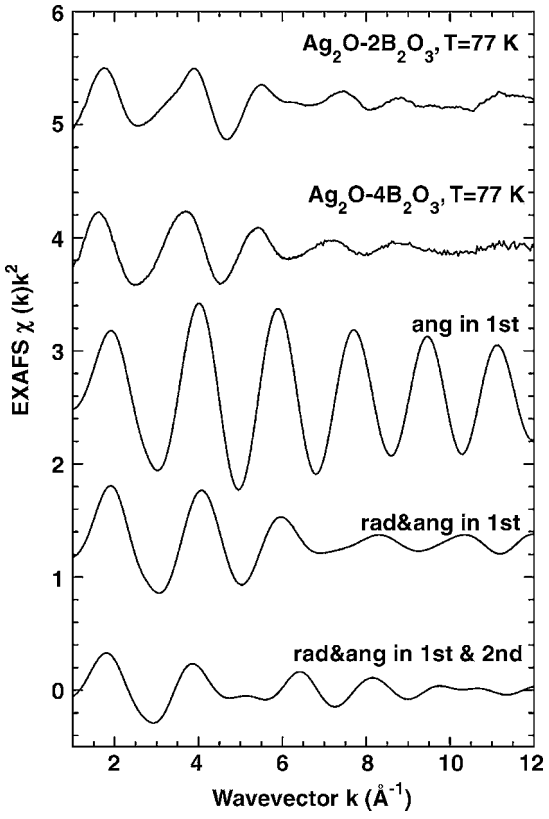

Fig. 3. Comparison of experimental EXAFS with calculations for structural models obtained by gradually introducing randomization, as described in the text.

In this way, a much better agreement with XANES experimental spectra has been obtained, but it is still difficult to identify the *good* model, if any. We have thus developed a new software code, able to calculate and average not only XANES, but also EXAFS spectra from each set of *randomly* generated clusters. Preliminary results are very promising, as shown in Fig. 3, where theoretical EXAFS curves for models explored in Fig. 2 are presented (third from the top curve represent a model with angular randomization applied for the first-shell atoms, below is the curve for a model with both angular and radial randomization of the first shell atoms and bottom curve corresponds to both angular and radial randomization in both the first and the second shells). It is quite clear (as expected) that EXAFS is much more sensitive to details of the distribution of radial distances, while XANES is more able to appreciate the influence of angular parameters, which change the multiple scattering contributions.

A first result of the comparison between XANES and EXAFS is the identification of the "wrong" distributions of generated clusters. Moreover, a careful analysis of the trends of the obtained spectra allows us to check the actual influence of each parameter on the configurationally-averaged spectra and to identify for each parameter the most probable value.

We should remember, however, that for silver borate glasses (and in general for systems where a description in terms of single-configuration is not realistic) the obtained values do not describe the local structure of Ag ions, but only a *mean* situation. In fact, the experimental spectrum is due to the superposition of several absorption spectra, corresponding to silver atoms in a quite different configuration. Work is in progress to go beyond the limits of the *random* generation of possible local clusters, aiming to build a bestfit procedure able to manage with more physical constraints for the identification of local sites of Ag ions in borate glasses.

Abstract

In this paper we present a detailed quantitative analysis of the iron K-edge XANES data of potassium ferrocyanide in water solution. The right structural determination as been obtained from the XANES data by using the MXAN procedure to fit the experimental data despite the presence of small discrepancies between experimental data and best-fit calculations at low energy. The origin of such discrepancies is also discussed in terms of non muffin-tin corrections and the role of the right charge density of the cluster.

1. Introduction

In this paper we present a detailed quantitative structural analysis of the XANES spectrum (from the edge up to 150 eV) of potassium ferrocyanide (III) in water at the iron K-edge. The structural results are compared with a previous EXAFS analysis performed by the GNXAS package [1]. The XANES energy region has been fitted with the help of the MXAN procedure [2], using the Fe-C and C-N distances and the Fe-C-N angles as parameters in the fitting procedure. The structural determination fully agrees with the one obtained by EXAFS analysis despite the presence of small discrepancies between the experimental data and the fitted theoretical spectrum in the low energy region (within the first 50–60 eV), confirming the dominance of the geometrical structure in the determination of the XANES shape. We discuss the origin of such discrepancies both in terms of the need of the self-consistent field calculation of the potential, using the formal valency of the atomic species, and possible correction to the muffin-tin approximation of the shape of the potential. This work has been motivated by the need to test potential applications of the MXAN procedure to systems of biological interest.

2. Theory

Recently, a new method to perform a quantitative analysis of the XANES energy range, i.e. from the edge up to 200 eV, was proposed in the literature. The method, called MXAN [2], is based on a comparison between experimental data and many theoretical calculations performed by varying selected structural parameters starting from a putative structure, i.e. from a well defined initial geometrical configuration around the absorber. The calculation of XANES spectra related to the hundreds of different geometrical configurations needed to obtain the best fit of the experimental data is done in a reasonable time and the optimization in the space of parameters is achieved by minimization of the square residual function in parameter space. The calculations are performed in the energy space without involving any Fourier transform algorithm. The MXAN method is based on the muffin-tin approximation for the shape of the potential and the use of the concept of complex optical potential, based on the local density approximation of the self-energy of the excited photoelectron. The real part is calculated by the Hedin-Lundqvist potential using the whole charge density. Inelastic processes are taken into account by a convolution with a broadening Lorentzian function having an energy dependent width of the form $\Gamma(E) = \Gamma_c + \Gamma_{mfp}(E)$. The constant part Γ_c includes the core hole lifetime and the experimental resolution, while the energy dependent term represents all the intrinsic and extrinsic inelastic processes. The $\Gamma_{mfp}(E)$ function is zero below an onset energy E_s (which in extended systems corresponds to the plasmon excitation energy) and begins to increase from a value A_s following the universal functional form of the mean free path in solids. Both the onset energy E_s and the jump A_s are introduced in the $\Gamma_{mfp}(E)$ function via an arctangent functional form to avoid discontinuities and to simulate the electron-hole pair excitations. Their numerical values are derived at each step of computation (i.e. for each geometrical configuration) on the basis of a Monte Carlo fit [3]. The full potential calculations are based on the Finite Difference Method (FDM) which does not require any approximation for the shape of the potential. This method essentially writes the Schrodinger equation on a three-dimensional grid obtaining a large system of linear equations connecting the values of the wave function on all the grid points. We have used the program FDMNES developed by Y. Joly and we refer to reference [4] for details. The potential has been calculated on the basis of $Z + 1$ approximation for the final state.

3. Results and Discussion

In Fig. 1 we report the comparison between the experimental data and the calculation at the best fit conditions.

The Fe K-edge X-ray absorption spectrum of a 0.5 M $K_3Fe(CN)_6$ water solution was recorded at the ESRF (Grenoble, France), beam-line BM29. The data were recorded in transmission mode using a Si(311) double-crystal monochromator, detuned to 50% of the rocking curve full width at half maximum, for harmonic rejection. Data points were collected for 1 s each and several spectra were recorded and averaged. The solutions were kept in cells with Kapton film windows and Teflon spacers of 1 mm.

The best-fit conditions correspond to an octahedral geometry with Fe-C and C-N distances of 1.93 Å and 1.147 Å respectively. These values are in good agreement with those obtained by EXAFS analysis of solid $K_3Fe(CN)_6$, within the statistical error bar that is about 2% of the bond length. It is important to stress

that in water solution the Fe(III) ion forms a very stable complex where the short-range environment of the iron ion is equal to the crystalline phase one. In aqueous solution the water molecules do not contribute to the XAS spectra as they give rise to a far and disordered hydration shell. This is confirmed by Fourier Transform of the EXAFS spectrum which does not show the presence of any peak above 3.5 Å. For the sake of brevity the EXAFS analysis will be presented elsewhere.

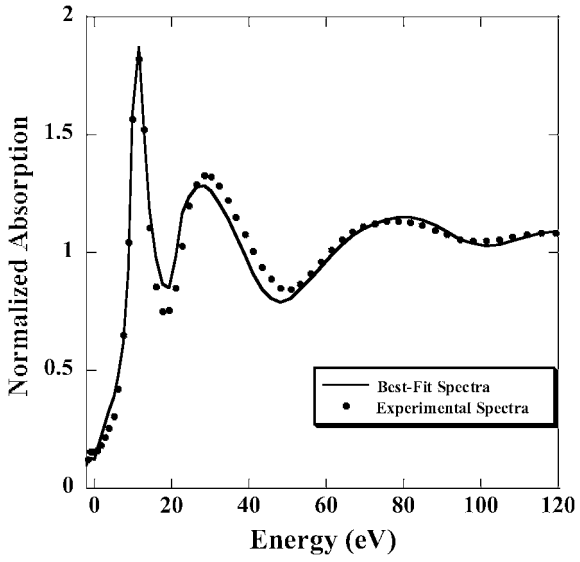

Fig. 1. Comparison between the experimental Fe K-edge data of $Fe(CN)_6$ (dotted line) and the best-fit calculation performed by the MXAN procedure (solid line).

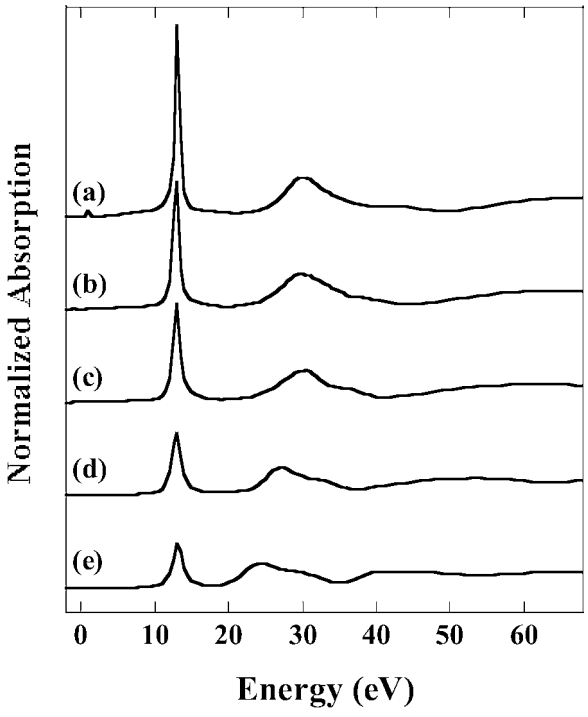

Fig. 2. The effect of electronic structure on non-muffin-tin potential using FDM program. The electronic structure of (a) is Fe: $3d^64s^2$, C: $2s^12p^3$, N: $2s^22p^3$ (cluster-charge = 0), (b) Fe: $3d^{6.5}4s^2$, C: $2s^12p^3$, N: $2s^22p^3$ (cluster-charge = −0.5), (c) Fe: $3d^74s^2$, C: $2s^12p^3$, N: $2s^22p^3$ (cluster-charge = −1), (d) Fe: $3d^84s^2$, C: $2s^12p^3$, N: $2s^22p^3$ (cluster-charge = −2) and (e) Fe: $3d^94s^2$, C: $2s^12p^3$, N: $2s^22p^3$ (cluster-charge = −3).

The used electronic structure is the typical one of the neutral atoms case, i.e. Fe: $3d^64s^2$, C: $2s^12p^3$ and N: $2s^22p^3$, with a total cluster charge equal to zero. The agreement between experimental data and the best fit calculation is rather good in the whole energy range. Small discrepancies appear in the energy range between 15 and 40 eV although they do not affect the structural reconstruction.

To understand the origin of such discrepancies, which are larger than in other systems, we have used the FDMNES program to check in details the influence of the non-muffin-tin corrections to the calculation. The geometrical structure is the same as the one obtained by MXAN at the best fit condition. In Fig. 2 we report a set of raw FDM calculations without damping. They refer to different electronic structures (see the figure caption for details). As expected the influence of changing the electronic structure is essentially confined in the low energy range and it appears rather strong in the energy range 10 eV to 40 eV.

In Fig. 3 we compare the experimental data with three fits starting from the raw calculations shown in Fig. 2 and using as fitting parameters the quantities that define the Lorentzian broadening functions. In this way we can apply our

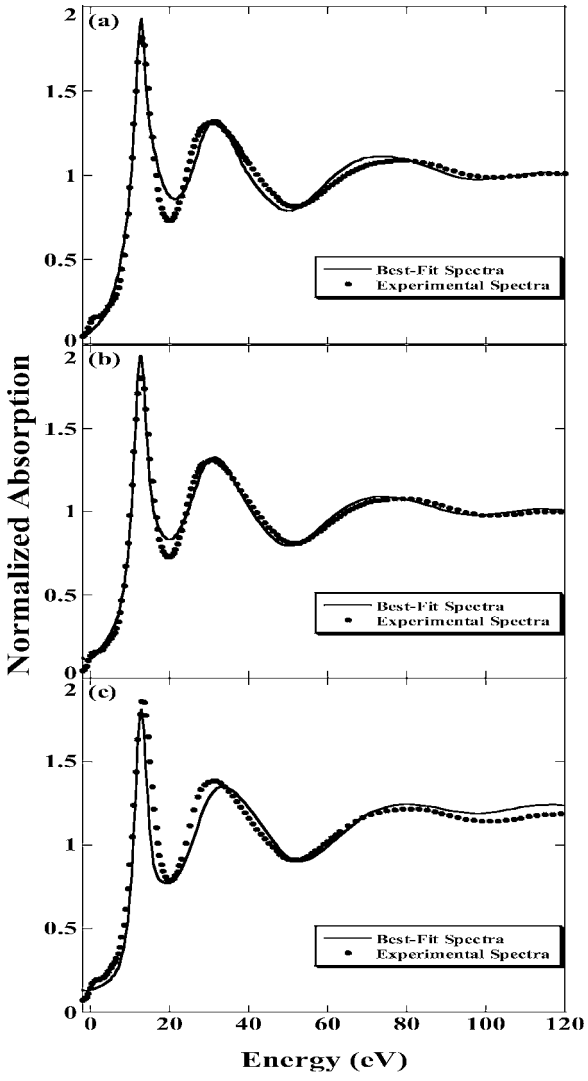

Fig. 3. Comparison between the best fit theoretical XANES spectra (solid line) performed by the MXAN procedure to non-muffin-tin potential (FDM program) and the experimental data (dotted line). The electronic structure of (a) is Fe: $3d^64s^2$, C: $2s^12p^3$, N: $2s^22p^3$ (cluster-charge = 0), (b) Fe: $3d^{6.5}4s^2$, C: $2s^12p^3$, N: $2s^22p^3$ (cluster-charge = −0.5) and (c) Fe: $3d^84s^2$, C: $2s^12p^3$, N: $2s^22p^3$ (cluster-charge = −2).

phenomenological damping method also to the FDM calculations quantifying both the non-muffin-tin corrections and the changes of charge density. Details of the calculations are in the figure caption. Panel (a) of Fig. 3 refers to the same charge density of the MXAN calculation. The agreement between the experiments and theory is better than in Fig. 1 (the error function decreases by about 20%) but the improvement is not dramatic, confirming the goodness of the muffin-tin approximation for the calculation of the absorbing cross-section in most of the systems. On the other hand changes in the electronic configuration produce strong changes in the theoretical calculations (see panels (b) and (c) of Fig. 3). In particular the calculation shown in panel (b) produces a decrease of the error function of about 50%, going from 20.4 to 11.3, indicating the need of a good charge density. Small changes in the charge distribution (from case (a) to case (b)) generate larger differences than the one produced going from muffin-tin to non muffin-tin calculations. The small discrepancies still present can be due to the use of a potential that is not self-consistent.

4. Conclusion

We performed a quantitative analysis of XANES data of potassium ferrocyanide (III) at the iron K-edge. We have demonstrated that the MXAN procedure can obtain a good structural reconstruction even in the presence of small discrepancies between experimental data and the best fit calculation. The importance of the muffin-tin approximation for the shape of the potential is discussed as well, showing that the muffin-tin approximation is good enough for structural determination. The importance of the correct charge density in theoretical calculations to construct the optical potential has also been emphasized.

Abstract

Approximations in the treatment of Debye-Waller factors in multiple scattering calculations are one of the principal remaining uncertainties in XAFS calculations. The amplitude of each path varies as a function of the mean square variation in path length. This quantity depends on the many-body correlations involving atoms in the path, as well as the mean square displacement of individual atoms. The correlations normal as well as parallel to interatomic vectors are required, and the effects of anharmonicity must be taken into account. Although difficult to calculate accurately, these quantities can be extracted directly from molecular dynamics (MD) simulations. Here we present temperature dependent results for copper, using a semi-empirical potential based on a tight-binding model, from which the cumulants of the variation in path length as well as the correlation functions are derived. XAFS calculations based on extracted parameters are compared with those calculated directly from the MD atomic coordinates, and with results using Debye model and lattice dynamic calculations.

1. The XAFS Debye-Waller factor

The XAFS Debye-Waller factor arises from a configurational average over all possible atomic positions:

$$\iiint \mathrm{d}x_1\mathrm{d}y_1\mathrm{d}z_1 \ldots \iiint \mathrm{d}x_n\mathrm{d}y_n\mathrm{d}z_n\ \chi(k,\underline{r_1}\ldots\underline{r_n}) \times g(\underline{r_1}\ldots\underline{r_n}). \tag{1}$$

If the many-body distribution functions are replaced by products of pair distribution functions then it is given by:

$$\iiint \mathrm{d}x_1\mathrm{d}y_1\mathrm{d}z_1 \ldots \iiint \mathrm{d}x_n\mathrm{d}y_n\mathrm{d}z_n \chi(k,\underline{r_1}\ldots\underline{r_n}) \times g_{x01}\ldots\times g_{zn0}. \tag{2}$$

A further simplification arises from treating each leg of a scattering path individually, in one dimension. An approximate solution to this problem was devised by Tranquada and Ingalls [1] who approximated the interesting bit of the XAFS function, the angular momentum sum over the Hankel functions, by its asymptotic limit (plane wave approximation):

$$\int_0^\infty \mathrm{d}r\, g(r)\frac{1}{r^2}\exp^{2\mathrm{i}kr} = \frac{1}{r_0^2}\exp^{2\mathrm{i}kr'}\,\mathrm{e}^{-1/2\acute{o}_p^2k^2+1/24\acute{e}_{p4}k^4}, \tag{3}$$

$$r' = r_0 - \frac{\sigma_p^2}{2r_0} - 1/12\kappa_{p3}k^2. \tag{4}$$

Here $2r_0 = 2\langle \boldsymbol{r}\rangle$ (1st cumulant), σ_p^2 is the mean square variation in path length (2nd cumulant), and κ_{p3} and κ_{p4} the 3rd and 4th cumulants of the path, respectively. For single scattering, σ_p is given by:

$$\sigma_p^2 = 4\sigma_{ab}^2, \tag{5}$$

$$\sigma_{ab}^2 = (\langle u_a^2\rangle + \langle u_b^2\rangle)(1 - C_{ab}), \tag{6}$$

where u_i^2 is the mean square displacement of the ith individual atom, and the C_{ab} the correlations between their atomic motions.

For multiple scattering paths of order n (i.e. including atoms a to n), where legs of the path involve angles α, σ_p^2 can be given by

$$\langle u_a^2\rangle(1 - Ce_a)\cos^2(\acute{a}_a/2) + \cdots + \langle u_n^2\rangle(1 - Ce_n)\cos^2(\acute{a}_n/2), \tag{7}$$

$$Ce_a = \frac{C_{ab}\cos^2(\alpha_b/2) + C_{ac}\cos^2(\alpha_c/2)\cdots + C_{az}\cos^2(\alpha_z/2)}{\cos^2(\alpha_b/2) + \cos^2(\alpha_c/2)\cdots + \cos^2(\alpha_z/2)}. \tag{8}$$

This is the basis of the functions used to describe the mean square variation in path length in the programs EXCURVE [2] and P [3]. In EXCURVE and for the simplest disorder option in P, only the shell-dependent Debye-Waller terms are used in the calculation, rather than the individual atomic displacements and the correlation terms, so a further simplification is used:

$$\sigma_p^2 = \sum_a 1/2\sigma_{0a}^2\cos^2(\alpha_a/2). \tag{9}$$

There are some exceptions to the use of this rule, most notably when legs are used twice in the same paths (e.g. 0-*a*-0-*a*-0). Because the motion of the photoelectron is fast compared to the atomic motion, the same change in leg length applies equally to both parts of the total multiple scattering path. Thus for the case where n legs are shared:

$$\sigma_{p'}^2 = n^2\sigma_p^2, \tag{10}$$

where σ_p^2 is calculated as above.

In this paper we will discuss both cumulants of the path and cumulants of an individual distance. These can be readily interconverted by employing the relationship:

$$\kappa_{pn} = 2^n\kappa_{dn}. \tag{11}$$

The nth cumulant is in units of Å^n in each case. We note also that the EXCURVE and P parameters A and B are $2\sigma^2$ and $\kappa_3 \times 1000$, respectively, where σ^2 and κ_3 are cumulants for the distance not the path. Thus far we have ignored any three dimensional effects, but P (and some versions of EXCURVE) have the following two options:

- r_0 above may be increased to reflect motion normal to the bond, using the assumption that both $\langle u^2\rangle$ and the inter-atomic correlation are isotropic (single scattering only).
- For near-colinear bonds, the effective bond angle is reduced, according to the effect of the Debye-Waller terms on each atom in the path.

Both EXCURVE and P restrict the use of higher cumulants to single scattering paths.

The number of approximations is clearly very large. Previously, some of the approximations involved in the single scattering paths have been evaluated. For example, by using numerical integrals,

use of the plane wave approximation and truncation of the Taylor series involved in the use of Tranquada and Ingalls equation can be avoided. Where XAFS Debye-Waller terms are quite small, these effects are also small. Moreover, when the product of the wavevector and interatomic distance kr is small, and spherical wave effects tend to be large, $k^2\sigma^2$ tends to be small. In a previous MD paper [4] the difference between r_{ab} and r_0 was evaluated, the importance of higher cumulants described, and the anharmonic oscillator model (which can be used to calculate third cumulants) was tested. However, for the generalised case there is no easy way of evaluating the effect of thermal disorder on the multiple scattering paths.

Here we attempt to provide further tests of our assumptions, using lattice dynamics calculations and derivations of the multiple scattering cumulants from MD studies to gain insight into the nature of thermal motion as it effects XAFS.

2. Lattice dynamics

The displacement-displacement correlation function for face centred cubic (FCC) copper, using the 300 K crystallographic lattice parameter of 3.615 Å was calculated in the harmonic approximation from [5]:

$$\langle u_\alpha(i)u_\beta(j)\rangle = 1/(Nm_i^{1/2}m_j^{1/2})\sum_{k,v}\langle Q(k,v)Q(-k,v)\rangle \times e_\alpha(i,k,v)e_\beta(j,-k,v),$$

$$\langle |Q(k,v)|^2\rangle = E(k,v)/\omega^2(k,v). \quad (12)$$

The displacements u of atoms i, j of mass m are calculated from the N eigenvectors e and eigenvalues (frequencies) ω^2 of the mass-weighted dynamic matrix. Q are the normal mode amplitudes associated with wavevector k for which the vibrational energy is E. A sum over 10^6 equally spaced points in the Brillouin zone for the single longitudinal and two transverse modes v was used. The dynamic matrix was calculated using the force-constants of the 6-shell model of Sinha [6] who determined their numerical value by fitting room-temperature inelastic neutron scattering data. Displacements were calculated for the first 10 shells around Cu. For the case $i = j$, the displacement matrix is diagonal, with non-zero terms equal to the isotropic mean square displacement $\langle u^2\rangle$ of an individual atom. In the uncorrelated case, the XAFS Debye-Waller term σ^2_∞ is $2\langle u^2\rangle$. The phonon frequency distribution spectrum was in good agreement with previous results [6]. Table I shows the displacements in terms of the crystal lattice coordinates, together with the bond-parallel and bond-normal (averaged over two directions) values. The effective correlation for each component ($1 - \sigma/\sigma_\infty$, where σ^2_∞ is $2\langle u^2\rangle$) is also displayed.

The results for the bond-parallel component are very similar to those derived from Debye theory using the experimental Debye temperature of 317 K. The near isotropy of the interatomic correlation in bond-normal and bond-parallel directions justifies the optional three-dimensional correction available in P. The off diagonal terms are very weak – the largest being the $0x$-$4y$ correlation, which will tend to accentuate the departure of the 0-1-4 angle from 180 degrees. Atoms remain correlated to at least the 10th shell.

3. Molecular dynamics

MD simulations were performed as in our previous paper [4], using the semi-empirical tight-binding potential used initially by Rosato *et al*. [7]. The previous paper also describes the method for extracting the cumulants from the moments of the atomic distributions within an anharmonic oscillator model. The same approach is used here, but in this work we extend the analysis to the multiple scattering paths, which are the principal subject of this paper. However, for reasons of compatibility with the program P (which was used to calculate an EXAFS spectrum from actual simulation coordinates) we have increased the system size to 2916 atoms.

The cumulants for some representative single and multiple scattering paths calculated according to [4] are listed in Table II. Statistics are presented for copper simulated at 100 K and 300 K to demonstrate the temperature dependence of the cumulants. Table II also includes the values calculated by EXCURVE given the same single scattering Debye-Waller factors. The 100 K data is almost entirely harmonic. At both temperatures the 0-1-4-1-0, 0-1-4-0 and 0-4-0 paths have remarkably similar cumulants, and the motion of the intermediate atom has surprisingly little effect. For this reason, the EXCURVE derived values for the MS paths are remarkably good. The main exception is for the collinear 0-1-0-1′-0 path, which should be identical to 0-1-4-1-0 (it is irrelevant where the central atom is in the path). However, EXCURVE estimates one of these from the first shell and one from the fourth shell single scattering values, so introduces a difference in their values. Figure 1 is a distribution of scattering angles at 100 K and 300 K for the 0-1-4-1-0 path extracted from the MD simulation. Clearly, although often assumed to be colinear, the probability of the scattering angle actually being 180 degrees is very small. The displacement of the maxima of the

distribution to smaller scattering angle and a general broadening and growing asymmetry in the distributions at higher temperature is the inevitable consequence of the greater vibrational amplitude of the atoms. The peak in the angle distribution (e.g. 176° at 300 K) is very close to that calculated by the 3D correction in EXCURVE, justifying its use.

4. Calculated XAFS spectra

A number of XAFS calculations were performed using a cluster size limited to a radius of 5.5 Å. Spectra were calculated initially using (a) Debye-model parameters, (b) scattering path parameters derived from Molecular Dynamics and Lattice Dynamics methods, and (c) by using refined parameters. In addition, a spectrum was calculated directly from the 2916 atomic coordinates at a single moment in the MD simulation, by means of an average of spectra calculated for each atom individually. In each case we used the 300 K crystallographic lattice parameter of 3.615 Å, an energy zero (EF) of −11 eV, an effective core-width + resolution term (CW) of 2 eV, and the high-energy limit of the single-electron transition ratio (AFAC) of 0.95. These values were estimated from the calculation which used Debye model parameters.

The statistically optimum fit (which is compared to the experimental spectrum in Figure 2, used κ_{p3} values from the MD calculation, first shell κ_{p2} values from lattice dynamics, while the second cumulants for shells 2–4 were refined. This was very close to the best refined fit, yet required only three refined parameters. It serves as a baseline for discussion of the other fits. The calculated third cumulants improved the fit index R_{exafs} [3] by about 4%, a noticeable amount. Its inclusion is therefore important, although it is not normally possible to refine values because of correlation with other parameters, except perhaps where a series of temperature dependent spectra are available. MD is therefore very useful in either obtaining third cumulants, or testing the models used in their calculation. The accuracy required is not as great as for the second cumulants, for which inaccuracies inherent in the MD method may preclude direct use of values derived from the simulation.

The refined values of the second cumulants were, in terms of $2\sigma^2_{ab}$, .002 to .004 Å^2 higher than those calculated from the lattice dynamics values. We explain the discrepancy by our neglect of higher cumulants in the multiple scattering component of our calculation, and to a lesser extent due to the errors in estimating the mean square variations in path lengths for scattering paths within the first shell, a consequence of the simplistic algorithm used by EXCURVE as discussed above. The fit using actual MD

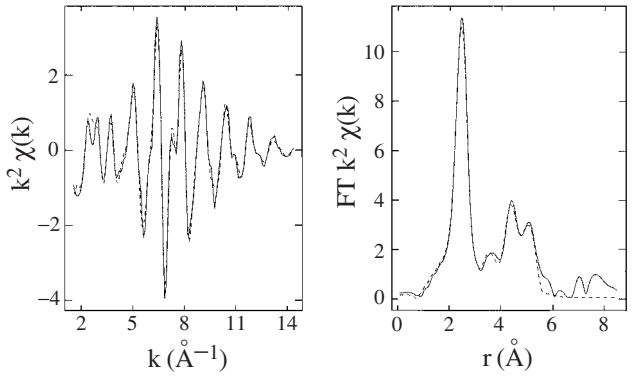

Fig. 2. EXAFS and Fourier transform for Cu at 300 K calculated using MD 3rd cumulants for all shells, 1st shell second cumulant from lattice dynamics, and refined second cumulants for other shells. Experimental data are presented as a solid line and the calculated spectrum as a dashed line.

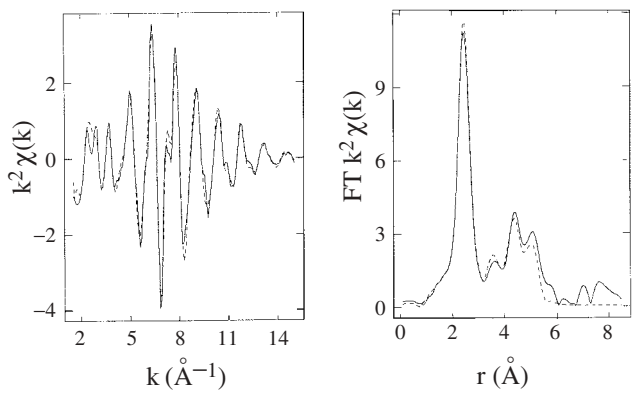

Fig. 3. EXAFS and Fourier transform for Cu at 300 K calculated directly from MD coordinates Experimental data are presented as a solid line and the calculated spectrum as a dashed line.

coordinates (figure 3) is considerably worse. The discrepancy in the first shell is to be expected, given the overall lower value of MD second cumulants compared with those obtained by lattice dynamics, Debye theory and by refining the values. More surprising is the reduction in amplitude for higher shells. This is the opposite of what we would expect, given the apparent success of the EXCURVE algorithm in estimating the second cumulants for most multiple scattering paths. We have no adequate explanation for this at present, but note that our choice of values for CW and AFAC will effect our results, and the values that were used may mask other errors used in the previous calculations.

We commented previously that the small correction due to motion normal to the bond, which can optionally be included when using P or recent versions of EXCURVE, appeared to be justified by our results. However, when used, it makes the fit slightly poorer rather than slightly better. Again, we have no explanation for this at present.

5. Conclusions

Overall we find our results to justify the unsophisticated approximations made in the calculation of multiple scattering pathlengths. The main improvement we would wish to make is to include higher cumulants in the MS paths. The close relationship between higher cumulants for the single shell and multiple scattering paths revealed by MD suggest this may be possible without introducing more variables. The third cumulants for the 1st and 4th shells may be calculated from the anharmonic oscillator model given the thermal expansion corefficient, but for the other shells it cannot. As we do not regard it as practicable to refine higher cumulant parameters, we need to develop models allowing these terms to be calculated for different lattice types. So far we have restricted out attention to a lattice with a single atom. Where optical modes contribute, estimating r_0 and the multiple scattering mean square variation in pathlength may be more complex, as different atom types can be strongly anti-correlated. Lattice dynamic calculations will be invaluable in studying these effects further.

Using Bond Valence Sums as Restraints in XAFS Analysis

M. Newville

Consortium for Advanced Radiation Sources, The University of Chicago, Chicago, IL 60637, USA

Received June 26, 2003; revised version July 21, 2003; accepted November 4, 2003

Abstract

The Bond Valence model gives a simple, accurate relationship between the bond distance, co-ordination number, and formal valence of ions in many systems. This empirical model thus gives complementary information to EXAFS and XANES, and has been used as an independent check of XAFS results by many workers. More generally, the Bond Valence represents *prior knowledge* of the system that can be used to constrain the XAFS analysis itself. Since Bond Valence sums are not perfectly satisfied, their use as exact constraints in XAFS analysis may not be warranted and they are probably best suited as *restraints* – inexact conditions placed on the analysis that act as additional data or prior knowledge of the system. The practical use of Bond Valence sums as constraints and restraints in EXAFS analysis is demonstrated for iron oxides, and the use of Bond Valence sums as prior knowledge that can be applied to a wide-range of XAFS analyses is discussed.

1. Introduction

X-ray absorption fine-structure (XAFS) spectroscopy is ideally suited for studying the formal valence state, near-neighbor bond length, coordination number, and near-neighbor species of selected atoms. Unfortunately, determining all of these quantities independently from real experimental XAFS data is not always easy. Because of this, XAFS results are often scrutinized for "chemical plausibility" by comparing to results from other chemical and structural measurements.

An important approach to assessing the chemical plausibility is the Bond Valence Model [1]. This model gives an empirical description of chemical bonding and charge balance at an atomic scale, and relates the formal valence of an ion to the near-neighbor distances and co-ordination numbers. Originally applied by Brown and Altermatt [1, 2] to assess the quality of the data in the crystallographic literature for inorganic crystals, this model has been widely used in crystal chemistry to relate bond lengths, coordination numbers and formal charges of ions.

Recently, there has been growing interest in the formal use of Bayesian analysis for XAFS, in which prior information about the system can be statistically accounted for in XAFS analysis [3, 4]. In addition, the successful combination of EXAFS and diffraction analysis [5, 6] and more recently the combined analysis of EXAFS and XANES [7–9] have shown that information from other measurements can, in fact, be included in XAFS analysis. In this work, I will argue that the Bond Valence Model represents another form of prior knowledge that can be used in the XAFS analysis for a wide range of systems.

2. The Bond Valence Model

The Bond Valence Model begins with a simple description of chemical bonds at an atomic scale, using "bond" for neighboring cation-anion pairs (a view quite suitable for XAFS), derived from Pauling's 2nd rule of electrostatic valence [10]. *The total strength of the valency bonds which reach an ion from all neighboring atoms is equal to the charge of the ion*. The model parameterizes charge balance for interatomic bonds with a relationship between formal valence, bond distance, and coordination number, and writes the valence of a cation i as

$$V_i = \sum_j s_{ij} \tag{1}$$

where the sum is over neighboring atoms j, with the bond between atoms i and j having a *bond valence* s_{ij}. The bond valence is commonly parameterized [1, 2, 11] as

$$s_{ij} = \exp[(R'_{ij} - R_{ij})/b] \tag{2}$$

where R_{ij} is the distance between atoms i and j and R'_{ij} and b are parameters to be determined empirically. Brown and Altermatt found that b could be set to the universal value 0.37 ($\approx 1/e$), and tabulated R'_{ij} for many cation-anion pairs, so that good agreement could be found for formal valence states of very many atomic sites in the crystallographic literature.

Bond Valence sums from Eqs. (1) and (2) have been applied successfully to XAFS data by several workers [12–18] to verify the reliability of results from XAFS analysis. In general, the agreement between XAFS results and Bond Valence sums are quite good for the species measured by XAFS and can also be used to predict the valence of the anions bonded to the metal sites probed by XAFS.

3. Use of Bond Valence Sums in XAFS Analysis

The agreement of Bond Valence sums with crystallographic and XAFS data suggests that this model could be included directly in XAFS analysis as prior knowledge of the system. As a first possibility, Eqs. (1) and (2) could fully constrain R, N, and valence V. For a system with one near-neighbor pair, this can be done by setting the near-neighbor distance to

$$R_{ij} = R'_{ij} + 0.37 \log(N_{ij}/V_i) \tag{3}$$

which eliminates one of the parameters in the analysis. With this model, the parameters R and N, which are normally uncorrelated in XAFS analysis, become fully correlated with one another and with valence.

As an example use of Eq. (3) consider FeO, with regular rock-salt structure. Knowing the formal valence of Fe is $V = +2$, the Fe-O coordination number and distance can be linked, reducing the number of parameters in the fit. This leads to results shown in Fig. 1 and Table I. For this fit to the first 2 paths of FeO (Fe-O and Fe-Fe), $S_0^2 = 0.75$, $N_{\mathrm{Fe-Fe}} = 12$, and the parameters E_0, $N_{\mathrm{Fe-o}}$, $R_{\mathrm{Fe-Fe}}$, $\sigma^2_{\mathrm{Fe-O}}$, and $\sigma^2_{\mathrm{Fe-Fe}}$ were adjusted in the fit. $R_{\mathrm{Fe-O}}$ was tied to the value of $N_{\mathrm{Fe-O}}$ and $V = +2$ with Eq. (3), and parameter $R'_{\mathrm{Fe-O}} = 1.734$. The analysis was done using IFEFFIT [19] with calculations from FEFF [20]. The results show that Bond Valence sum can be used in XAFS analysis to constrain R and N for absorbing atoms with known valence state and simple coordination environment.

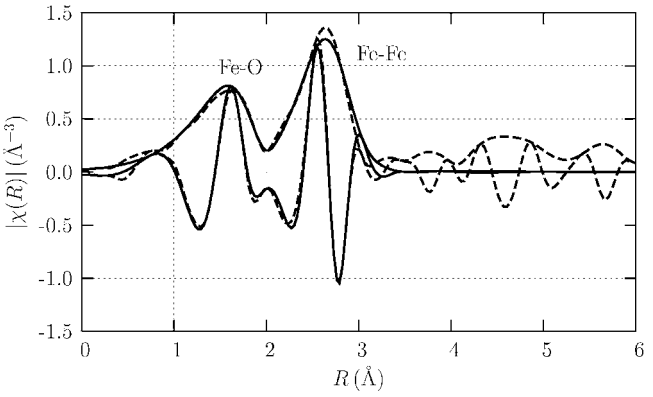

Fig. 1. Fit to FeO using a Bond Valence sum to fully constrain N and R for the Fe-O bond according to Eq. 3, with results shown in Table I. Shown are both $|\chi(R)|$ and Re$[\chi(R)]$ for data (dashed) and best-fit (solid). Bond Valence sums can be used to link the R and N parameters for simple fits.

Table I. *Fit results for FeO, using Eq. (3) to constrain R and N for the first Fe-O distance. Data were fitted in R-space, between* $R =$ *[1.1, 3.1]Å, with Fourier transform done with* $k =$ *[2.5, 14.0]Å^{-1}, a Hanning window with* $dk = 3.0$Å^{-1}, *and* k-weight $= 2$.

Parameter	Value	Parameter	Value
E_0	0.44 (0.73)	S_0^2	0.75 (fixed)
$N_{\mathrm{Fe-O}}$	5.5 (0.2)	$N_{\mathrm{Fe-Fe}}$	12.0 (fixed)
$R_{\mathrm{Fe-O}}$	2.11 (derived)	$R_{\mathrm{Fe-Fe}}$	3.05 (0.01)
$\sigma^2_{\mathrm{Fe-O}}$	0.014 (0.002)	$\sigma^2_{\mathrm{Fe-Fe}}$	0.014 (0.001)
$\mathcal{R}$	0.013	χ^2	356.0

4. Restraints in EXAFS Data Modeling

The Bond-Valence Model is simple and powerful, but it is not exact. The sums given by Eq. (1) are typically accurate to about 10%. Thus, their use as rigid constraints as for the FeO example above will not be appropriate in many cases, especially for systems with multiple sites for the absorbing atom and mixed first-shells. Still, the Bond Valence sums provide information about the relation between R, N, and valence V that may be used in XAFS analysis, even if not as the exact condition of Eq. (3).

For inexact conditions such as the Bond Valence sum, for which imposing a constraint on the analysis may be unwarranted, using a *restraint* may be more appropriate. Whereas a constraint is an exact mathematical relationship between variables in the fitting model, a restraint is a statistical preference for a particular value that includes some uncertainty. Restraints for EXAFS analysis are discussed by Binsted, *et al.* [21], and have been part of the EXCURVE analysis tools for some time, though seem to be used only to restrain bond distances and angles. As far as I know, inexact restraints are not available in other XAFS analysis methods.

A restraint adds another term, λ, to the least-squares minimization problem in the analysis, so that χ^2 becomes

$$\chi^2 \sim \frac{1}{N-P}\sum_i^N \left[\frac{\chi_i^{\mathrm{data}} - \chi_i^{\mathrm{model}}(\boldsymbol{x})}{\epsilon_i}\right]^2 + \lambda(\boldsymbol{x},\boldsymbol{b}) \qquad (4)$$

where the sum is done over N data points, χ_i^{data} and χ_i^{model} are the data and model XAFS, $\boldsymbol{x}$ is the set of p fitted variables (typically R, N, $E_0, \ldots$), and ϵ_i is the estimated uncertainty in the data. In general, the restraint $\lambda(\boldsymbol{x}, \boldsymbol{b})$ can depend on the fitted variables $\boldsymbol{x}$ and other physical parameters $\boldsymbol{b}$.

A useful form for the restraint is

$$\lambda(\boldsymbol{x},\boldsymbol{b}) = \left[\frac{V_0 - V(\boldsymbol{x},\boldsymbol{b})}{\delta V}\right]^2 \qquad (5)$$

which conveniently makes the restraint look like just another term in the χ^2 sum. V_0 represents another "measurement" for the system which can be modeled in terms of the parameters of the fit as $V(\boldsymbol{x},\boldsymbol{b})$ with uncertainty δV. This general form allows us to impose a variety of restraints on the fit based external measurements or *prior knowledge* of the system even if this knowledge is, like our measured EXAFS data, imperfect.

For the Bond Valence model, V_0 would be the formal valence, $V(\boldsymbol{x}, \boldsymbol{b})$ would be the sum from Eq. (1). In a sense, this makes the experimentally determined valence another data point in the EXAFS fit modeled with the Bond Valence sum. δV represents our confidence in both V_0 and in the Bond Valence model itself. Thus, as $\delta V \to 0$, the free parameters $\boldsymbol{x}$ will be forced to make $V(\boldsymbol{x}, \boldsymbol{b}) = V_0$, as if the Bond Valence sum was imposed as a constraint. On the other hand, as $\delta V \to \infty$, $V(\boldsymbol{x}, \boldsymbol{b})$, is determined solely the data alone, as if there was no prior knowledge of the valence. Of the parameters $\boldsymbol{x}$ that are consistent with the data, a finite δV causes the fit to chose those that bring $V(\boldsymbol{x}, \boldsymbol{b})$ closest to V_0.

5. Application of Bond Valence Restraints

As an example application of using Bond Valence sums as restraints, consider hematite Fe_2O_3. This structure has 2 distinct Fe-O near-neighbors, and the limited information in the first shell (for data to $k \approx 14.0$ Å^{-1}) can make getting unambiguous results for R and N for both oxygen sub-shells difficult.

To use the Bond Valence sum, two different distances go into Eq. (1), along with the parameter $R'_{\mathrm{Fe-O}} = 1.759$ for Fe(III)[2,11]. V_0 is set to $+3$, and δV is set to 0.1. As with the analysis of FeO, S_0^2 is set to 0.75, while E_0 is adjusted in the fit. Two oxygen distances $R_{\mathrm{Fe-O_1}}$, and $R_{\mathrm{Fe-O_2}}$ are adjusted in the fit, along with $N_{\mathrm{Fe-O_1}}$. To cut down on the number of free parameters, $N_{\mathrm{Fe-O_2}}$ is constrained to equal to $N_{\mathrm{Fe-O_1}}$, and a single σ^2 is used for the Fe-O near-neighbors. To account for the overlap from the Fe second shell, a crude model of this shell is made with one N, R, and σ^2 varied in the fit.

The results of this restrained fit are shown in Fig. 2 and Table II. The coordination numbers for the first shell come out remarkably

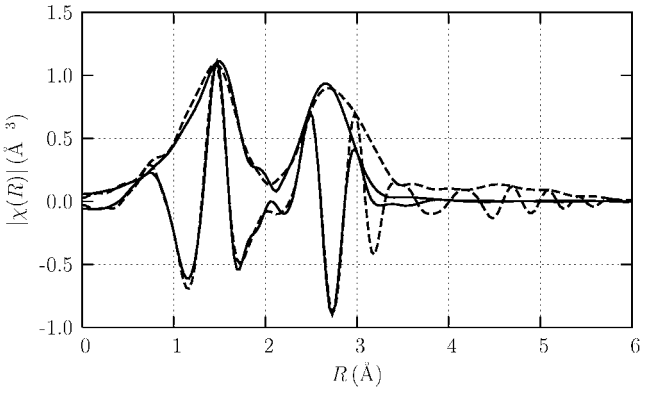

Fig. 2. Fit to Fe_2O_3 using Bond Valence sums as a restraint for the split first Fe-O shell. Results for this fit are shown in Table I. Shown are both $|\chi(R)|$ and Re$[\chi(R)]$ for data (dashed) and best-fit (solid).

Table II. *Fit results for Fe_2O_3, restraining R, N, and V for the first Fe-O distances. Data were fitted in R-space, between R = [1.1, 2.9]Å, with Fourier transform done with k = [3.0, 13.5]Å^{-1}, a Hanning window with dk = 2.0 Å^{-1}, and k-weight = 2. Best-fit values and estimated uncertainties are given for fitted parameters.*

Parameter	Value	Parameter	Value
E_0	0.7 (2.0)	S_0^2	0.75 (fixed)
$N_{\mathrm{Fe-O_1}}$	3.0 (0.4)	$N_{\mathrm{Fe-O_2}}$	3.0 (0.4)
$R_{\mathrm{Fe-O_1}}$	1.94 (0.03)	$R_{\mathrm{Fe-O_2}}$	2.07 (0.08)
$R_{\mathrm{Fe-Fe}}$	3.03 (0.05)	$N_{\mathrm{Fe-Fe}}$	6.1 (3.0)
$\sigma^2_{\mathrm{Fe-O}}$	0.005 (0.002)	$\sigma^2_{\mathrm{Fe-Fe}}$	0.015 (0.007)
V	3.17 (derived)		
$\mathcal{R}$	0.017	χ^2	223.4

well, though the uncertainties in these and all other parameters are high because the number of fitted parameters for the first shell (6) is close to amount of information available in this shell [22]. The shorter Fe-O distance is very close to its expected value, while the longer Fe-O distance of ≈2.07 Å is a bit shorter than expected and consequently the calculated valence of 3.17 is a bit higher than expected. Still, the resulting valence for Fe is within the acceptable uncertainty for Bond Valence sums, and the imposed uncertainty of $\delta V = 0.1$ for the restraint. Since this fit is near the limit of information available, the use of even this weak restraint on the Bond Valence sum improves the confidence in the validity of the results.

6. Conclusions

As has been shown by several workers, Bond Valence sums can be used to assess the validity of XAFS results. Here, Bond Valence sums have also been shown to be a viable way to constrain *R* and *N* for simple systems for which the formal valence *V* is known. More generally, Bond Valence sums provide *prior knowledge* that can be imposed to restrain the analysis of XAFS data for a wide range of systems.

Abstract

The complicated as to their composition and crystal structure semiconductors $TlAsS_2$, Tl_3AsS_3, Tl_3AsS_4, called briefly TAS, and Tl_3PS_4 represent a class of compounds promising in the devices of quantum electronics. The electron energy structure of these compounds is investigated both experimentally with X-ray spectroscopy and theoretically by calculations of the local partial electron densities of states (LDOS) and X-ray K-absorption spectra of S and P using FEFF8 code. All theoretical K-absorption spectra and LDOS were calculated *ab initio* without any adjusting parameters according to the scheme: the self-consistent mt-potentials obtained for the clusters of about 35 atoms were then used in the calculations of the absorption spectra and LDOS for clusters of 87 atoms in the full multiple scattering approximation. The comparison of the calculated K-absorption spectra of S and P of sulfides investigated with their experimental analogues shows that in all cases the theoretical curve reflects good enough the energy positions of all features of the experimental curve. The results of the calculations of LDOS and the experimental emission K- and $L_{2,3}$-spectra of S and P gave the possibility to determine the energy positions of the electron occupied states of all elements in the semiconductors TAS and Tl_3PS_4 and to get the information about the hybridization of the electron states in the valence band. The compounds Tl_3AsS_3 and Tl_3AsS_4 have the same crystal structure, this leads to the likeness of their K-absorption spectrum of S and the electron energy structure of their valence bands.

1. Introduction

The complicated TAS semiconductors: $TlAsS_2$, Tl_3AsS_3, Tl_3AsSe_3, Tl_3AsS_4 and Tl_3PS_4 are widely applied in quantum electronics due to their particular physical properties [1–3]. The crystal structure of lorandite $TlAsS_2$ belongs to monoclinic system, its space group $P2_1/c - C_{2h}^5$, the parameters of the crystal lattice: $\mathbf{a} = 6.101$ Å, $\mathbf{b} = 11.30$ Å, $\mathbf{c} = 12.28$ Å, $\boldsymbol{\beta} = 104°5'$. The number of formula units in the elementary cell is equal to 4 [1]. The first atomic shell of sulfur atom in the bridge contains two atoms of As and two atoms of Ga where as every side atoms of S is surrounded by tetrahedron of one As atom and three atoms of Tl. These tetrahedra are slightly distorted. The atoms of Tl are in the centres of distorted tetrahedra of S atoms. With the inter-atomic distances Tl–S in the range 2.96–3.93 Å.

The compound Tl_3AsS_3 belongs to the space group R3m with the lattice parameters: $\mathbf{a} = 9.667$ Å, $\mathbf{c} = 7.061$ Å [1]. Its hexagonal elementary cell contains 3 formula units. This structure is formed by trigonal pyramids $[AsS_3]$ flattened a bit along axe Z. The compound Tl_3AsSe_3 isoelectronic to Tl_3AsS_3 has the lattice parameters: $\mathbf{a} = 9.870$ Å and $\mathbf{c} = 7.094$ Å. In the elementary cell of Tl_3AsS_3 and Tl_3AsSe_3 there are 21 atoms. The compounds Tl_3AsS_4 and Tl_3PS_4 crystallize into structural type K_3PS_4 [1] with the space group Pnma $- D_{2h}^{16}$. The number atoms in the elementary sell is 32. The lattice parameters (in Å) of these compounds are: $\mathbf{a} = 8.70$, $\mathbf{b} = 10.72$, $\mathbf{c} = 9.00$ for Tl_3PS_4 and $\mathbf{a} = 8.86$ (8.877), $\mathbf{b} = 10.85$ (10.877), $\mathbf{c} = 9.18$ (9.084) for Tl_3AsS_4. It is difficult to apply the traditional solid state methods (OPW, APW, KKR and of the kind) to these compounds with such a complicated structure. The code FEFF8 based on the multiple scattering theory has the advantage in this case. This method described in detail [4] was used for these compounds. In this method the crystal self-consistent mt-potentials were calculated in the approximation of full multiple scattering for clusters with about 35 atoms. Using these potentials LDOS and X-ray K-absorption spectra of sulfur and phosphorus were calculated for clusters of 87 atoms in the full multiple scattering approximation. In addition the significant paths of single scattering for the clusters of 1000 atoms were taken into account.

2. Experiment

The X-ray fluorescence bands of P and S and their K-absorption spectra were studied with the vacuum X-ray spectrograph DRS-2 with Johann's scheme of X-ray focusing and the resolution 0.2 eV. As the dispersive element the quartz crystal cut along the planes $(10\bar{1}0)$ curved to the radius 50 cm was used. The reference lines were Bi$M\alpha_1$- and Bi$M\beta$-lines with the energies 2422.5 and 2525.6 eV correspondingly [5]. Every spectrum is the average of 3 photo-films measured along 5 paths. The intensities were determined at 250 equidistant points.

The primary $L_{2,3}$-emission bands of S and P were obtained with X-ray spectrometer RSM-500 with concave spherical grating (radius of curvature = 2 m) with 600 scratches per mm. The spherical mirrors suppressed the short-wave-lengths part of the spectrum up to 52 Å, when $L_{2,3}$-emission band of S was studied, and up to 82 Å for $L_{2,3}$-emission band of P. In the first case the radius of the mirror was 1369 mm and for the second case −700 mm.

The spectra of S and P were superimposed to the common energy scale by the Kα_1-lines of P and S. X-ray spectra were corrected (deconvoluted) to take into account the inner level width and the width of the spectrometer window to determine accurately the energy position of the valence band top E_v which was chosen as energy zero. In Fig. 1–4 nevertheless uncorrected forms of X-ray spectra are presented to exclude any connections between the features of the experimental curves with deconvolution procedure.

3. Results and discussion

The calculated LDOS and X-ray K-absorption spectra of P and S for Tl_3PS_4 are compared in Fig. 1 with experimental X-ray emission and absorption spectra. The analysis of these data shows that the upper part of the valence band is formed of p-states of S and p-states of P are shifted to the higher binding energies by about 3.5 eV. The lower part of the valence band consists of s-states of S and P. There is a correspondence between positions of LDOS maxima from one side and peaks and other features of experimental emission bands. The good accordance between theory and experiment one can see also for K-absorption edges of P and S. The calculations gave us possibility to know the charge transfer: the found charges of ions are: +0.180 for

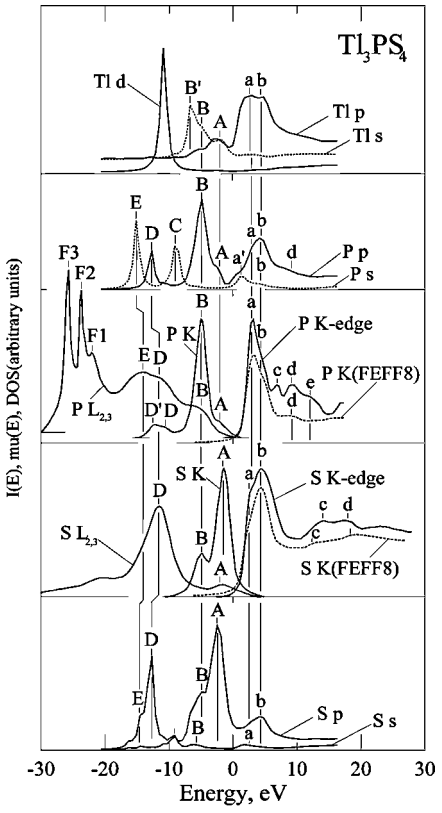

Fig. 1. The calculated local partial densities of electron states of Tl_3PS_4, depicted in the common relative energy scale with the X-ray emission and absorption spectra of sulfur and phosphorus. Energy zero is chosen at the top of the valence band.

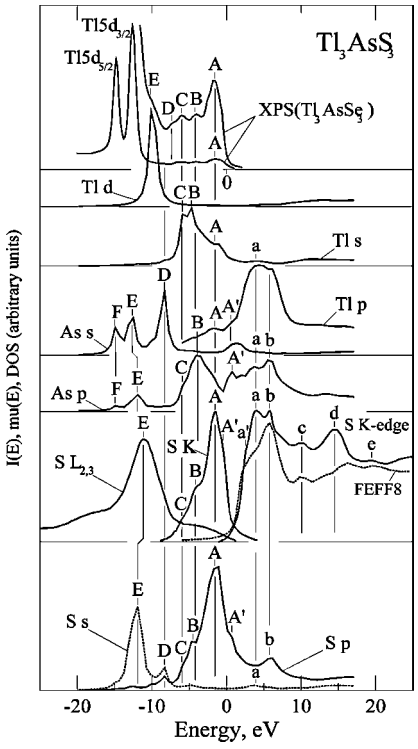

Fig. 3. The calculated densities of electron states for Tl_3AsS_3, shown in the common relative energy scale with the experimental X-ray emission and absorption spectra and the XPS-spectrum of Tl_3AsSe_3 [8]. The energy zero was chosen at the top of the valence band.

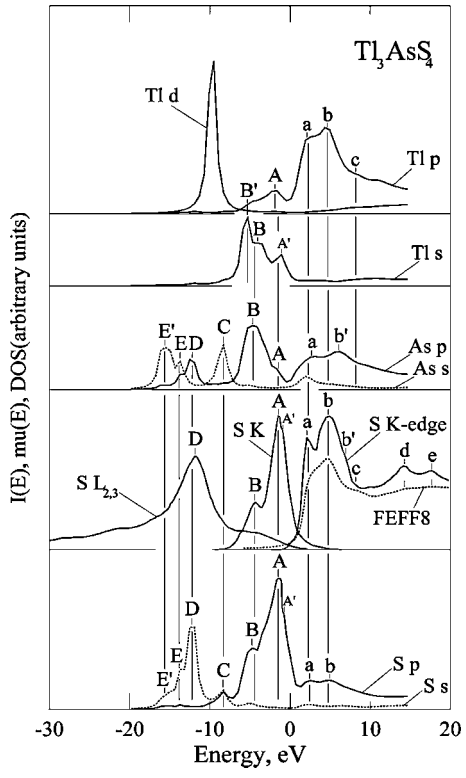

Fig. 2. The calculated local partial densities of electron states in Tl_3AsS_4, shown in the common relative energy scale with the X-ray emission and absorption spectra of sulfur. Energy zero corresponds to the top of the valence band.

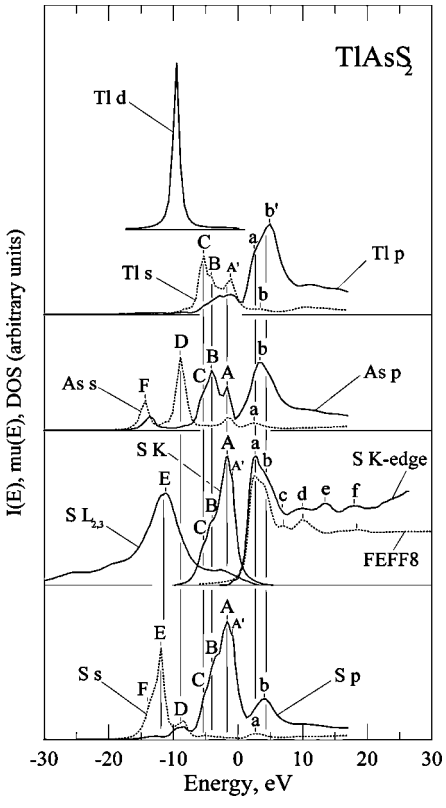

Fig. 4. The calculated local partial densities of electron states in $TlAsS_2$, presented in the common relative energy scale with the X-ray emission and absorption spectra of sulfur. Zero of the energy scale corresponding to the top of the valence band.

Tl, +0.393 for P, and −0.233 for S. It is quite understandable account electronegativity of these elements [6]. The energy correspondence of some maxima of K-emission bands and LDOS for p-states of S and P tells us about the existence of covalent bond between them, but with the ionic contribution to the chemical bonding.

The form of LDOS and of the X-ray spectra of isoelectronic compounds, which belong to the same crystallographic type, are

alike. The comparison of the X-ray K- and L-emission spectra of S in Tl_3PS_4 (Fig. 1) and Tl_3AsS_4 (Fig. 2), which do not contain the noble metals, confirms this rule [7]. The change of crystallographic structure in the row Tl_3AsS_4 - Tl_3AsS_3 - $TlAsS_2$ leads to the transformation of the X-ray spectra form (Fig. 2–4). The significant change of K-emission spectrum of sulfur occurs because of various surroundings of S atom in these compounds. These distinctions of SK-bands in TAS compounds are due to the difference of chemical interactions of atoms As-S and Tl-S in these compounds. The main structural elements of these TAS compounds are [1] the pyramids [AsS_3] and [TlS_3]. We suppose that three p-electrons of As form the strong covalent bonds with the nearest three S atoms due to the overlapping of their p-orbital. In trigonal pyramids [TlS_3] of the compounds $TlAsS_2$ and Tl_3AsS_3 [1] the chemical bond Tl–S arises, apparently, because of the overlapping p-orbital of S with the hybridized sp-orbitals of Tl. The chemical bond Tl–S has the significant ionic contribution because the inter-atomic distance Tl–S is greater than the sum of the tetrahedral covalent radii of Tl and S.

The crystallographic structure of Tl_3AsS_4 differs from ones of $TlAsS_2$ and Tl_3AsS_3 by existence coordination tetrahedra [AsS_4] and [TlS_4] instead of trigonal pyramids of $TlAsS_2$ and Tl_3AsS_3 [1]. Probably one p-electron of As transits from As to S providing the additional bond Tl-S so that every atom of Tl form 4 hybridized bonds with the 4 S atoms in the distorted tetrahedron [TlS_3]. Such an approach gives us the possibility to explain the hump **C** on the SK-emission band as due to the admixture of p-states of S to sp-states of Tl. Because of greater ionicity of the chemical bond Tl-S in Tl_3AsS_4 the hump **C** has greater binding energy (about 6.5 eV from E_v) comparing to $TlAsS_2$ and Tl_3AsS_3 where this binding energy is equal to 6.0 eV from E_v. The remaining four valence electrons of As form in Tl_3AsS_4 four sp^3 hybridized orbitals directed to S atoms. The formation of such sp^3-hybridization was discussed in [8]. The binding energy of sp^3-states of As corresponds to the feature **B** of SK-emission band in Tl_3AsS_4 (4.0 eV from E_v). The chemical bond As-S in Tl_3AsS_4 has covalent-ionic character of the same type as P-S bond in Tl_3PS_4.

From the analysis of Fig. 3, where the X-ray SK-emission band in Tl_3AsS_3, the XPS-spectrum of the isoelectronic and isostructural Tl_3AsSe_3 and calculated LDOS are shown, it follows that in the upper part of the valence band of this compound there are p-states of S mainly. The hump **B** of the SK-emission band corresponds by energy to the p-states of As and s- and p-states of Tl.

At the bottom of the valence band of all compounds investigated s-states of S are localized (Fig. 1–4). These states nearly do not take part in the chemical bonding. Only small, nearly negligible admixture of s-states of S to the valence states in the upper part of the valence band one can notice for all compounds in question.

Summarizing the results of comparison of calculated LDOS with experimental data we can affirm the correspondence of energy positions of all features of the theoretical and experimental curves. It includes the experimental and calculated using the FEFF8 code K-absorption spectra of S and P. To obtain the adequate theoretical K-absorption edges the self-consistent mt-potentials were calculated for the clusters of 35 atoms, then after the full multiple scattering calculations the contributions of single scattering paths in the clusters of about 1000 atoms were taking into account. Unfortunately the compounds investigated in the present work have rather low symmetry. That is why we had to take into account the great number of scattering centres to reproduce the main features of K-absorption spectra of sulfur and phosphorus. Here the approximation of full multiple scattering was necessary.

In the calculated LDOS there is the noticeable density of electron states in the energy gap region. That is connected firstly with the cluster method of the calculations and secondly with the smearing of LDOS curves due to the inner level width and the spectrometer window, we carried out to simplify the comparison of the theoretical curves with the experimental ones.

Abstract

Sodium K edge XANES calculations were performed for sodium halides, using the last version of the *ab-initio* FEFF code, and compared with the experimental data. Several FEFF parameters were varied during calculations, aiming to investigate their influence on the theoretical results. The origin of the differences between the experimental data of the series are analyzed and discussed, supported by the theoretical calculation.

1. Introduction

Up to now, several different analysis of the XANES structure in alkali-halides have been performed by mean of multiple-scattering analysis [1–12]. The study of these highly symmetric materials is important to improve the degree of comprehension of the XANES spectra, as well as to test the reliability of the theoretical codes available today, for which one of the crucial problems is the construction of the muffin-tin (MT) potential of a system.

In this work, we analyze the Na K-edge XANES spectra of four sodium halides with the 'rock salt' structure, by means of full-multiple scattering (FMS) calculations, aiming to identify the physical origin of their differences.

2. Experimental

The experimental XANES spectra were recorded at the sodium K-edge (1070.8 eV) using the SA32 beam-line of the Super-ACO ring at LURE, Orsay, France. The experiments were performed from 1060 to 1135 eV, using a 0.2 eV step and total electron yield (TEY) detection mode. The beam was monochromatized by a double-crystal monochromator, equipped with two Beryl (10 $\bar{1}$ 0) single crystals, and calibrated on a NaCl sample (1075.6 eV at the inflexion point) before each data collection.

3. Results

3.1. *Experimental*

Figure 1 shows the experimental XANES spectra of NaX (X = F, Cl, Br and I), in agreement with previously published data [6, 11]. A progressive shift of the experimental Na-K threshold position is observed: the absorption edge energy of NaI is found 0.7 eV lower than that of NaF.

For the sake of clarity, the different features present in all the spectra are identified by a letter (A-E). Their energy position are shifted to higher values as we go to lighter anions and shorter interatomic distances. As well the relative amplitudes of the oscillations vary with the backscattering halide atom. But beyond these differences the XANES spectra of NaI, NaBr and NaCl are very similar while the NaF one is peculiar (weakness of feature A, strong amplitude of peak B, intensity inversion of E oscillations).

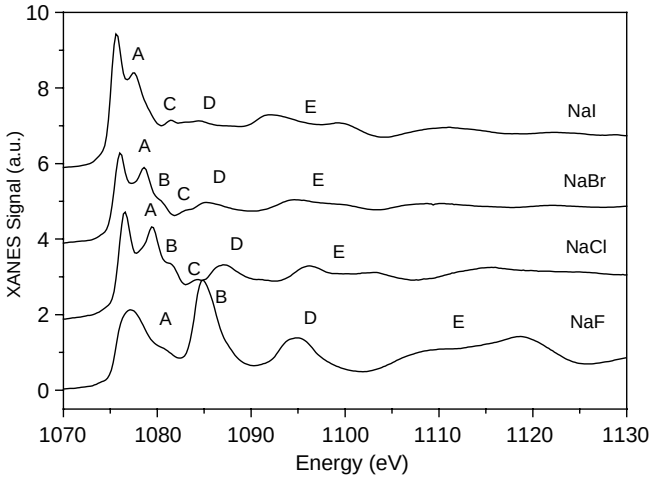

Fig. 1. Experimental data.

3.2. *Calculation*

The crystallographic 'NaCl' structure is face-centered cubic. The lattice parameters are 6.47 Å for NaI, 5.97 Å for NaBr, 5.64 Å for NaCl and 4.62 Å for NaF.

The *ab-initio* FEFF8 code [13–15] was used in this work to generate multiple-scattering simulations, and several calculation parameters of the code were varied, aiming to analyze their influence on the theoretical spectra. However, only the FMS and SCF (self-consistent field) atomic potential calculation routines are crucial to obtain a good XANES simulation, and the other instructions have only a minor importance for the final results.

After some tests, and in agreement with other works [16], the Hedin-Lundqvist exchange potential was chosen, and used in all calculations presented here.

For the calculation of the SCF muffin-tin atomic potential a 33 atoms cluster (4 shells) gives reasonable results, which can be slightly improved by increasing the size of the cluster. But the code is unable to reproduce the experimental 0.7 eV shift of the Na K-edge energy along the series.

The quality of the results very near the threshold (white-line intensity and relative energy position of the edge) was improved by using a trick as it can be seen in figure 2: the best simulation of the XANES is obtained doing the "$Z + 1$ approximation", by using Mg as the central atom in place of Na. The theoretical data for NaCl, NaBr and NaI in figure 3 were generated using this $Z + 1$ approach. This approach is no more correct for calculating

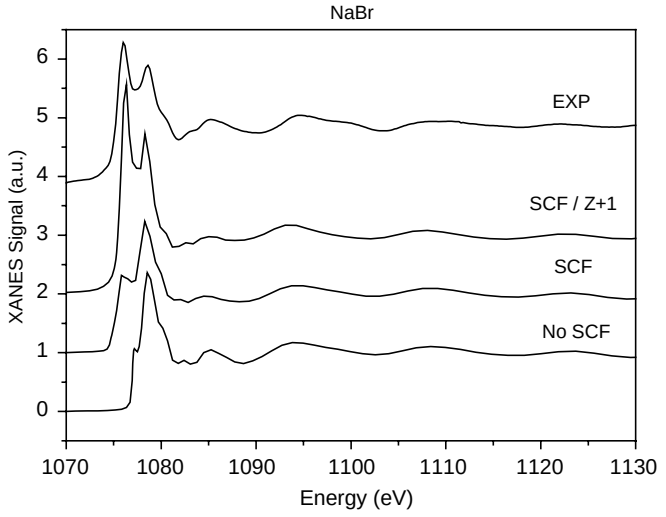

Fig. 2. FMS calculation of the XANES spectra for a NaBr cluster having 250 atoms.

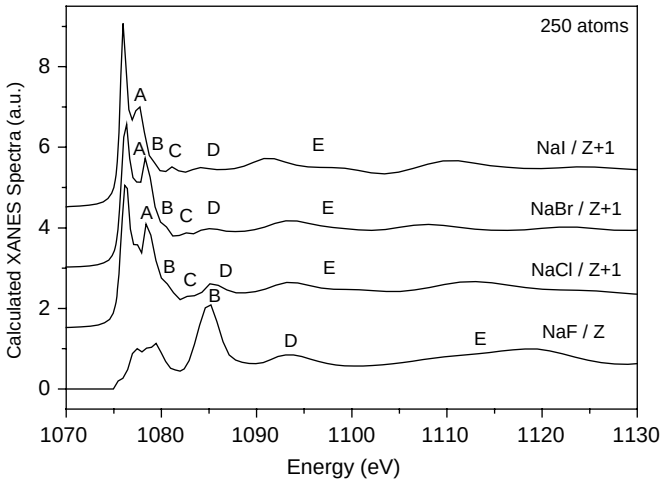

Fig. 3. Theoretical XANES spectra for the series. For sake of clarity the spectra have been shifted to their experimental positions.

the NaF spectrum, as it generates a too sharp and intense white line when compared to the experimental spectrum.

In figure 3 the NaF and NaCl spectra were shifted to their correct experimental positions in order to make easy the comparison with experimental data (figure 1). However, the spectra of NaBr and NaI were shifted of the same quantity used for NaCl, in order to keep the calculated edge's shift and show the good agreement with experience.

The FMS algorithms [14] implemented in FEFF8 code were tested for all materials analyzed here. During our tests, the different algorithms generated equivalent results for each calculation, however some were faster: the Lower-Upper decomposition (default option) was the slowest algorithm, and the Van der Vorst algorithm the fastest one (more or less three times faster than the default option for all simulations).

The main oscillatory structure of the XANES spectra is reproduced with a five-shells cluster (57 atoms). However, for NaI, the energy range around 1080–1085 eV is better reproduced when considering an eight-shells (123 atoms) cluster, while for NaF, the simulation of the threshold region is improved for clusters with more than 200 atoms. Figure 4 shows the evolution of the theoretical XANES spectra as a function of the FMS cluster's size for NaF.

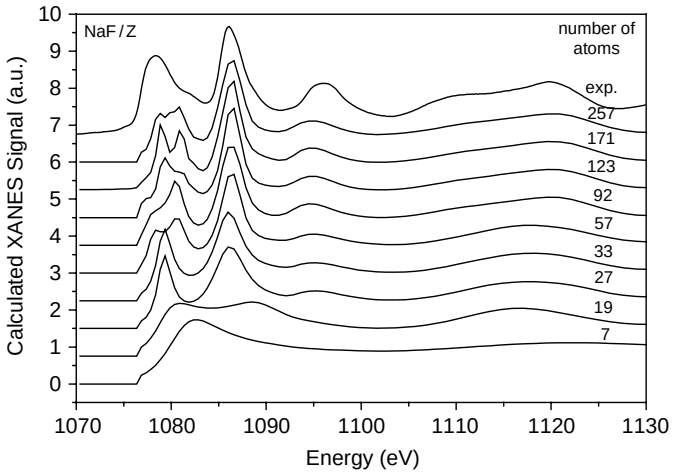

Fig. 4. Theoretical XANES spectra for different sizes of clusters.

Finally all the calculations presented here were done with an lmax = 3 for the limit of the angular momentum bases for both the self-consistent potential and the full multiple scattering calculations. This is necessary to better reproduce the oscillations above the feature E.

4. Discussion

In a first approximation, the evolution of the experimental data, (energy shifts of the maxima A, B and C) can be explained by the change of the lattice parameter (see figure 5), according to the $1/R^2$ Natoli's rule [17], therefore their origin is structural.

While a good simulation of the data was already obtained with the FEFF5 code [12], taking into account the contributions up to seventh-order MS and a very large cluster (18-shell), we show here that to reproduce all the structures including the one very near the edge, a full-multiple scattering calculation is necessary.

The calculated XANES spectra are in good agreement with the experimental ones, and the experimental differences among these last ones are fully reproduced by theory (see figures 1 and 3). However, theoretical data seem broadened, in comparison with the experimental ones, while the multiple scattering (MS) approximation based on the path expansion formalism gives always the correct amplitudes for the oscillations.

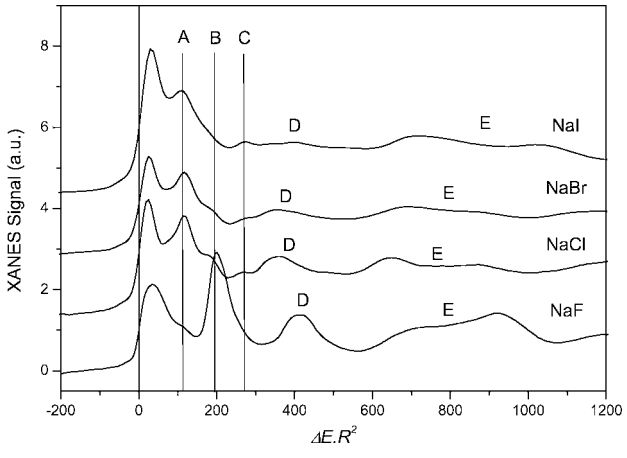

Fig. 5. Verification of the Natoli's rule for features A, B and C.

Furthermore, without considering the $Z + 1$ (Mg) absorber atom approximation, FEFF8 is unable to reproduce the experimental shift of the edge for the series, neither the relative intensity of the white-lines for NaCl, NaBr and NaI.

Another parameter, always discussed in papers dealing with simulation is the size of the cluster necessary to reproduce correctly all the features of the spectra. In the case of sodium halides, FEFF8.2 gives a satisfactory general result for a cluster of 5 shells (57 atoms), but the structure C only appears in the calculation for a cluster of 123 atoms for NaI and 251 atoms for NaCl and NaBr.

However, in a previous work [16], a cluster of only 133 atoms was necessary to reproduce feature C in the calculated NaCl spectrum. Consequently, it seems that the excessive broadness of the XANES spectra generated by FEFF, using the chosen calculation parameters, is responsible for the absence of the C feature in NaBr and NaCl for a cluster of 133 atoms.

The scattering properties of the surrounding atoms affects the structure of XANES in alkali halides, but this effect is predominant when the Na-X bond changes from ionic to a more covalent character, as it is the case for NaF, while NaCl, NaBr and NaI are purely ionic compounds [18]. This is striking, because F is more electronegative than the other halides (therefore, the common sense tell us that NaF should be more ionic than others sodium halides), however one has to point out that this covalent character of NaF is related to the very small size and/or larger chemical hardness of F atom, which places this compound apart of the series.

5. Conclusion

This work shows the importance of the FMS routine to simulate the XANES spectra of alkali-halides.

In a general way, the quality of the XANES spectra generated by FEFF is good, reproducing almost all the features of the experimental data, as well as some subtle behaviors of the series. However, these goals were obtained when considering the $Z + 1$ (Mg) absorber atom, which still remain physically understood. Moreover, theoretical data seem too much broadened, hiding small features in the theoretical spectra.

Acknowledgments

The authors are grateful to M. Henry, G. Hug, M. Jaouen and V. Briois for fruitful discussions and suggestions. Thanks are also due to CAPES (Brazilian financing agency), for the post-doc support of R. J. Prado, and for the SuperACO machine staff for providing beam.

Abstract

The structural parameters of Ti coordination environment in glassy titanite ($CaTiSiO_5$), natisite (Na_2TiSiO_5) and radiation damaged $CaTiSiO_5$ are determined by the method proposed earlier, based on the Fourier-transform analysis of Ti K-XANES over the short k-range of photoelectrons wave numbers. The accuracy of the determined parameters is tested for the model crystals $CaTiSiO_5$, Na_2TiSiO_5. The modelling of the extracted contribution into Ti-XANES, arising from the oxygen-polyhedron around the ionised Ti atom in amorphous titanites and natisite, performed via the single-shell fit and the two-shells fit, returns not only the averaged structural parameters, but also reveals the main groups of the Ti-O distances for this polyhedron.

1. Introduction

The Ti atoms in amorphous oxide-type compounds are often coordinated by the oxygen-polyhedron (considered as the first shell with N_1 atoms), which is characterized by a more or less complex radial distribution of Ti-O distances (R_1). Such coordination environment can be modelled into a number of sub-shells, so containing $N_{1,j}$ atoms ($N_1 = \Sigma_j N_{1,j}$, j is the sub-shell's number), located at $R_{1,j}$ – distance. For example, the available structural information for crystalline titanites [1] suggests that the Ti-O distances of the oxygen-octahedron around Ti are distributed by $\sim$0.2 Å under the diffused second and more distant shells and this local disorder increases in amorphous materials [2, 3]. In this case, the X-ray absorption spectroscopy (XAS) provides important structural information of Ti local environment [4–6]. However, the application of XAS to a wide number of these objects, which are either glassy or radiation-damaged ("metamict"), is often limited by the analysis of near edge structure (XANES), since XANES is much faster to collect than the EXAFS, often unobserved for these compounds. In addition, the XANES is richer in structural information (pre-edge and edge-crest features). At the same time, the most current approaches of the XANES analysis are based on indirect and qualitative information on the studied structure estimated by comparing "unknowns" with models. As a consequence, more quantitative tools are needed to analyse the high-resolution XANES spectra available nowadays.

In this paper, we use the method proposed in [3, 7] to determine the Ti-O distances and coordination numbers for Ti in amorphous (glassy and radiation-damaged) $CaTiSiO_5$ (titanite) and in glassy Na_2TiSiO_5 (natisite). This method, originally developed for crystalline minerals and glasses with low-Z atoms (Z < 20), is based on the Fourier-transform (FT) analysis of XANES within the short range of the photoelectron's wave numbers (k), followed by a model of the contribution related to the first neighbours.

2. The accuracy of structural parameters determined for model compounds via the FT of Ti K-XANES

The XANES calculations for the model crystalline titanite $CaTiSiO_5$ performed by the Full Multiple-Scattering (MS) approach using the FEFF8.2 package [8] and by the Low-angle scattering approach [9, 10], reveal the significant effect of the medium range order-MRO (the single-scattering from the second and more distant shells) and MS-terms on the main edge crest features of Fig. 12 in [2]. At the same time, the dominant role of the first shell's term in the Ti K-XANES formation at the higher energies ($E > 5010$ eV) was revealed. This result permits to conclude that the effect of the MRO-term in the studied crystalline compounds (which can decrease the accuracy of the determined R_1, N_1 in contrast to the MS-term [3, 7]) can be minimized by the choosing adequately the corresponding k-interval for the FT ($k = 0.2625 * (E - E_{MT})^{1/2}$, where E_{MT} is the interstitial potential for the compound studied). This conclusion is justified also by the values of structural parameters, which are obtained for the model crystals $CaTiSiO_5$, Na_2TiSiO_5 in agreement with the diffraction data, using the FT of the Ti-XANES. Moreover, the comparison of XANES formation in the model crystal and in its glass-equivalents [3] reveals that even when the MRO-term is not negligible for the crystal, the affect of the MRO-term on the first shell's peak in FT is necessarily negligible for the glasses, due to the diffusion of atoms for the second and more distant shells. Therefore, for crystalline and amorphous $CaTiSiO_5$ and Na_2TiSiO_5 the FT was applied to the $\chi(k)$ over the k-range: 3.9–5.8 Å^{-1}. This range excludes the main edge crest features (at $k < 3.9$ Å^{-1}) and the small value of k_{max} makes it even more pertinent for disordered compounds. The $\chi(k)$ was extracted from the experimental Ti K-XANES by the equation:

$$\chi(k) = \sigma^{exper}(k)/\sigma_{at}(k) - 1 \quad (1)$$

and the factorised "atomic" part of the absorption cross-section $\sigma_{at}(\varepsilon)$, obtained from the experimental Ti-XANES by the procedure proposed in [3]. The FT of the extracted $\chi(k)$ and the R-space fit (0.3–2.5 Å) of the first oxygen shell's peak were performed by FEFFIT [11]. The photoelectron phase shifts and scattering amplitudes were calculated using Hartree-Fock (HF) MT-potential model [12], which provides the values of E_{MT} for the compounds studied. The photoelectron extrinsic losses, core hole width and experimental energy resolution were accounted by $\exp(-0.2625(\Gamma_{exper} + \Gamma_h + \Gamma_{el})2R/k)$, where Γ_{exper} is the energy parameter (eV) for the experimental resolution, Γ_h and Γ_{el} are the energy widths of the core hole and the excited electron states respectively. This exponential can also be rewritten as $\exp(-2R/\lambda_{eff})$ with the effective mean free path length λ_{eff} for

*e-mail: bugaev@rsu.ru

Table I. *Structural parameters used to calculate χ for crystalline titanite and their values returned via FT of χ over the k-range 3.9–5.8 Å^{-1} and fit.*

		N_1(oxygen's number around Ti)		R_1(Ti-O distance), Å	
χ	Fit	used for χ calculation	FT, fit	used for χ calculation	FT, fit
$\chi_{1.1}$	Single-shell	2	1.99	1.89	1.892
$\chi_{1.2}$	Single-shell	4	3.99	2.02	2.016
$\chi_1 =$	Single-shell	6	6.00	1.98	1.985
$\chi_{1,1} + \chi_{1,2}$	Two-shell	$N_{1.1} = 2$	not	$R_{1,1} = 1.89$	1.893
		$N_{1.2} = 4$	varied	$R_{1,2} = 2.02$	2.022

the photoelectron: $1/\lambda_{\text{eff}} = 0.2625(\Gamma_{\text{exper}} + \Gamma_{\text{h}})/k + 1/\lambda_{\text{el}}$. The Γ_{h} and the electron mean free path length $\lambda_{\text{el}}(k) = k/(0.2625\Gamma_{\text{el}})$ for Ti-compounds were taken from [13].

The analysis of the accuracy of R_1 and N_1 values, determined via FT of XANES over the short k-interval ~2.5 Å^{-1} performed in [3], revealed that the R_1 and N_1 are determined with inaccuracy to ≤1% and ≤3–5% respectively. However, in the studied compounds the oxygen-polyhedron around Ti is often characterised by a number of Ti-O distances and hence, can be considered as a number of corresponding sub-shells. Therefore, to confirm the accuracy of R_1 and N_1 determination in the studied compounds, the FT was preliminary applied over the k-range 3.9–5.8 Å^{-1} to: *i*) the two theoretical χ-functions $\chi_{1,1}$ and $\chi_{1,2}$, which model the split of the O_6-octahedron around Ti in the reference crystal $CaTiSiO_5$ [1] ($\chi_{1,1}$-contribution of 2 oxygens at $R_{\text{Ti-O}} =$ 1.89 Å; $\chi_{1,2}$ – contribution of 4 oxygens at $R_{\text{Ti-O}} = 2.02$ Å) and to *ii*) the available references – $CaTiSiO_5$, Na_2TiSiO_5 crystals. The values of structural parameters for $CaTiSiO_5$-crystal, used for the calculated χ, are compared in Table I with their values returnedvia the FT of theoretical χ over the k-range 3.9–5.8 Å^{-1}. As can be seen, the structural parameters returned by i) the single-shell fit with three variables N_1, R_1, σ^2 or ii) the two-shell fit for the model with fixed $N_{1,1}$, $N_{1,2}$ and three variables $R_{1,1}$, $R_{1,2}$ (Ti-O distances for $\chi_{1,1}$, $\chi_{1,2}$ respectively) and σ^2, are in agreement with the values of corresponding parameters used for the direct calculations of these χ-functions.

For the crystalline titanite, the magnitude $|F(R)|$ for the FT of $\chi(k)$, extracted from the experimental Ti-XANES, is compared in Fig. 1a with the results of the single-shell model with the three variables N_1, R_1, σ^2. The obtained value of the DW-parameter σ^2 can be tested accurately by the known value of $N_1 = 6$ for the oxygen-octahedron around Ti. At the same time, the single-shell fit of the Ti-O contribution in the three amorphous titanites is performed first (next section) with the two variables N_1, R_1 using the value of σ^2 for crystalline $CaTiSiO_5$. The use of the same σ^2 for both the crystalline and the amorphous titanites can be validated if the values of structural parameters for the amorphous titanites (determined using two variables N_1, R_1, and the fixed σ^2) remain stable as compared to these with the three variables N_1, R_1, and σ^2.

The used scheme of HF MT-potential generation [12] applied to the crystalline titanite and natisite, provides a constant value of $E_{MT} = 4953$ eV and therefore the parameter E_{MT} – the beginning for the k-scale was not varied. The structural parameters for the first oxygen-shell around Ti in the model crystal $CaTiSiO_5$, determined via the single-shell fit: $N_1 = 6.1$, $R_1 = 1.99$ Å, $\sigma^2 = 0.005$ Å^2 are in agreement with the available structural information [1] (see Table II).

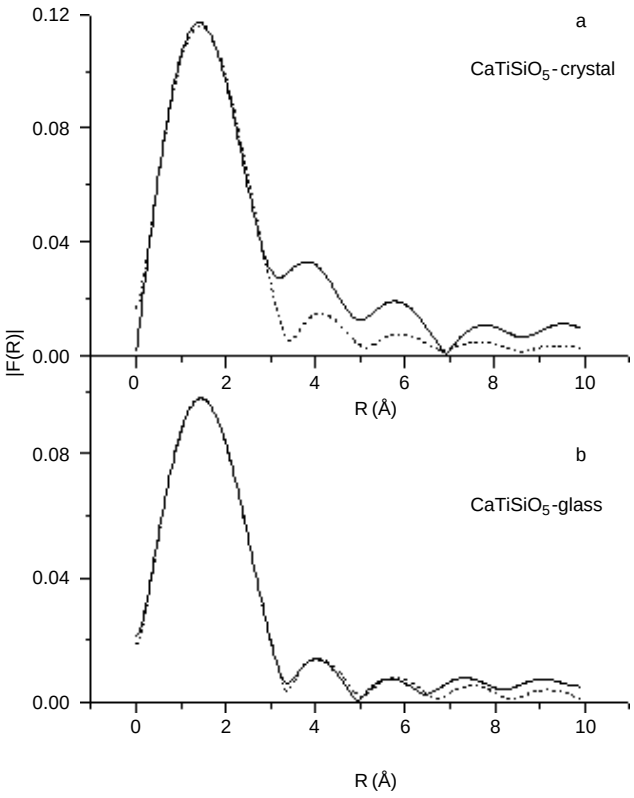

Fig. 1. $|F(R)|$ for crystalline (a) and glassy (b) $CaTiSiO_5$: solid curves – the FT of the $\chi(k)$ extracted from the Ti K-XANES and dashed curves – the results of the single-shell fit.

Table II. *Structural parameters for Ti coordination in various polymorphs of $CaTiSiO_5$ determined via the single-shell fit (the diffraction data for crystalline $CaTiSiO_5$ are in brackets).*

Samples	N_1	R_1 (Ti−O), Å
$CaTiSiO_5$ – crystalline	6.1 (6.0)	1.99 (1.98)
$CaTiSiO_5$ – glass	4.9	1.95
Egansville (metamict)	5.75	1.98
Ontario (metamict)	5.57	1.97

The number of varied parameters does not exceed the possible number of independent variables (3 or 4), found according to [11] for the chosen k-range. In this case, the effect on the determined R_1 and N_1 from the uncertainties in the used values of other parameters, traditionally varied for EXAFS and fixed in the performed XANES-analysis, can be estimated via the model simulations. According to them: *i*) the variations of Γ up to ±0.5 eV around the used value $\Gamma = 3$ eV does not destroy the above accuracy of R_1 and N_1 determination. However, the Γ variations by ±1.5 eV result in the increase of inaccuracy for N_1 up to ~10% under approximately unchanged accuracy for R_1; *ii*) the compulsory shifts of the obtained E_{MT} (or E_0) by ±2.5 eV shows the increase of errors in R_1 and N_1 determination up to 3–4% and 10% respectively. Besides, it is revealed that the HF scattering amplitudes calculated by $R_{\text{Ti-O}} = 1.9$ Å (averaged Ti-O distance for the studied titanites) provide the R_1 and N_1 determination with the above inaccuracies of ≤1% and ≤3–5% respectively for compounds with $R_{\text{Ti-O}} = 1.9 \pm 0.2$ Å. In conclusion, it must be noted that effect of the used data uncertainties and the

validity of the whole amount of the fixed parameters used within the XANES-analysis, is tested by the values of structural parameters determined for the reference crystals $CaTiSiO_5$, Na_2TiSiO_5 and is justified for the amorphous compounds of Sec.3 by the agreement of the obtained structural information with NMR-results.

3. Ti–coordination in glassy and radiation-damaged $CaTiSiO_5$ and in glassy Na_2 $TiSiO_5$

The method was applied to one glassy and two radiation-damaged titanites ($CaTiSiO_5$) and one glassy natisite (Na_2TiSiO_5) to reveal the structural changes in the environment of Ti related to two types of amorphization (temperature and radiation induced). The radiation-damaged titanites are named as "Egansville" and "Ontario". The single-shell fit of the Ti-O contribution for the above samples is performed first with a fixed value of σ^2 (taken as for the crystalline titanite) = 0.005 Å^2. The comparison of the experimental $\sigma(E)$ for the studied compounds of $CaTiSiO_5$ (figure 12 in [2]) shows the coincidence within ~1 eV in the energy position of their main near–edge peaks, suggesting the use of the same value of E_{MT} for all titanites. We use also the same values for $S_0{}^2 = 0.8$ and $\Lambda_{eff}(k)$ as for the model crystalline titanite. For the glassy titanite, the $|F(R)|$ for the FT of the $\chi(k)$, extracted from the experimental Ti K-XANES, is compared in Fig. 1b with the result of the single-shell fit. The obtained structural parameters for glassy $CaTiSiO_5$, Egansville and Ontario are presented in Table II, with the results for the model crystal $CaTiSiO_5$. Note that the fit with the three variables N_1, R_1, σ^2 gives approximately the same σ^2 value, as for the models with the two variables N_1, R_1. For the glass, $N_1 = 4.9 \pm 0.2$ [3], suggesting that the Ti–atom in glassy $CaTiSiO_5$ is coordinated by five oxygens, located at the average Ti−O distance of $R_1 = 1.95$ Å.

The single-shell models can be used as a basis for more thorough analysis of the first neighbours environment around Ti in titanites, performed via the fit, based on the two-shell model ($j = 1, 2$ is the shell's number): first shell corresponds to $\chi_{1,1}$-contribution of $N_{1,1}$ atoms located at $R_{1,1}$ and the second – to $\chi_{1,2}$-contribution of $N_{1,2}$ atoms at $R_{1,2}$. Its application permits to examine for the main groups of Ti−O pairs, while the number of variables is prevented to increase significantly. For amorphous samples the obtained $R_{1,1}$ and $R_{1,2}$ (which correspond to the best fit model with the fixed $N_{1,1}$ and $N_{1,2}$) reflect the asymmetry of the first shell's peak in the experimental $|F(R)|$, if the anharmonic effects for the studied compounds are much smaller than the static disorder. According to this approach, the oxygen–polyhedron with five atoms around Ti in glassy $CaTiSiO_5$ can be splitted into the two shells as: $1 + 4$ atoms (Model 1), $4 + 1$ (Model 2), $2 + 3$ (Model 3) or $3 + 2$ (Model 4). The results for the models 1,2 give the same distribution of distances: one Ti−O pair at $R_{1,1} = 1.85$ Å and four Ti−O pairs at $R_{1,2} = 1.97$ Å with $\sigma^2 = 0.0022$ Å^2. This σ^2 value is in agreement with its counterpart obtained for the model crystal (~0.0025 Å^2) via the two-shell fit. In parallel, the fit for the Models 3,4 return negative (non-physical) σ^2 values. Thus these models were treated as inadequate ones.

According to crystal structure information [14], the Ti-atom in crystalline natisite is coordinated by five oxygens: one at the short Ti-O distance $R_{1,1} = 1.695$ Å and the four others at $R_{1,2} = 1.99$ Å. The FT of the sum $\chi_{1,1} + \chi_{1,2}$ of the corresponding theoretical χ-functions and the fit of the corresponding Ti-O peak in $|F(R)|$ reveal that when the difference in $R_{1,1}$ and $R_{1,2}$ exceeds ~0.25 Å, then a single-shell fit doesn't provide the sufficient accuracy for the averaged values of structural parameters. However, in this case, the fit based on the two-shells model returns not only the accurate $R_{1,1}$ and $R_{1,2}$ values but permits to identify the actual split model ($1 + 4$) among other possibilities (e.g., $2 + 3$, $2 + 4$, $1 + 5$ etc.). The last result permits also to obtain the total N_1 value via the two-shell models for the oxygen-polyhedron around Ti in amorphous compounds, where this parameter can not be determined accurately via the single-shell fit. Thus, for the glassy natisite, the best fit is obtained for the model $N_{1,1} = 1$, $N_{1,2} = 4$ with the values of variables: $R_{1,1} = 1.70$ Å, $R_{1,2} = 1.94$ Å, $\sigma^2 = 0.0025$ Å^2.

4. Summary and conclusions

The obtained results can be summarized as follows:

(*i*) the sufficient accuracy for the Ti-O distances and the number of nearest oxygens for Ti-environment in the model crystalline titanite and natisite is obtained applying the FT to χ over the k-range: 3.9–5.8 Å^{-1}. This range corresponds to the Ti-XANES energies region >5010 eV (after the first main edge crest features) and is formed dominantly by the scattering contribution of the oxygen-polyhedron around the absorbing Ti-atom. The validity and the accuracy of this FT-procedure increase for amorphous compounds;

(*ii*) the R_1, N_1 for Ti-coordination environment in glassy titanite and in two modifications of radiation-damaged $CaTiSiO_5$ are determined via the single-shell fit of the oxygen-polyhedron's contribution into $|F(R)|$ using the two variables R_1, N_1 and the σ^2 value obtained for the model crystal $CaTiSiO_5$. The stability of the obtained R_1, N_1 values, as well as the used σ^2 value, is confirmed via the fit with the three variables R_1, N_1, σ^2. The values of R_1 and N_1 for radiation-damaged $CaTiSiO_5$ appear to be intermediate between the corresponding values for crystalline $CaTiSiO_5$ and its amorphous equivalent – titanite glass;

(*iii*) if the difference in Ti-O distances for the oxygen-polyhedron around Ti exceeds ~0.25 Å (the presence of the short titanyl-bonds), then the single-shell fit of such polyhedron's contribution into $|F(R)|$ does not provide the sufficient accuracy for the determined averaged values of R_1, N_1. In this case, the application of the two-shell fit with three variables $R_{1,1}$, $R_{1,2}$, σ^2 performed for the alternative models of the split of the oxygen-polyhedron into two shells ($N_1 = N_{1,1} + N_{1,2}$), permits to reveal an adequate split-model (tested for the model crystal Na_2TiSiO_5). This model gives that the Ti in glassy Na_2TiSiO_5 is coordinated by one oxygen at Ti-O distance $R_{1,1} = 1.70$ Å and 4 oxygens at $R_{1,1} = 1.94$ Å. For amorphous compound the revealed split-model reflects the asymmetry of the oxygen-polyhedron's peak in $|F(R)|$ and hence, can be validated if the anharmonicity effects are negligible.

Abstract

We present the Al K-edge XANES spectrum of synthetic mica with mixed fourfold coordinated and sixfold coordinated Al (preiswerkite). Experimental analysis and multiple scattering simulations of XANES spectra demonstrate that octahedral contributions may overlap the tetrahedral ones so that the lower energy structures in mixed coordination compounds may be associated to Al octahedral site. This unexpected behavior can be explained as due to a large local distortion of the Al octahedral site.

1. Introduction

Micas are abundant and structurally significant minerals on Earth characterized by a layered structure composed by sheets of tetrahedra and octahedra cornered by O or OH. These sheets alternate with ones centered by very large alkali and alkaline-earth atoms that are loosely coordinating only tetrahedral oxygen. Aluminium, one of the most significant constituents, may occur either in the tetrahedra or in the octahedra only, or in both these coordination polyhedra simultaneously. The line shape of the XANES spectra at the Al K edge is dominated by the first coordination sphere around the absorber, i.e., by the surrounding four and/or six O atoms, respectively. In the experimental XANES spectra recorded on micas with Al in mixed coordination, the main edge consists of two or three peaks [1, 2]. Usually these peaks are assigned to either the tetrahedral (T) or octahedral (O) sites, respectively, in terms of ligand electronegativity. However, without a careful and accurate theoretical analysis a clear interpretation is impossible or misleading because: (1) many investigations utilize the average K-edge position, neglecting possible variations in the coordination polyhedron bonding distances (i.e., large distortion that indeed may affect the edge features) and, (2) the edge position also depends on the chemical environment, such as the next-near neighbor O-H units and even higher-shell cations. As a matter of fact, recent investigations carried out on the atomic structure of model compounds, sometimes exhibit a significant disagreement [3, 4].

In order to determine a reliable relationship between type of first coordination shell and energy position of the relevant edge feature we analyzed the spectroscopic properties by comparison with a detailed full multiple scattering (MS) analysis, a strategy proved successful in the interpretation of many systems [5–9]. In this paper we present experimental data and *ab initio* full MS calculations of the XANES spectra at the Al K edge for preiswerkite (Pwk), a system having Al in both, i.e., T + O coordinations. The Al K-edge spectrum had been previously interpreted according to the ligand electronegativity model by the fingerprinting method, i.e., by comparison with the spectra of model compounds albite (CN = 4) and grossular (CN = 6) [1]. Results were satisfactory in the case of the micas with one type Al only, but certainly not clear in the case where both Al types were mixed. The resulting data presented in this manuscript suggest in fact a new kind of relationships i.e., the lower energy structure in the Al K-edge XANES spectrum of mixed-coordination compound may be attributed to the octahedral sites, or it originates mainly from the octahedral contribution. This may be due to a reduced ligand field strength owing to a rather large polyhedral distortion. This behavior is supported also by the recent analysis of the XAS spectra of Fe^{2+} and Ti^{4+} bearing compounds [10, 11].

2. Experimental and theoretical details

The preiswerkite system is a synthetic material whose preparation procedure is described in Ref. [1]. XAFS experiment was carried out at SSRL (Stanford, CA, USA), with the SPEAR storage ring operating at energy 3 GeV and injection current 100 mA, at beam line SB03-3, which is equipped with the JUMBO monochromator of the double-crystal type consisting of two plates of a single YB_{66} crystal cut along the (400) plane, with resolution less than 0.55 eV. Spectrum was recorded in the total electron yield mode by scanning the Al K edge from 1540 to 1690 eV in steps of 0.3 eV, and was corrected for background contribution from lower energy absorption edges by linear fitting of the baseline, and normalized in energy to +60 eV from the first inflection of the edge i.e., at the uppermost energy value for XANES [12]. Pwk contains one Al in the octahedral sheet and two Al in the tetrahedral sheet [13] and clearly exhibits three structures at the edge with fairly similar intensities (see Figure 1).

The Al XANES spectra have been computed using full MS theory [9]. In the muffin-tin model and one-electron approximation, the local density potentials for the Al clusters have been constructed according to Mattheiss prescription [14] by superposition of neutral atomic charge densities using the Clementi-Roetti basis set tables [15]. For the exchange-correlation part of the potential, for practical reasons, we used the energy-independent X_α potential with α equal to 0.60 for the excited Al atom. The calculated spectra have been further convoluted with a Lorentzian shaped function with a full width $\Gamma_h = 0.42$ eV [16] to account for the core hole lifetime and $\Gamma_{exp} = 0.55$ eV for the experimental resolution. We have chosen the muffin-tin radii according to Norman's criterion [17] and allowed a 10% overlap between contiguous spheres to simulate the atomic bond. The z axis in all our calculations is along the c axis of the compound.

3. Discussion

Bond length vs. edge-peak position behavior is shown in Fig. 2(a) and 2(b) where a series of SCF-MS calculated spectra by using simplified cluster models (e.g., tetrahedra and octahedra) are plotted as a function of the bond distances. A clear shift of the edge towards lower energies with increasing Al-O bond length is observed. The observed shift is estimated ca. 20.4 eV/Å for fourfold-coordinated Al over the range 1.70–1.80 Å and ca. 13.6 eV/Å for six-fold-coordinated Al over the range 1.90–2.00 Å. These rates are similar to those experimentally observed for both Ti K-edge [11] and Si K-edge structures [18].

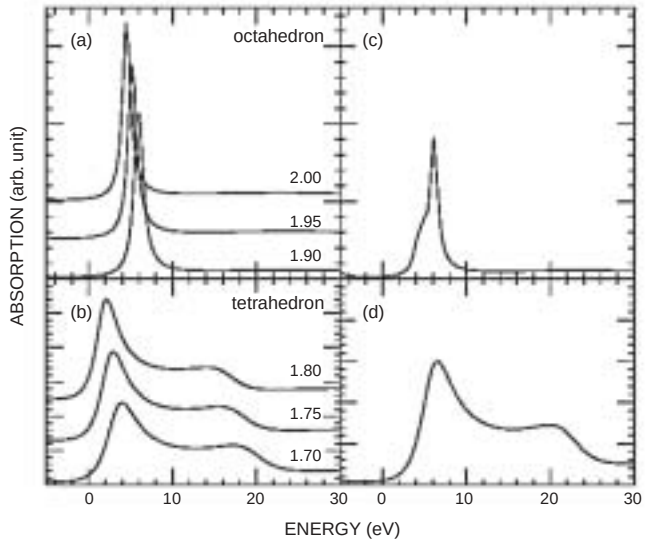

Fig. 2. On the left panels: Al K edge simplified self-consistent model calculations for different bond distances (given in Ångstrom) for: (a) octahedral clusters and (b) tetrahedral clusters. On the right panels: (c) real sixfold cluster SCF-calculations in Pwk and (d) real fourfold cluster SCF-calculations in Pwk.

In Fig. 2(c) and 2(d) we present similar SCF-potential calculations taking into account the distortions observed in the real crystal structures of Pwk. These results clearly show that the main peak of the octahedral cluster is at lower energy with respect to the tetrahedral one. The observed "anomalous chemical shift" is mainly due to the larger distortion around the photoabsorber. On the contrary, the results obtained in the ideal model case exhibit a net shift of ca. 2.2 eV (with the fourfold coordinated site contribution being followed by the sixfold coordinated site contribution). These Al K-edge calculations address the role of the structural distortion in determining the details of the transition features in compounds with mixed coordination.

In comparison to the experimental data, Fig. 1 shows also the calculated Al XANES spectra of this mica having Al in two coordination states (one octahedral $^{[6]}$Al and two tetrahedral $^{[4]}$Al) [13]. We first calculated the convergent 91-atom cluster for each site, then we combined them in the proportion 1 $^{[6]}$Al + 2 $^{[4]}$Al. Peak A originates from the O-site contribution, peak B from a superposition of contributions from both sites, while C is dominated by the T-site contribution. This result is not surprising if one notices that, according to the crystal structure determination, the Al-O bond lengths are about 2.02 Å and 1.69 Å for octahedral and tetrahedral sites, respectively. The large octahedral bond distance shifts the edge position towards lower energy (see Fig. 2), whereas the opposite occurs for Al clusters having a short tetrahedral length. Furthermore the large distortion of the tetrahedral site shifts the peak position toward higher energy by more than 2.0 eV [6]. As a matter of fact, MS calculations indicate that all features are determined by the superposition of contributions from both sites. However, although peaks A and B are mainly, but not only of octahedral origin, C is essentially due to the tetrahedral contribution. Another strong evidence of the above assignments is associated to the energy region at about 20 eV from the edge where the spectral feature E, typical of the tetrahedral Al XANES spectrum, occurs in contrast to the octahedral shape that is substantially flat in this energy range [1].

In this system we carried out a further test, albeit preliminary, on the possible effects induced by O-H bonds onto the $^{[6]}$Al spectrum. This test is actually important because of the special configuration of the Al coordination polyhedron in micas: it consists of four O anions in common with the tetrahedral sheet plus two OH located at the center of the O hexagonal network. Because the formation of the O-H bond reduces the total electronegativity of the Al-O bonds on two opposite directions, it should lead to an edge shift towards lower energies, as shown in Fig. 3. Here we present the calculations for a simplified small cluster that contains only a first-coordination oxygen shell with one O anion linked to hydrogen. Theoretical data in Fig. 3 shows that formation of the O-H bond shifts the edge position towards low energy (ca. 1.0 eV), and decreases the intensity of the main edge with a concomitant formation of new states near the Fermi level. Data support our previous assignment in agreement with other data available in literature [19–21]. Actually, the increase of the bond length, the O-H bond formation and a large site distortion are mechanisms competitive with the increasing of coordination numbers.

In conclusion, a detailed experimental and theoretical investigation of the Al K-edge XANES has been performed on preiswerkite, a mica that contains Al in the different coordinations,

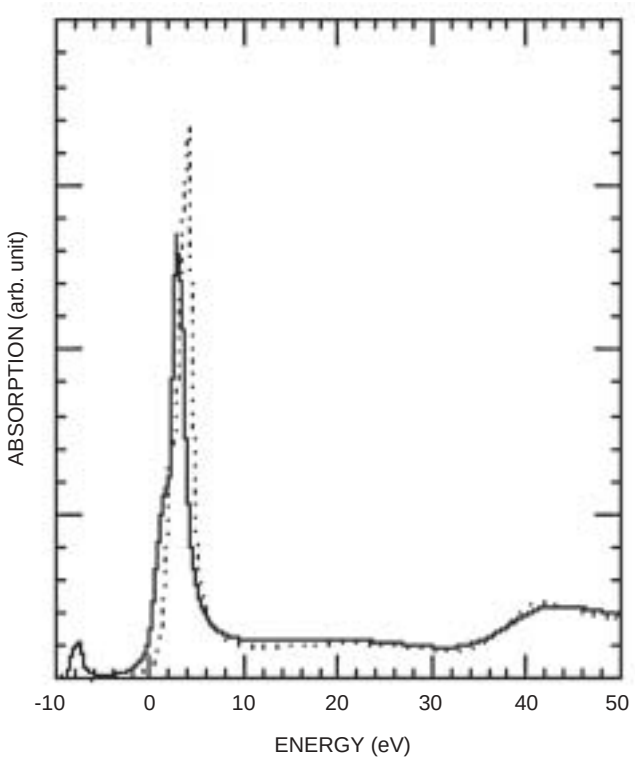

Fig. 3. Comparison of MS calculations at the Al K-edge of preiswerkite for the smallest Al cluster (Al + 6 oxygens) with (solid curve) and without (dot curve) hydrogens.

our analysis clearly demonstrates that the coordination is not the only parameter that affects the edge position. Bond length, OH formation and, most important, the site distortion have to be considered. The observed anomalous chemical shift contribution to the Al K-edge peak also indicates that a simple fingerprinting technique based on the extrapolation of the results of the four-fold and six-fold structures in the spectra of model compounds is reliable only if supported by a theoretical analysis. This is particularly significant in the analysis of compounds relevant in mineralogy and geochemistry, where Al may occur in different coordination sites and with different bond lengths, distortions and chemical environments.

Acknowledgments

The authors thank the entire SSRL staff for the experimental assistance during experimental runs. A special thanks is devoted to J.-L. Robert for providing the synthetic micas. Financial support was provided by MURST, Italy (Project *Crystal-chemical, kinetic and thermodynamic aspects of minerals*). Abstract

The mean square variation of the half-scattering path length in X-ray absorption fine structure Debye-Waller factors has been expressed as a function of the first shell radial distance and an angle (where applicable) for Zn^{+2} active sites of metalloproteins enabling direct and accurate calculation of the single and multiple scattering Debye-Waller factors at arbitrary temperatures. The local character of the filled d-orbital Zn^{+2} element does not obstruct us from extending this technique to other metals with unfilled d-orbital. In this report we present initial results based on one-dimensional radial models applicable to the d^9 Cu(I) and Cu(II) histidine/imidazole and cystein complexes. Results from these new models are compared with large reference structures of homogeneous and heterogeneous Cu metal ligation built and optimized by non-local Density Functional Theory.

1. Introduction

The X-ray Absorption Fine Structure (XAFS [1, 2]) Debye-Waller factor (DWF) is an exponential term of the form $e^{-2k^2\sigma_j^2}$ that reduces the amplitude of the XAFS $\chi(k)$ spectra and accounts for the structural and thermal disorder of a given sample. The temperature-dependent parameter σ_j^2 is the mean square variation of the half-length of the j-th single (SS) or multiple (MS) scattering path, and is directly related to the phonon normal mode spectrum of the sample (eigenfrequencies and eigenvectors). Evidently, the influence of the DWF parameter in the XAFS spectra is more important at higher photoelectron wavenumber $\boldsymbol{k}$ value. Depending on the sample geometry the actual number of all SS and MS DWF parameters can be on the order of several hundred in a low symmetry structure. Since experimental data can only fit a limited number of parameters (about $2\Delta k\Delta R/\pi \cong 20$–$30$ [3], where Δk and ΔR are the $\boldsymbol{k}$- and $\boldsymbol{R}$-range data ranges) the DWF parameters must be known from an alternative source to fit the experimental data without any unjustified assumptions. Considerable progress has been reported for DWF calculations using self-consistent (SCF) [4, 5, 6, 7] and force-field model (FFM) methods [8, 9, 10] to calculate the phonon normal mode spectrum. These models are alternatives to the single parameter Einstein and correlated Debye model that are insufficient to describe either single or multiple scattering paths in systems with heterogeneous bond strengths.

SCF Density Functional Theory (DFT) [11, 12, 13] methods are preferred over FFM models due to their reliability and accuracy. However calculations on the large active site structures are not always possible or feasible. Poor SCF energy and geometry convergence, high CPU demand (execution times for DFT scale as N^3 where N is the number of atomic basis sets used) and saddle points on the conformational potential energy surface lead us to investigate alternative mechanisms for the DWF calculations.

Active sites of metalloproteins consist of a central metal atom that binds to amino-acid residues from the protein. Although metal-residue distance may vary depending on many factors like ligand-coordination number and possible hydrogen bonding between residues, internal residue structure remains fairly rigid. Thus the mean square variation of a half scattering SS/MS path σ_j^2 could be expressed as a direct function of the radial distance separating the metal from the residue itself (first shell distance) at a given sample temperature. In some cases an angle can be also used as a parameter for formations involving cysteines and carboxylate amino acids. Expressing the σ_j^2 as a function of a the first shell radial distance (and angle where applicable) allows experimentalists to use temperature-dependent functions in fitting procedures to analyze XAFS spectra without the need to perform complex and time-consuming DFT calculations. Initial results for Zn^{+2} and histidine ligands using an imidazole ring have been reported [7, 14] and provided accuracy sufficient for use with XAFS data analysis.

The localized character of the filled d-orbital for Zn metalloproteins is not an impediment for extending this technique to other metals with unfilled d-orbital. Selecting the closest element to Zn, we describe two similar one dimensional models (first shell metal-ligand distance variation) that are applicable to Cu-histidine and Cu-cysteine structures (Fig. 1). Similarities and apparent differences between Cu(I) and Cu(II)-histidine and cystein models are discussed and modeled-calculated DWFs are compared with DFT optimized structures which have the advantage over experimental XAFS spectra of allowing direct path-by-path DWF comparison rather than an computing average DWF over a particular shell. DFT calculated normal mode frequencies of optimized structures under non-local functionals are in most cases within 95–98% of the corresponding experimentally reported infrared or Raman normal mode frequency [15].

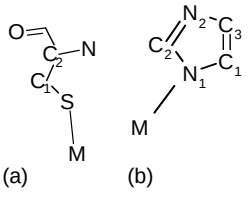

Fig. 1. (a) Cu-cysteine and (b) Cu-histidine models. Another sulfur/nitrogen atom that directly binds to the metal and opposite to the residue is not shown here.

*e-mail: dimakis@biocat2.phys.iit.edu

2. Computational Method

A small cluster that consists of the Cu metal, the amino acid residue[1] and another atom that binds directly to the metal and opposite to the residue (Fig. 1) is geometrically optimized using the non-local B88-LYP [16, 17, 18, 19] functional of the DFT method with double zeta (DZV) [20] basis set specifically optimized for DFT. The phonon normal mode eigenfrequencies and eigenvectors are calculated from the DFT optimized modeled cluster and are inputted to a program made by the authors that evaluates all possible SS and MS DWFs at any arbitrary temperature. High spin configuration was used in all clusters as it corresponds to the ground state energy of the particular cluster formation. Once the first "equilibrium" metal-ligand cluster is obtained, the first shell Cu–$N^{(1)}$/S interatomic distance(s) is perturbed and the procedure is repeated. For these subsequent clusters in addition to the Cu metal, the following residue atoms are kept "frozen" during geometry optimization: 1) $N^{(1)}$, $C^{(1)}$, and $C^{(2)}$ for Cu-histidine, and 2) S, and $C^{(1)}$ atoms for Cu cysteine model. All model clusters converge to an energy minimum and not to a saddle energy point, i.e. no negative frequencies appear in the phonon normal mode spectrum.

In general σ_j^2 are expressed as a mixture of polynomial and exponential expressions over ΔR. Similar to Zn^{+2} models, it was identified that for Cu(II)-imidazole and Cu-cystein models σ_j^2 is expressed as [14]

$$\sigma_j^2(\Delta R, T) = \sum_{i=1}^{2} C_{ij}(T)\Delta R^i + e^{A(T)+B_j(T)\Delta R} \quad (1)$$

and for Cu(I)-imidazole

$$\sigma_j^2(\Delta R, T) = \sum_{i=1}^{2} C'_{ij}(T)\Delta R^i \quad (2)$$

where A, B and C' are temperature dependent coefficients that can be approximated as a third order polynomial over temperature, $\Delta R = R - R_0$ is changes of the perturbed radial distance with respect to the equilibrium position R_0, and $C'_{0j} \equiv \sigma_j^2(R_0, T)$ are a distance-independent parameters.

The exponential growth of the σ_j^2 where applicable, dictates that amino acid residues will be non-XAFS detectable when Cu-residue distance exceeds a "cut-off" value. Figures 2 and 3 indicate that for Cu(II)-histidine and Cu(II)-cysteine formations the metal-residue distance cut-off value is approximately 2.3 Å and 2.45 Å respectively. No exponential behavior appears for the Cu(I)-histidine case for $R_{Cu\text{-}N(1)}$ values up to 2.2 Å, whereas for Cu(I)-cysteines σ_j^2 exponential growth does not rise as rapid as in the corresponding Cu(II) case. For the Cu(I)-histidine model the equilibrium distance Cu(I)–$N^{(1)}$ is detected at 1.931 approximately 0.07 Å shorter than the corresponding Cu(II)–imidazole structures. It is difficult to identify a common model for DWFs of Cu(I) and Cu(II)-histidine formations. However for Cu-cystein models shifting the value $\Delta R_{Cu\text{-}S}$ of the Cu(II)-cysteine by about −0.055 Å, σ_j^2 of the SS Cu–S shell for either Cu(I) or Cu(II) cysteine models coincide (fig. 4). Therefore in contrast with the Cu-histidine case, a single model is adequate to describe either Cu ion bound to cysteine amino acids.

[1]Metal-Histidine structures can be sufficiently mimicked by metal-imidazole rings.

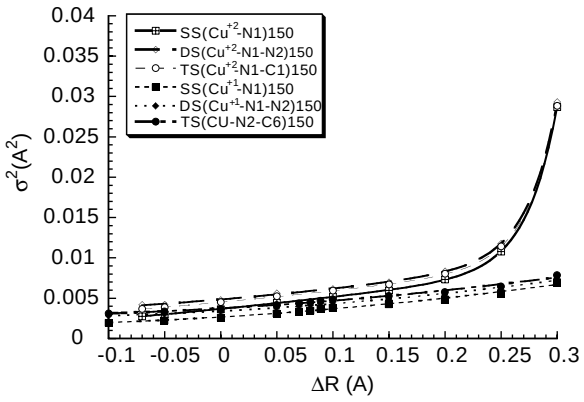

Fig. 2. Various DFT calculated σ^2 for single and multiple-scattering paths of the Cu(I)- and Cu(II)-imidazole model vs. linearly translated ΔR for the first radial shell Cu–$N^{(1)}$. R_0 is 1.995, and 1.930 Å for Cu(II) and Cu(I) respectively.

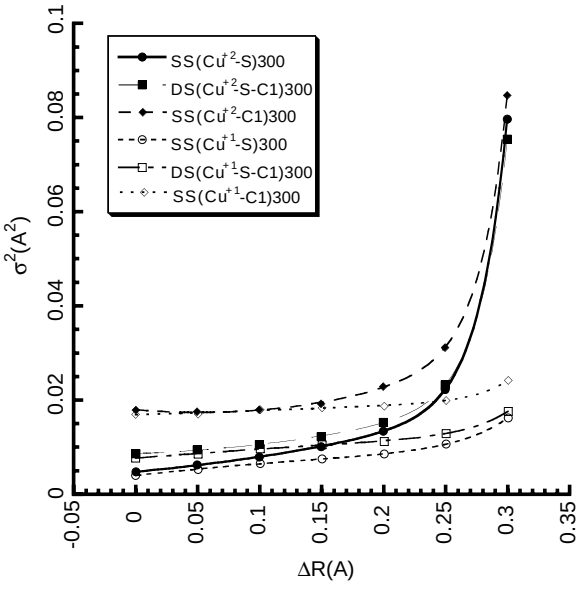

Fig. 3. Various DFT calculated σ^2 for single and multiple-scattering paths of the Cu(I)- and Cu(II)-cystein models vs. linearly translated ΔR for the first radial shell Cu-S. R_0 is 2.20 Å for either Cu(II) or Cu(I) metal.

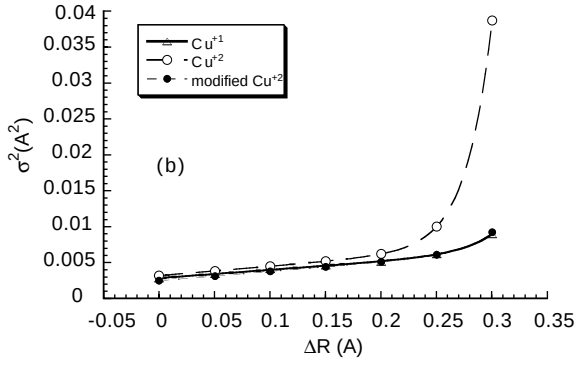

Fig. 4. DFT calculated σ^2 for the single-scattering path of the Cu-S for Cu-cystein model. Shifting the $R_{Cu(II)\text{-}S}$ by additional 0.055 Å Cu(I) and Cu(II) models coincide.

3. Results and Discussion

3.1. *Cu histidine models-homogeneous ligation*

DFT Cu–imidazole optimized structures with different imidazole-coordination number have been built, optimized and their phonon normal mode spectrum was used to calculate the corresponding

DWFs at 150 °K. For large DFT-optimized bio-structures, saddle points might appear in the energy spectrum. This is because there are multiple structural conformations with very small SCF energy differences e.g. the imidazole ring rotations about the metal-$N^{(1)}$ axis. Depending on the size of the negative eigenfrequency and the particular mode of the saddle point, its presence might affect the DWFs of the structure. The Cu(II) imidazole model is tested using Cu(II) with coordinated to three imidazole rings and also for symmetry reasons to a spare NH_2 group. One negative frequency at $-25.42\,\mathrm{cm}^{-1}$ appear in the normal mode spectrum. This frequency corresponds to carbon and nitrogen stretching modes perpendicular to the plane of the imidazole ring and thus do not affect the σ_j^2 themselves that are related to the planar imidazole modes. The Cu(I) coordinated to two imidazole rings was used as a test structure for Cu(I) model. No saddle points were observed for the later structure.

Similarly to the Zn^{+2} case, imidazole ring deformations might occur and are caused by different metal-residue and residue-residue interactions between reference and modeled metal-residue structures. For the Cu(II) complex it has been observed that $N^{(1)}$–$N^{(2)}$ and $N^{(1)}$–$C^{(3)}$ interatomic distances are overestimated from our model by about 0.07 Å and 0.03 Å respectively. These deformations will affect σ_j^2 SS Cu–$N^{(2)}$, Cu–$C^{(3)}$, double (DS)- and triple (TS)-scattering Cu–$N^{(1)}$–$N^{(2)}$, Cu–$N^{(1)}$–$C^{(3)}$ paths. Due to the almost collinear geometry of the absorbing metal with $N^{(1)}$ and $N^{(2)}/C^{(3)}$ atoms, the DS/TS of these scattering paths are very important in terms of their contribution in the amplitude of the XAFS spectrum. It has been found that adding these "extra" distances into the ΔR value compensates for these deformations and improved the accuracy of the modeled DWFs for the affected paths. No significant imidazole deformation was observed for the Cu(I) case when compared with its corresponding reference structure. The average Cu–$N^{(1)}$ first shell interatomic distance for the three-imidazole and two imidazole structures was observed at 1.995 Å and 1.883 Å respectively. The NH_2 group in the Cu(II) case was also 1.88 Å away from the Cu(II) central atom. For this SS Cu–$N^{(1)}$ path at 150 °K our models give 3.39×10^{-3} Å^2 and 2.27×10^{-3} Å^2 for Cu(II) and Cu(I) respectively vs. $3.23 \pm 0.15 \times 10^{-3}$ Å^2 and 2.24×10^{-3} Å^2 of the corresponding reference structures. For the SS Cu–$C^{(1,2)2}$ the average model-calculated σ_j^2 for both paths is 5.65×10^{-3} Å^2 and 5.10×10^{-3} Å^2 for Cu(II) and Cu(I) respectively vs. $5.89 \pm 0.8 \times 10^{-3}$ Å^2 and $4.68 \pm 0.25 \times 10^{-3}$ Å^2 of the corresponding reference structures. These short photoelectron paths range correspond to the bending $N^{(1)}$–Cu–$C^{(1,2)}$ mode. For the DS/TS Cu–$N^{(1)}$–$N^{(2)}$ similar accuracy is obtained for either case. For example for the Cu(I) case model-calculated σ_j^2 value is 3.07×10^{-3} Å^2 vs. 3.23×10^{-3} Å^2 for the reference structure. Using atom positions from the reference structures as inputs to FEFF [21] program together with DWFs from models/references XAFS $\chi(k)$ spectra are generated and their corresponding Fourier transform are shown in fig. 5. An excellent agreement between modeled and referenced spectra is obtained.

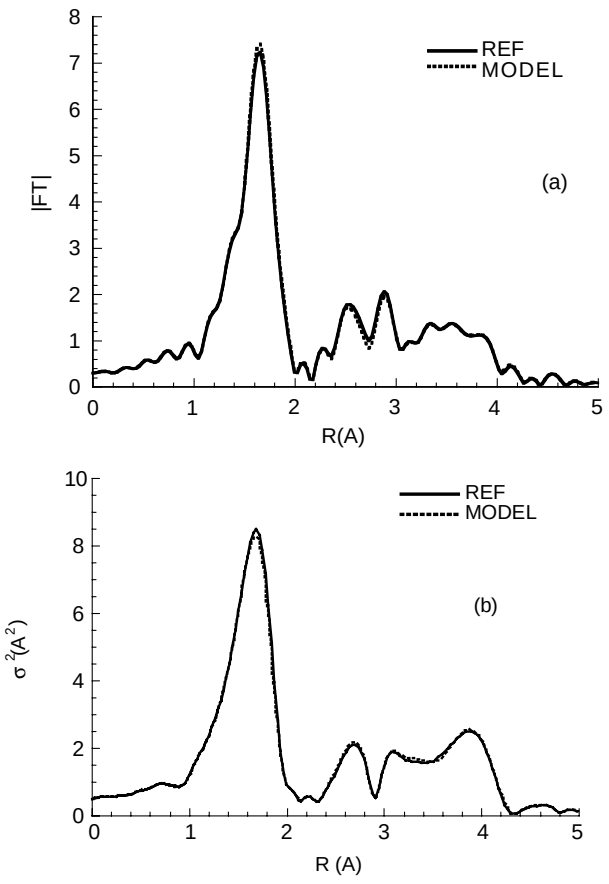

Fig. 5. Fourier Transform of calculated DWFs vs. corresponding reference structures for a) Cu^{+1} and b) Cu^{+2}-histidine formations at 150 °K.

3.2. *Cu cysteine models-heterogeneous ligation*

The Cu-cysteine model is tested using the DFT optimized Cu-Cys/His structures that serves as references for the Cu-cysteine model. Although no saddle points appear in the phonon normal mode spectrum of the Cu(II)-Cys/His reference structure, its first normal mode frequency of $0.142\,\mathrm{cm}^{-1}$ that corresponds to a translational mode of the whole molecule will not be included in the DWF calculations. However, for corresponding Cu(I) reference structure one saddle point at $-23.04\,\mathrm{cm}^{-1}$ does appear in the phonon spectrum. This corresponds to a mixture of the following modes: 1) stretching modes perpendicular to the imidazole ring, 2) stretching modes perpendicular to the plane defined by Cu(I), S and $C^{(1)}$ atoms, and 3) bending modes of the alpha carbon cysteine tail. This mode is omitted and does not affect the DWF calculations.

Interatomic distances Cu(II)–$N^{(1)}$ and Cu(II)–S of the first two shells, were detected at 1.913 Å and 2.145 Å, whereas the corresponding distances for Cu(I) were observed at 1.908 Å and 2.138 Å respectively. The "short" Cu–S bond length arises because the two ligands are on the opposite sides of the metal and their electrostatic interaction is minimal. The one-dimensional Cu-cysteine model is adequate to be used here since angle variation $\Delta\Theta$ between model and reference structures is not more than 0.3°. The first two shells can be resolved by XAFS since their corresponding interatomic distances differ by more than 0.2 Å. At 150 °K, the σ_j^2 for the SS Cu–S path of the reference structure was predicted at 2.36×10^{-3} Å^2 for either Cu ion. For the σ_j^2 of the same path and temperature our model gives 2.55×10^{-3} Å^2 and 2.22×10^{-3} Å^2 for Cu(II) and Cu(I) ions respectively. Similarly for the SS Cu–$N^{(1)}$ path and Cu(II) ion our model gave 2.62×10^{-3} Å^2 vs. 2.68×10^{-3} Å^2 for the reference structure whereas the corresponding values for the Cu(I) ion are 2.49×10^{-3} Å^2 and 2.57×10^{-3} Å^2 respectively. The Fourier transform of FEFF [22]-generated XAFS spectra using atomic positions from the

[2]Since XAFS cannot distinguish $C^{(1)}$ from $C^{(2)}$ atom, these paths are treated as a single paths with the DWF to be the average of the two.

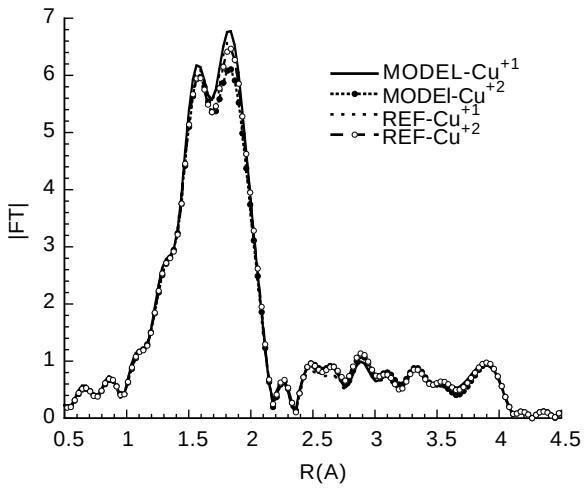

Fig. 6. Fourier Transform of calculated DWFs vs. reference for Cu-Cys/His structure at 150 °K.

reference structures are shown in fig. 6 with the corresponding DWFs being inputted from either reference or modeled compounds.

The small variation of second peak in fig. 6 between experimental and Cu(II)-modeled structures is not only due different σ_j^2 for SS Cu–S path but also due to variations on the σ_j^2 of the DS Cu(II)–S–$C^{(1)}$ path. The modeled σ_j^2 for the DS Cu(II)–S–$C^{(1)}$ path is detected at 5.4×10^{-3} Å^2 vs. 4.4×10^{-3} Å^2 for the corresponding value for the Cu(II)-Cys/His case. Similar to Zn^{+2}, for Cu-cysteine case better agreement is expected at larger metal-cysteine distances [14]. Corrections due to the imidazole ring reformation as discussed previously were also included.

4. Conclusions

- Analytical expressions that describe SS and MS σ_j^2 for Cu(I) and Cu(II) histidine and cysteine structures have been derived using the non-local DFT method for small metal-ligand structures. A single model can be used for either Cu(I) or Cu(II) bound to a cysteine amino acid residue. However although it is possible to use a single model for either Cu(I) and Cu(II) imidazole DWF calculations, two distinct models are preferred. Generalization of these models to an arbitrary temperature is underway.
- Cu-cysteine and Cu-histidine models were used to analyze active sites with heterogeneous ligation like the Cu-Cys/His structure. Similarly to the homogenous case the accuracy is sufficient for XAFS data analysis.

Abstract

K edge XANES spectra of $CuGaSe_2$, $ZnGeAs_2$ and $CuFeS_2$ are studied both experimentally and theoretically. While spectra of $CuGaSe_2$ and $ZnGeAs_2$ are remarkably similar, spectra of $CuFeS_2$ differ significantly, especially in the pre-edge region. Full-potential band structure calculations without any core hole give essentially the same results as real-space multiple-scattering calculations for a muffin-tin potential with a core hole included; the notable exception is the Cu edge in $CuGaSe_2$, where non-muffin-tin effects possibly occur. The distinct pre-peak visible at all three spectra of $CuFeS_2$ arises from transitions to delocalized multiple-scattering resonances which are confined almost exclusively to the Fe sites.

1. Introduction

Ternary semiconductors of the I-III-VI_2 and II-IV-V_2 types share the same chalcopyrite structure. Their electronic properties were extensively studied in the past, both due to fundamental reasons (they offer an opportunity to study systematic variations of their properties with chemical composition) as well as due to their technological relevance. Among the techniques which probe the low-lying unoccupied states, X-ray absorption near-edge structure (XANES) spectroscopy holds a unique position as it offers a local view from a chemically specific site. Earlier XANES studies suggested that while spectra at analogous K edges of I-III-VI_2 compounds are quite similar to each other, the spectra of the "archetypal" chalcopyrite $CuFeS_2$ exhibit remarkable differences, especially in the pre-edge region. To our knowledge, no XANES spectra of the II-IV-V_2 compounds have been published so far.

When interpreting XANES spectra, it is often assumed that the pre-edge region corresponds to semi-bound states. In accord with this reasoning and with the results of band-structure calculations, the pre-peak in $CuFeS_2$ has been interpreted as transitions to states arising from the Fe 3d band hybridized with the S and/or Cu states [1, 2, 3]. On the other hand, McKeown [4] suggested that the pre-peaks at the Cu and Fe K edge spectra may be caused by interference effects of the photoelectron wave function from the crystal structure. It is the purpose of this paper to compare experimental and theoretical XANES spectra of $CuFeS_2$ with analogous spectra of a I-III-VI_2 compound $CuGaSe_2$ and of a II-IV-V_2 compound $ZnGeAs_2$, to identify their similarities and differences and to present a comprehensive interpretation of the pre-edge region in the XANES of $CuFeS_2$.

2. Experimental and theoretical methods

The spectra of $CuGaSe_2$ and $ZnGeAs_2$ polycrystalline samples were measured using a two-crystal spectrometer and an X-ray spectrometry tube. The energy resolution varied from 0.36 eV for the Cu edge to 0.52 eV for the Se edge. The spectra were collected in a transmission mode, each measured data point represents an average of repeated measurements. The measured spectra were deconvoluted by the apparatus smearing function. The Cu and Fe K edge spectra of polycrystalline $CuFeS_2$ were measured using synchrotron radiation at HASYLAB, Hamburg. Both edges were recorded in the transmission mode at the Al beamline with a two-crystal monochromator. The energy resolution of the monochromator was about 1 eV at 7 keV. The S K edge of $CuFeS_2$ was digitized from the work [2].

Theoretical spectra were obtained within the local density approximation framework, in a twofold way: via an all-electron full-potential band-structure calculation based on a pseudopotential technique and via a real-space multiple-scattering (RSMS) method involving a self-consistent muffn-tin potential. In the latter case, we investigated both the situation without a core hole (ground state) and with a relaxed and screened core hole. More details of our application of the pseudopotential formalism can be found in Ref. [5, 6], our implementation of the RSMS formalism was described in Ref. [6, 7].

In order to facilitate the interpretation of the pre-edge region in $CuFeS_2$, wave function probability densities associated with the excited photoelectron were calculated in the RSMS formalism [8]. In that way, one can gain a well-defined picture of the spatial distribution of the photoelectrons which participate in the formation of specific XANES features.

3. Results and discussion

Our results are summarized in Figs. 1–3. The energy ranges in these figures were set using the $kR = \text{const}$ prescription, where $k = \sqrt{(2E)}$ is the photoelectron wave vector and R is a typical interatomic distance in the given compound. The horizontal alignment of the theoretical spectra at different edges of the same compound was provided by the calculation itself, the block-wise alignment of the band-structure and the RSMS calculations as well as of the experimental spectra was performed by hand. The zero of the energy scale was set to the bottom of the conduction band of the pseudopotential calculation.

$CuGaSe_2$ and $ZnGeAs_2$ spectra are quite similar to each other while $CuFeS_2$ spectra visibly differ. The resemblance of $CuGaSe_2$ and $ZnGeAs_2$ on the one hand and uniqueness of $CuFeS_2$ on the other hand gets reflected in our theoretical spectra as well. The similarity of $CuGaSe_2$ and $ZnGeAs_2$ spectra evokes the similarity of spectra of their binary isoelectronic analogues ZnSe and GaAs [9, 10]. As previous works already showed that spectra of various compounds of the I-III-VI_2 group look quite similar to each other [2, 11, 12], it is reasonable to assume that corresponding spectra

*e-mail: sipr@fzu.cz

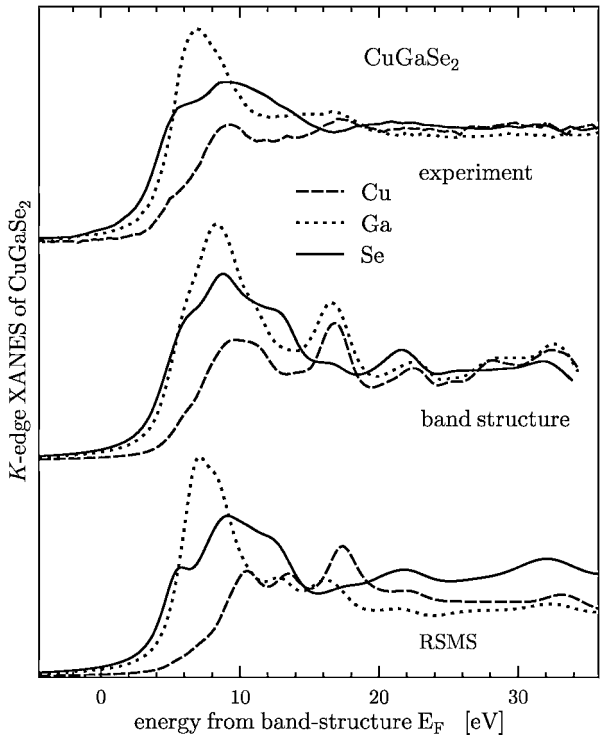

Fig. 1. K edge XANES spectra of Cu (dashed line), Ga (dotted line) and Se (full line) in $CuGaSe_2$, as provided by the experiment (uppermost panel), by the band structure calculation (middle panel) and by the RSMS calculation (lowermost panel).

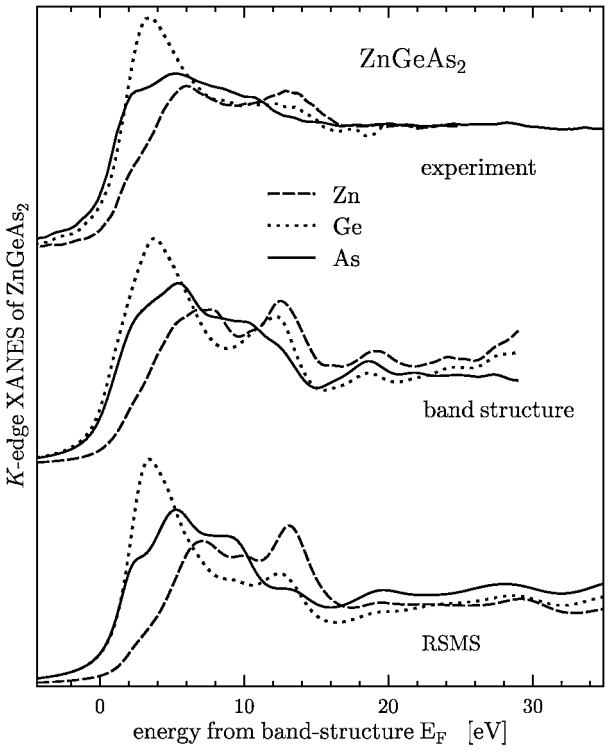

Fig. 2. Experimental and theoretical Zn, Ge and As K edge XANES spectra of $ZnGeAs_2$.

the II-IV-V_2 compounds will be similar as well. The $CuFeS_2$ case then stands out quite prominently.

The RSMS curves presented here have been obtained for a potential which accounts for the core hole. The ground state potential gives rise to spectra which are quite similar to those

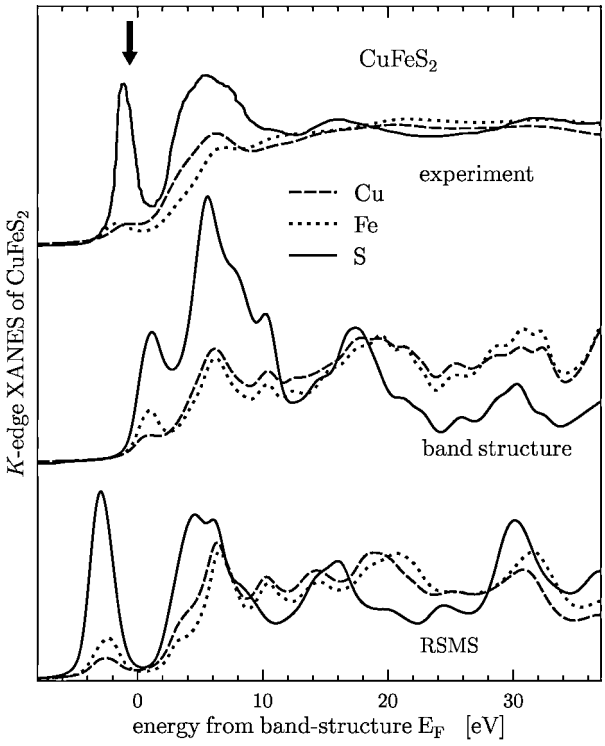

Fig. 3. Experimental and theoretical Cu, Fe and S K edge XANES spectra of $CuFeS_2$. The pre-peak is marked by an arrow.

shown here, just their peak heights at the low energy side are typically about 10% smaller. Therefore, we do not show them here for brevity. The results of the band structure calculation and of the RSMS calculation generally agree. Interestingly, the RSMS calculation does not correctly reproduce the Cu edge of $CuGaSe_2$ – the intensity of the first maximum at $E \approx 10\,\text{eV}$ in Fig. 1 is too low, being on par with the middle peak at $E \approx 13\,\text{eV}$ which itself is hardly distinguishable in the experiment. Our band-structure calculation seems to describe the Cu spectrum of $CuGaSe_2$ better. As suggested earlier [11], this difference may be a manifestation of the muffin-tin approximation, which was imposed on the RSMS calculation but not on the pseudopotential band-structure calculation.

Let us now concentrate on $CuFeS_2$ and its distinctiveness. The largest difference between $CuFeS_2$ and $CuGaSe_2$ or $ZnGeAs_2$ spectra occurs in the pre-edge region; there are no pre-peaks in the $CuGaSe_2$ or $ZnGeAs_2$ spectra, in contrast to $CuFeS_2$, where a well-defined pre-peak appears at each of the three edges (Fig. 3). The reproduction of this pre-peak by the theory is not perfect, nevertheless, it is good enough to substantiate a theory-based investigation of the mechanism of its formation. The differences between $CuFeS_2$ and $CuGaSe_2$ or $ZnGeAs_2$ spectra occur in the main peaks region as well, however, they are not so marked as at the pre-peak.

The relative roles of individual atomic sites in the formation of a particular spectral peak can be quantitatively assessed by comparing the wave function probability densities (WFPD) around those sites [8]. By performing this analysis for all the three edges, we found that the excited photoelectron is located *almost exclusively* on Fe atoms at the pre-peak energy; the calculated WFPD around the Fe sites is by three orders of magnitude higher than around any of the Cu or S sites. This is remarkably different from the main peak region, where the photoelectron WFPD is more-or-less uniformly spread among all the sites of the cluster,

as one would expect for a truly multiple-scattering resonance (we do not plot the corresponding curves here for brevity). The strong dominance of Fe sites in the WFPD distribution at the pre-edge energy is consistent with the interpretation of the pre-peak as transition to unoccupied Fe 3*d* states hybridized with Cu and/or S states [1, 2, 3]; however, these states are located on many Fe atoms simultaneously, not just a single one, and hence they correspond to a resonance which arises from multiple scattering by the Fe atoms. In this respect, it represents a crystal structure interference effect as well [4]. So both views on the origin of the pre-peak in the XANES of $CuFeS_2$ can be related and reconciled within the WFPD concept.

4. Conclusions

Analogous K edge XANES spectra of compounds of the I-III-VI_2 type ($CuGaSe_2$) and of the II-IV-V_2 type ($ZnGeAs_2$) are quite similar to each other while spectra of $CuFeS_2$ differ. The spectra can be reasonably well reproduced by one-electron calculations. Full-potential band structure calculations without any core hole give essentially the same picture as RSMS calculations for a muffin-tin potential with a core hole included; the notable exception is the Cu edge in $CuGaSe_2$, where significant non-muffin-tin effects possibly occur. The distinctiveness of $CuFeS_2$ spectra is caused by the presence of Fe atoms. Pre-peak in the XANES of $CuFeS_2$ arises from transitions to delocalized multiple-scattering resonances which are confined almost exclusively to the Fe sites.

Abstract

The hole doping effects on the O 1s X-ray absorption spectrum (XAS) of a quasi-one-dimensional charge-transfer insulator, $Ca_{2+x}Y_{2-x}Cu_5O_{10}$, are discussed on the basis of numerically-exact diagonalization calculations applied to finite-size cluster models. The angle-resolved photoemission and inverse one are also calculated to understand the characteristic features in the XAS. The role of "edge-share"-type crystal structure, as well as that of electron correlation, is emphasized to understand the localized nature of the electronic states. The *dp* model Hamiltonian used in the O 1s XAS calculation can be mapped onto a single-band Hubbard model with the intra-atomic Coulomb repulsion, U, and the first and second neighbor hoppings, t_1 and t_2 ($t_1 \approx t_2$).

Core-level X-ray absorption (XA) spectroscopy provides element-selective information on the unoccupied part of the electronic states in solids. In the case of cuprates, the XA spectra from the O 1s and Cu 2p core states are often used to discuss the electronic states near the Fermi energy. In contrast to the Cu 2p X-ray absorption spectrum (XAS), the O 1s XAS is almost free from the core-hole effects. This enables us to discuss the electronic state of the ground state by means of the O 1s XAS more easily.

As is well known, the O 1s XAS in $La_{2-x}Sr_xCuO_4$ consists of two peaks separated by 1.5–2 eV [1]. The higher and lower energy peaks correspond to the absorption to the upper Hubbard band (UHB) and the Zhang-Rice singlet (ZRS) band [2], respectively. In a CuO_4 model description, as shown later, they are assigned to the d^{10} and d^9 final states, respectively. The similar double-peak feature was seen in a recent experiment for $Ca_{2+x}Y_{2-x}Cu_5O_{10}$ reported by Nakamura *et al.* [3, 4]. However, the details of hole doping dependence of the O 1s XAS spectrum differs for $Ca_{2+x}Y_{2-x}Cu_5O_{10}$ and $La_{2-x}Sr_xCuO_4$. In the case of $Ca_{2+x}Y_{2-x}Cu_5O_{10}$, the UHB and ZRS peaks can be well identified as separate ones even in the nominally 40% hole doping regime. In other words, the localized nature of the valence band hole states is remarkable even in such a heavy doping regime. In the present study, we discuss the electronic state of this compound, calculating the hole doping dependence of the O 1s XAS. To understand the origin of such characteristic O 1s XAS features, we also calculate the dispersion curves of the Cu3d-O2p valence and conduction bands and derive an effective Hubbard model.

In the present study, we use an edge-share-type Cu_6O_{12} cluster model with the periodic boundary condition along the chain direction, which is illustrated in Fig. 1. The x axis is along the chain direction (= the a axis in $Ca_2Y_2Cu_5O_{10}$). The Hamiltonian, H_{pd}, is a conventional *dp* Hamiltonian and consists of one-body energy parts of Cu $3d_{xy}$ and O $2p_{x,y}$, nearest O-O and Cu-O hopping terms and an on-site Coulomb repulsion term for Cu 3d holes [5]. Since the average O 2p hole number per site is small in the following calculations, the effects of on-site Coulomb interactions at O sites

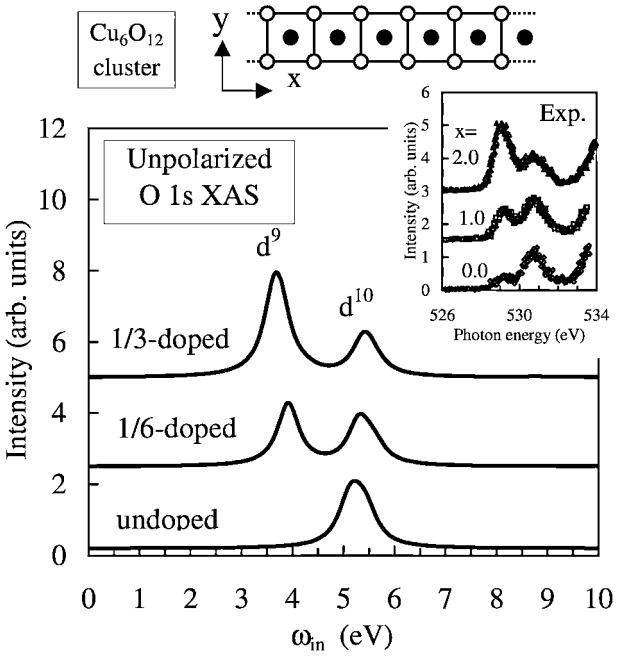

Fig. 1. Hole doping dependence of O 1s XAS. The cluster used in the calculation is also illustrated, where the open and closed circles represent the O and Cu ions, respectively. The inset shows the experiment for $Ca_{2+x}Y_{2-x}Cu_5O_{10}$ reported by Nakamura *et al.* [3].

are neglected for simplicity. The numerical values for the relevant parameters are as follows [4]. The Slater-Koster parameter for Cu $3d_{xy}$ and O $2p_{x,y}$ is taken as $(pd\sigma) = -1.5$ eV. For simplicity, the Cu-O-Cu bond angle is assumed to be 90 degrees, though it is 96 degrees in $Ca_2Y_2Cu_5O_{10}$ [6, 7]. The on-site Coulomb repulsion between Cu 3d holes (U_{dd}) is 8 eV. The CT energy between Cu $3d_{xy}$ and O $2p_{x,y}$ is taken as 3.5 eV. These numerical values are close to those estimated by Mizuno *et al.* [8].

For instance, the angle-resolved inverse photoemission spectrum (IPES) for $O2p_{\mu\sigma}$ with spin σ and orbital symmetry μ (= x, y) is given by

$$I^{\mathrm{IPES}}_{\mu,\sigma}(\varepsilon - \omega_{\mathrm{out}}, k) = \sum_f |\langle f|T^{\mathrm{IPES}}_{\mu,\sigma}(k)|g\rangle|^2 \delta(\varepsilon - \omega_{\mathrm{out}} - E_f + E_g) \quad (1)$$

for incident electron wave number k and energy ε and outgoing photon energy ω_{out}. The transition operator is given by

$$T^{\mathrm{IPES}}_{\mu,\sigma}(k) = \sum_j e^{ikr_j} p^\dagger_{j\mu\sigma}, \quad (2)$$

where $p^\dagger_{j\mu\sigma}$ creates an $O2p_{\mu\sigma}$ electron at the j-th O site. Since the core-hole potential effect is neglected for simplicity in the present

study, the O 1s XAS is equivalent to the angle-integrated IPES. The unpolarized O 1s XAS for incident energy $\omega_{\rm in}$ is given by

$$I^{\rm XAS}(\omega_{\rm in}) = \sum_{\mu,\sigma,k} I^{\rm IPES}_{\mu,\sigma}(\omega_{\rm in}, k). \quad (3)$$

In the following calculations, we adopt the Lanczos method to diagonalize H_{pd} in order to treat the electron correlation as exactly as possible. The obtained line spectra are convoluted with Lorentzian and Gaussian functions of an appropriate width, Γ. For the O 1s XAS, Γ is taken at 0.5 eV. For the photoemission and inverse photoemission, Γ is taken at 0.2 eV.

In the present study, a $(Cu_6O_{12})^{12-}$ cluster is called an "undoped system", while $(Cu_6O_{12})^{11-}$ is "1/6-doped" and so on. In the undoped case, the formal electron configuration of Cu ions is d^9 and that of O ions is p^6. However, owing to strong pd hybridization between Cu 3d and O 2p orbitals, the actual O 2p electron configuration deviates from p^6. Using this unoccupied part of O 2p states, the O 1s XAS process occurs, resulting in a sharp XAS peak. This O 1s XAS is also understood on the basis of a configuration-interaction (CI) picture. In the case of the undoped CuO_4 cluster, the ground state is described by a linear combination of d^9 and $d^{10}\underline{L}$ electron configurations, where $\underline{L}$ denotes a ligand (O 2p) hole [9]. The O 1s XAS process occurs using that $d^{10}\underline{L}$ weight contained in the ground state. The resulting XAS final state is purely d^{10}. In the calculated result shown in Fig. 1, the width of the d^{10} peak for the undoped case is about 1 eV, which is somewhat narrower than the experiment shown in the inset [3]. Since the lifetime of the O 1s core hole is assumed to be 0.5 eV in the present calculations, the intrinsic width of the d^{10} band in the theory is about 0.5 eV. With hole doping, the intensity of the d^{10} peak decreases and a new peak denoted as "d^9" grows up about 1.5 eV below the d^{10} peak instead.

In a CI picture, the ground state of "100%"-doped CuO_4, which is often called the ZRS state, is described by a linear combination of d^8, $d^9\underline{L}$ and $d^{10}\underline{L}^2$. For the ZRS-type initial state, there are two XAS final states, d^9 and $d^{10}\underline{L}$. According to numerical calculations (not shown here), the XAS intensity for d^9 is very high, while that to $d^{10}\underline{L}$ is negligible owing to phase matching between the initial- and final-state wave functions. In an approximation that regards the present doped six-plaquette cluster as the statistical average of undoped and 100%-doped isolated plaquettes, the lower energy peak (d^9) is interpreted as the XAS at the doped plaquettes, while the higher energy peak (d^{10}) the XAS at the undoped plaquettes. This simple statistical average approximation explains the doping dependence of the d^9 peak intensity relative to the d^{10} one shown in Fig. 1.

To understand the details of the O 1s XAS, we show the angle-resolved PES and IPES for the undoped system in Fig. 2, where the Cu $3d_{xy}$ and O $2p_{x,y}$ components are plotted separately for each k. Each k-integrated spectrum is the sum for $k/\pi = n/6\,(n = 0 - 5)$. In Fig. 2, the convolution width is 0.2 eV. If the convolution width is increased up to 0.5 eV, the sum of O $2p_{x,y}$ IPES coincides with the undoped case of the O 1s XAS shown in Fig. 1. As seen in Fig. 2, the intensity of the Cu 3d IPES is large over the Brillouin zone, which is contrast to the corner-share-type one-dimensional cuprates [10]. The band width seen in the present IPES is only about 0.5 eV. These show the localized nature of Cu 3d state. The origin of this small band width is in the fact that the Cu-O-Cu bond angle is 90 degrees. The coupling between Cu 3d orbitals occurs via the Cu-O-O-Cu path [11]. This make the effective Cu 3d band width small. Instead, owing to this small band width, the electron correlation effect is likely to be emphasized. For instance,

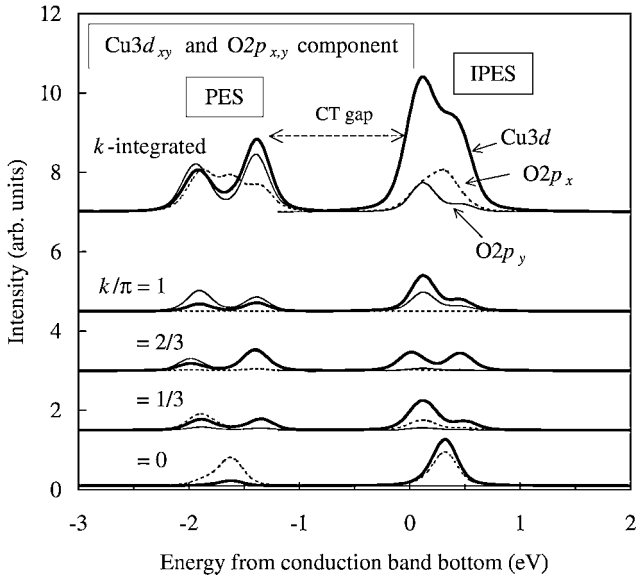

Fig. 2. The O $2p_x$ (dotted), O $2p_y$ (thin) and Cu $3d_{xy}$ (thick) components of the angle-resolved PES and IPES for the undoped case are plotted for each k point, together with the k-integrated spectra.

all the Cu 3d IPES intensity at $k/\pi = 2/3$ must be caused by the electron correlation, since there is no IPES intensity at this k point in the limit of vanishing U_{dd}. One may regard that the split IPES peaks at $k/\pi = 1/3, 2/3, 1$ represent dispersive *real* and *shadow* bands [12]. On the other hand, owing to the pd hybridization, the O $2p_x$ and $2p_y$ IPES is strong at $k/\pi = 0$ and 1, respectively. At $k/\pi = 2/3$, the O 2p contribution is very small. As a result, the O 2p component of the k-integrated IPES appears to be somewhat narrower than the Cu 3d component.

We show the angle-resolved IPES for the 1/3-doped case in Fig. 3. Upon hole doping, the Fermi energy shifts to the lower energy band below the CT energy gap. For each k point, the IPES consists of two peaks separated by the CT gap, which correspond to the d^9 and d^{10} peaks in the XAS. In contrast to the undoped case, there is no shadow band. It seems to be reasonable, since the antiferromagnetic spin fluctuations must be suppressed in the doped system.

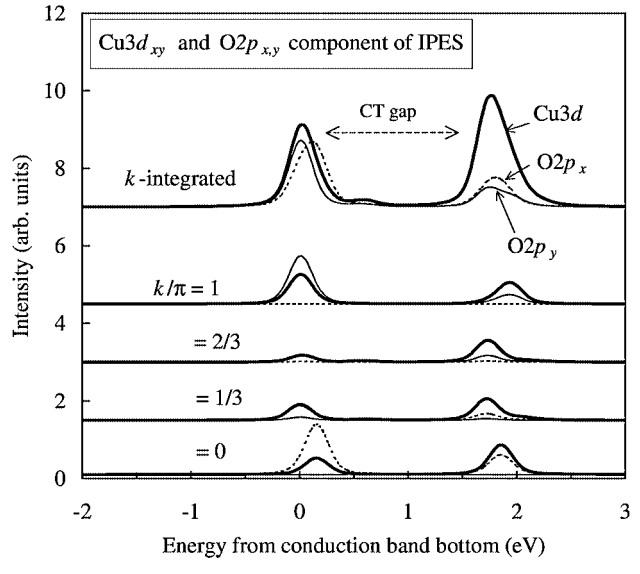

Fig. 3. The O $2p_x$ (dotted), O $2p_y$ (thin) and Cu $3d_{xy}$ (thick) components of the angle-resolved IPES for the 1/3-doped case are plotted for each k point, together with the k-integrated spectra.

To understand the angle-resolved spectra more in detail, we need to increase the cluster size. For this reason, we derive an effective single-band Hubbard Hamiltonian. The mapping procedure from the original *dp* Hamiltonian starts with an undoped CuO_4 plaquette. We define an effective d state by the ground state wave-function of the plaquette. Using this wave-function, we are able to calculate the effective hopping strength between the neighboring effective d states (t_1) and that between the next-neighbor pair (t_2) in larger clusters. With the present parameter values listed above, both t_1 and t_2 are estimated to be about 0.1 eV. The width of the corresponding tight-binding band (W) is about 0.6 eV. On the other hand, the effective Coulomb repulsion strength (U) is estimated to be about 1.8 eV to reproduce the insulating energy gap seen in the original pd model shown in Fig. 2. Thus U/W is about 3, which indicates the importance of electron correlation. Similarly, the mapping to a single band Hubbard model can be performed for the corner-share-type cuprates where the Cu-O-Cu bond angle is 180 degrees. With the parameter values used in the present study, t_1, t_2 and U are estimated to be about 0.35eV, zero and 2 eV, respectively [13]. In this case, U/W is 1.43, which is considerably smaller than that for the edge-share system. It is to be noted that the importance of t_2 in edge-share-type cuprates was suggested on the basis of theoretical calculations for Cu 2p core level photoemission [11].

In summary, we have discussed the O 1s XAS of edge-share-type cuprates. In this type of crystal structure, the effective hopping strength between Cu sites is very small. This is the reason why the localized nature of Cu 3d is emphasized. It is represented by the Cu 3d IPES component over the Brillouin zone. On the other hand, the k dispersion is small, since the effective hopping strength between Cu sites is small. These characteristic features are in contrast to the corner-share-type cuprates. The O $2p_{x,y}$ IPES component is strong only around $k/\pi = 0, 1$. As a result, the total width of k-integrated O $2p_{x,y}$ IPES is narrower than that of k-integrated Cu $3d_{xy}$ IPES. Even upon hole doping, the localized nature seen in the IPES remains unchanged. These characteristic features are consistent with the recent experiment.

We have also derived an effective single-band Hubbard model, which reproduces the band dispersion of the original *dp* Hamiltonian. A characteristic of the present system is that the hopping strength between the nearest neighbor sites is almost the same as that between the next-neighbor pairs.

Abstract

This paper describes a Path Integral approach to the thermal factor in EXAFS applied to one-dimensional systems with asymmetric double-well potentials, which is considered to be one of the models for chemical reactions, structual phase transitions and surfaces within of the clusters. For these systems quantum-tunneling effect plays an important role in both amplitude and phase of the EXAFS thermal factor. Classical approximation is not valid in the low temperature region, on the other hand cumulant expansion breaks at high temperature. We find an oscillating behavior in the phase of the thermal damping function, which is a specific feature for the case of asymmetric double-well potential.

1. Introduction

Theoretical approaches to the EXAFS thermal factor have been developed beyond harmonic approximation and classical approximation [1, 2]. The perturbation approaches are useful to describe weak anharmonicity in the analyses of temperature effects in EXAFS and they have provided interesting information based on cumulant expansion [3, 4, 5]. On the other hand, real space approaches have been widely used classical mechanically to relate the EXAFS Debye-Waller factors to interatomic potential [6]. Recently path integral technique is applied to EXAFS thermal factor for strongly anharmonic systems such as quartic and symmetric double-well [7], Morse potential [8] and some real systems [9]. This approach can be applied to strongly anharmonic systems, where the cumulant analyses break. In this paper we apply the path integral approach to the EXAFS thermal factors with asymmetric double-well potential which plays an important role for structral phase transition, chemical reactions and so on [10].

2. Theory

Let consider diatomic systems in a resorvir at temperature T whose relative vibrational motion is descrived by the Hamiltonian,

$$H = \frac{p^2}{2\mu} + V(q), \tag{1}$$

where μ is the reduced mass and q is the instantaneous interatomic distance. When we deal with statistical average of an operator A, we should calculate the trace $\langle A\rangle = \frac{1}{z}\mathrm{Tr}(A\rho)$ where ρ is the density operator defined by $\rho = \exp(-\beta H)$, $\beta = 1/k_B T$ and $Z = \exp(-\beta F) = \mathrm{Tr}(\rho)$ is the partition function for the system. The trace can be calculated by applying Feynman's path integral techniques, however, instead of summing over all paths in just one step, one can classify the paths into two groups as proposed by Feynman [11, 12]. The final expression for the average of a local operator A can be represented in terms of the probability density $P(q)$ just like in classical statistical mechanics

$$\langle A\rangle = \int A(q)P(q)\,\mathrm{d}q. \tag{2}$$

This expression, however, includes important quantum effects, and the probability is represented by

$$P(q) = \frac{1}{Z}\sqrt{\frac{\mu}{2\pi\beta}}\exp[-\beta V_L(q)], \tag{3}$$

where the local effective potential $V_L(q)$ is defined by

$$\exp[-\beta V_L] = \int \mathrm{d}q' \exp[-V_e(q+q')] \times \frac{1}{\sqrt{2\pi\alpha(q+q')}}\exp[-q'^2/2\alpha(q+q')]. \tag{4}$$

Now we used the self-consistent requirement [7, 12] to obtain the effective potential $V_e(q)$ and $\alpha(q)$. In the EXAFS analyses the operator A should be $\exp(2\mathrm{i}k\Delta q)$, where k is the wave vector of an ejected photoelectron, $k = |k|$ and Δ_q is the projected relative displacement, which is simply given by $\Delta q = q - q_0$ (q_0 is the equilibrium interatomic distance, in this case q_0 = 0) in one-dimensional cases. So what we should calculate to study EXAFS thermal factor is

$$G(k) = \langle\exp(2\mathrm{i}k\Delta q)\rangle = \int_{-\infty}^{\infty}\exp(2\mathrm{i}k\Delta q)P(q)\,\mathrm{d}q \tag{5}$$

in the plane wave approximation. When all the integrals in the cumulant and also the cumulant expansion converge, the thermal damping function $G(k)$ can be written,

$$G(k) = \exp\left\{-2k^2\langle q^2\rangle_c + \frac{2}{3}k^4\langle q^4\rangle_c - \cdots\right\} \times \exp\left\{\left[\mathrm{i}\left\{k\langle q\rangle_c - \frac{4}{3}k^3\langle q^3\rangle_c + \cdots\right\}\right]\right\}. \tag{6}$$

3. Result and Discussion

We now consider a strongly anharmonic system with asymmetric double-well potential

$$V(q)/\varepsilon = (q^2 - \sigma^2)^2 + \frac{q^3}{3} - q. \tag{7}$$

In the following applications we shall use the unit, $\sigma = \mu = 1$ for simplicity. (See Fig. 1.) The asymmetric potential $V(q)$ is also shown for reference. The two minima of $V(q)$ appear at $q = \pm 1$. Figure 1 shows the quantum and classical probability density $P(q)$ for the asymmetric double-well potential described by eq. (7). The

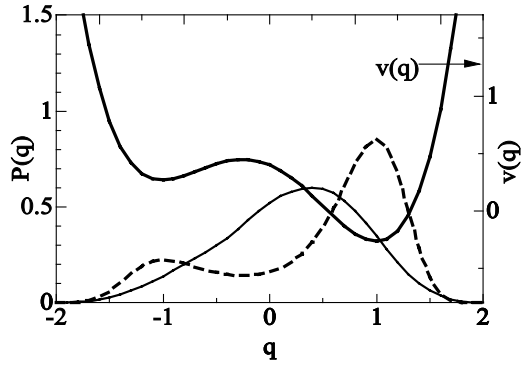

Fig. 1. An example of the quantum (solid line) and the classical (dashed line) probability density $P(q)$ for asymmetric double-well potential. The potential $V(q)$ is also presented (thick solid line).

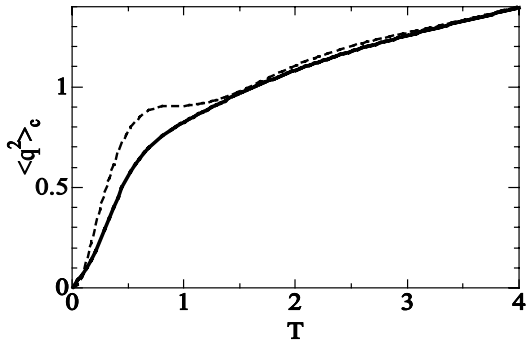

Fig. 2. The temperature dependence of the quantum (solid line) and the classical (dashed line) second order cumulant $\langle q^2\rangle_c$ for the asymmetric double-well potential. T is reduced temperature.

main peak position of the probability density is found at $q = 1$ in the classical case, on the other hand the peaks are shifted to the potential barrier in the quantum case because of the quantum tunneling effect. Figure 2 shows the second order cumulant $\langle q^2\rangle_c$ as a function of reduced temperature T calculated by use of the quantum (solid line) and the classical (dashed line) probability density $P(q)$. A classical particle in asymmetric double well potential is frozen at the lower bottom of the potential well at low temperature, so $\langle q\rangle = 1$ at $T = 0$. In the present asymmetric double-well potential, $\langle q^2\rangle_c = 0$ at $T = 0$, whereas $\langle q^2\rangle_c = 1$ for symmetric double-well potential [7]. In the quantum case, $\langle q^2\rangle_c$ for an asymmetric double-well potential shows similar behavior to that for quartic and symmetric double-well potentials [7].

Figure 3 shows the third order cumulant $\langle q^3\rangle_c$ as a function of reduced temperature T calculated by use of the quantum (solid line) and the classical (dashed line) probability density. The classical approximation gives good result at high temperature, on the other hand at low temperature that gives a poor result because of the quantum tunneling effect.

Figure 4 shows the amplitude $|G(k)|$ and phase ϕ in the thermal damping function at low temperature ($T = 0.016$) and Fig. 5 shows the same functions at high temperature ($T = 2$). They correspond to 8 K and 1000 K using the same parameter as for the symmetric double-well potential [7]. Although the symmetric double-well potential provides a real thermal factor as shown by eq. (5) because of the parity of $P(q)$, the asymmetric double-well potential gives complicated k-dependence of $|G(k)|$ and ϕ as shown in Fig. 4 and 5. The photoelectron wave number k is scaled for the case of potential minimum $\sigma = \pm 0.1$ Å. For the amplitude of the damping function $|G(k)|$, the

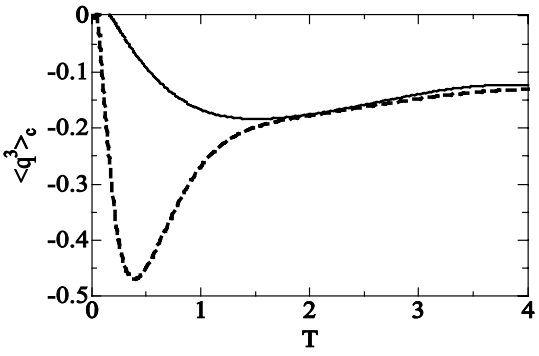

Fig. 3. The temperature dependence of the quantum (solid line) and the classical (dashed line) third order cumulant $\langle q^2\rangle_c$ for the asymmetric double-well potential. T is reduced temperature.

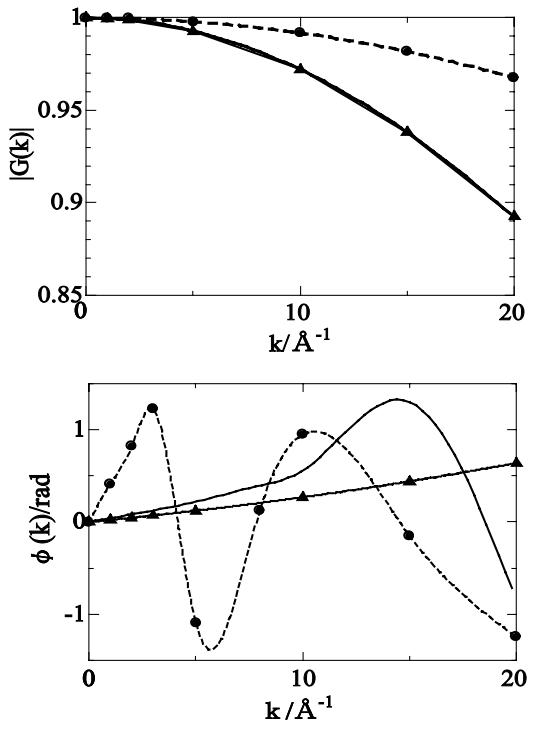

Fig. 4. The amplitude $|G(k)|$ and phase part ϕ in thermal damping function of EXAFS for the quantum (solid line) and the classical (dashed line with circle) probability density at $T = 0.016$ (this reduced temperature corresponds to 8 K using the same parameter as for the symmetric double-well potential). The cumulant expansion up to forth order (solid line with triangle) is also presented.

cumulant expansion provides much better result close to the self-consistent calculations obtained from eq. (5) than the classical approximation at lower temperature (Fig. 4). On the other hand, the result of the classical approximation is better than the cumulant expansion at higher temperature (Fig. 5).

For the phase function ϕ, the cumulant expansion is considerably good only at $k < 10$ Å^{-1} but it is poor at $k > 10$ Å^{-1} at lower temperature (Fig. 4). The classical approximation oscillates and gives poor results. At higher temperature (Fig. 5), the phase function in the classical and the self-consistent calculation show similar oscillations. This oscillation in the phase is characteristic for asymmetric double-well potentials due to the reflection of the photoelectron by two potential barriers. The cumulant expansion cannot predict such oscillating behavior any more.

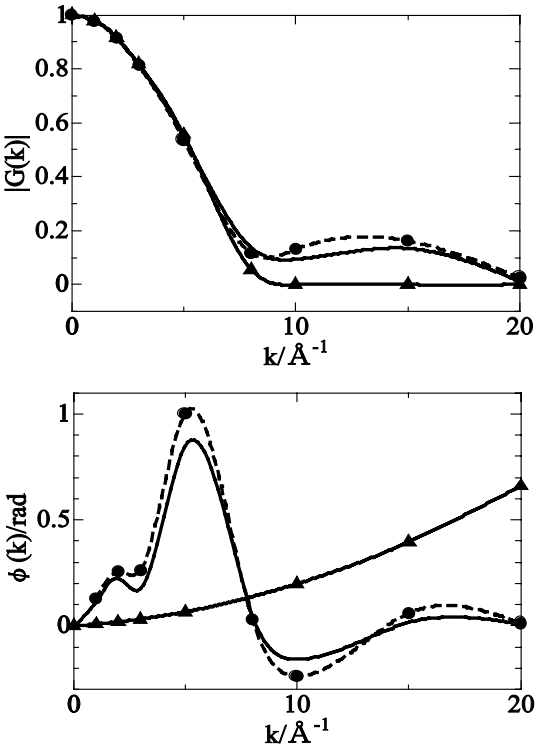

Fig. 5. The amplitude $|G(k)|$ and phase part ϕ in thermal damping function of EXAFS for the quantum (solid line) and the classical (dashed line with circle) probability density at $T = 2$ (this reduced temperature corresponds to 1000 K using the same parameter as for the symmetric double-well potential). The cumulant expansion up to forth order (solid line with triangle) is also presented.

4. Conclusion

The real space method based on finite temperature path integral theory has been applied to EXAFS thermal factor for strongly anharmonic systems as asymmetric double-well potentials. We can study the applicability of the cumulant expansion and the classical approximation in EXAFS analyses. First, the probability density $P(q)$ was calculated using a path integral approach for asymmetric double-well potentials. From the probability density, the second order cumulant $\langle q^2 \rangle_c$ and the third order cumulant $\langle q^3 \rangle_c$ were evaluated as a function of temperature. We also discuss a new feature observed in the phase oscillating of the EXAFS thermal factor for the present asymmetric double-well potential.

Abstract

A new scheme of capacitance-detection for the X-ray absorption fine structure (XAFS) was reported recently [M. Ishii, Phys. Rev. B **65**, 085310 (2002)]. The absorption of X-rays leads to oscillations in the steady state capacitance of a Schottky barrier diode which were interpreted as a "site-selective" detection of deep level centers. We have performed XAFS at the K-edge of gallium and arsenic on GaAs and AlGaAs Schottky-diodes containing DX and EL2 defect centers. For the detection, different techniques were applied: the photocurrent under short circuit conditions, the steady state impedance, and X-ray induced capacitance transients were measured. The results are compared with conventionally detected XAFS spectra (absorption, fluorescence). No evidence for a site-selectivity of the capacitance EXAFS is found in our studies. Based on a detailed analysis of the different detection techniques we strongly question the proposed "site-selectivity".

1. Introduction

The method of X-ray absorption fine structure (XAFS) analysis is ideally suited to determine the properties of point defects in semiconductors [1, 2]. The major limit of this technique is the incapability to separate signals from the same atoms located at different lattice sites. Point defects in semiconductors in concentrations lower than $10^{15}\,\mathrm{cm}^{-3}$ crucially determine material properties and their attributes are of eminent interest in device processing. The X-ray absorption on such highly diluted systems is hidden in the absorption background from elastic scattering and from photoionization of other elements and of higher atomic shells. Techniques, sensitive to defect specific properties, are used in routine studies of semiconductors [3]. Most prominent method is the Deep Level Transient Spectroscopy (DLTS) [4], which analyses thermally stimulated changes of deep level charge state. As a thermal spectroscopy the spectral resolution is limited, but their sensitivity is extremely high [4].

2. Experimental

Our experiments are based on (*i*) thin layers (5 µm) of $Al_xGa_{1-x}As$ ($x = 0.3$) grown by molecular beam epitaxy on highly conductive GaAs substrates doped with Se and on (*ii*) (100)-oriented, virtually gradient free (VGF) grown, n-type bulk GaAs from MCP Wafer Technology Ltd., which was nominally undoped. The free electron concentration is $1.3 \times 10^{17}\,\mathrm{cm}^{-3}$ in the epitaxial layers and is $2.5 \times 10^{16}\,\mathrm{cm}^{-3}$ in the bulk GaAs samples. The XAFS measurements were performed at HASYLAB, DESY, Hamburg using a double crystal Si(111) monochromator with a flux of up to 10^{10} photons $\mathrm{s}^{-1}\,\mathrm{mm}^{-2}$.

3. Principles of site-selectivity

One major limit of EXAFS technique is the incapability to separate signals from the same atoms located at different lattice sites. 'Site-selective' means to sort out just one lattice position of an atom from others by measuring the specific response of that configuration stimulated by the X-ray absorption at that atom. This can be, for example, a change in charge state of deep level center or an excitonic-like emission of photons.

Site-selectivity could be achieved by inner shell excitation of a defect atom and the de-excitation which results in the loss of an electron already trapped at the defect level. In a space charge region the density of fixed charges will change by this process and a junction capacitance response is observable.

There are different possibilities for the photon absorption:

(*i*) The X-ray photons interact directly with the defect by exciting the trapped electron to the conduction band.
(*ii*) The X-ray photons excite the K-shell electron to leave the defect and the trapped electron is consumed in the relaxation of the core hole (Fig. 1(a)).
(*iii*) The relaxation of the core hole occurs via Auger processes and the K-shell energy is transferred to electron hole pairs and subsequently an excess hole from the valenc band is captured by the defect with no distinction which atom (bulk or defect constituent) was primarily excited (Fig. 1(b)).

The relaxation times for processes (*i*) and (*ii*) are proportional to the absorption cross-section of the K-shell; whereas the process (*iii*) is proportional to amount of excess carriers from the photocurrent. The time constants of these two processes can be computed easily and have to be compared with the observed capacitance transients.

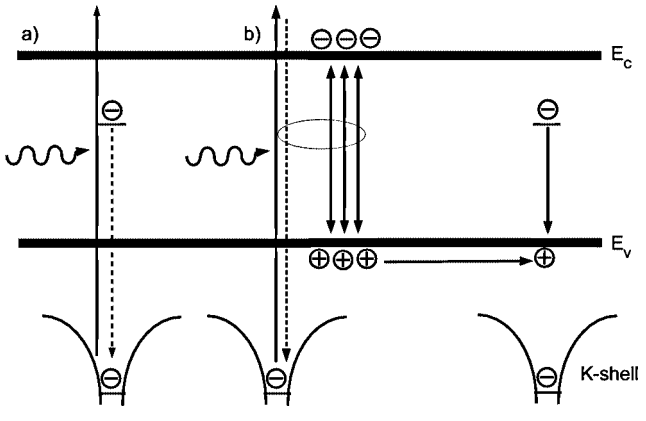

Fig. 1. Change of defect level occupation by bulk absorption of X-ray absorption: a) a site selective, direct absorption at the defect and successive capture of the devect electron, b) bulk absorption and subsequent generation of diffusing electron-hole pairs, subsequent recombination of minority carrier with the defect electron.

4. Results

4.1. *X-ray induced photocurrent*

The detection of X-ray absorption oscillations by induced currents in space charge structures is a rarely realized technique. Early reports on measurements of XAFS spectra on GaAs diodes show that the fluorescence signal and the photocurrent contain the same information if appropriate corrections are applied [5]. Furthermore, XAFS detection by X-ray stimulated photoconduction of bulk crystals was reported [6]. The relaxation of core holes inside the sample creates electron-hole pairs. The photocurrent generated directly in the space-charge region is negligible here, because the penetration depth of X-rays is much larger than the space-charge width of the junction (less than 1 μm). Therefore the dominant part of the photocurrent originates from minority charge carriers generated in bulk which diffuse with a diffusion lengths of some ten microns to the edge of the depletion region and and drift throughout that layer to the metal electrode.

4.2. *Changes in the steady-state capacitance due to X-ray irradiation*

Capacitance and photocurrent signals are within experimental error identical and show the expected energy of the Ga(K)-edge as well as a fine structure due to Ga atoms on undisturbed lattice sites in an almost perfect Al_xGa_{1-x} As crystal (Fig. 2).

The X-ray irradiation not only induces a photocurrent, but also leads to changes in the diode steady state capacitance. By phase-sensitive measurements of the alternating currents at small applied alternating bias one estimates the parameters of the overall sample as an electrical network with an imaginary and a real part. Such data are easily interpreted, if the sample is a passive two pole network dominated by its imaginary part. Under irradiation the Schottky barrier diode becomes an active two pole network with a more complex behavior. The photo current j_{photo} has now to be added to the network as a current source parallel to the capacitance and the total current density j_{total} is given by:

$$j_{total} = j_{diode} - j_{photo}.$$

Taking into account the dependence of j_{diode} on the (internal) voltage U over the depletion layer one obtains for the open circuit photo voltage U_{open}, i.e. $j_{total} \equiv 0$

$$U_{open} = U_T \ln(j_{photo}/j_0 + 1). \quad (1)$$

The saturation current j_0 contains all material and junction specific parameters as e.g. Schottky barrier height or band gap energy for pn-junctions. From current voltage measurements j_0 can be estimated experimentally and with (1) the actual voltage over the depletion layer in dependence on the photo current is obtained. That means, independent of the operation mode of the diode (open or short circuit conditions) the capacitance increases with increasing photocurrent because of the decreasing depletion width. For the relative change of capacitance by a relative variation of bias at the depletion layer one obtains:

$$\Delta C/C_0 = 0.5\left(1 - \frac{1}{1 + \Delta U/U_0}\right). \quad (2)$$

For our Schottky diodes j_0 was $10^{-9}\,\mathrm{A\,cm^{-2}}$ and j_{photo} under X-ray illumination was about $10^{-7}\,\mathrm{A\,cm^{-2}}$. From that a potential change of 50 mV can be expected, which would result in a capacitance change of up to one percent as observed in experiment.

From the above discussion we conclude, that the photocurrent is responsible for the changes in the steady state capacitance. Therefore, the capacitance-EXAFS spectrum can not contain additional or other information that what is obtained by the X-ray induced photo current.

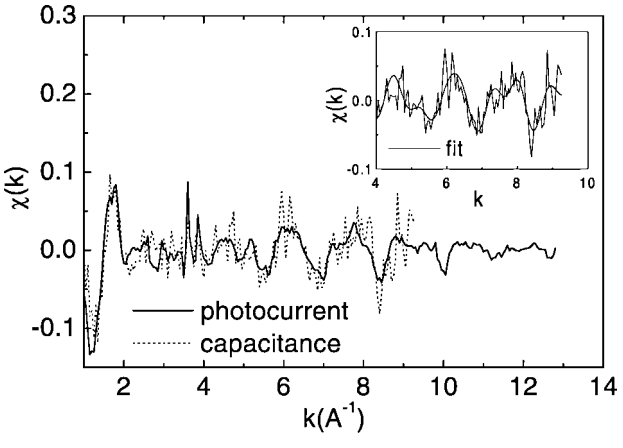

Fig. 2. EXAFS spectra $\chi(k)$, measured as steady-state capacitance and as photocurrent of a Schottky barrier diode on n-type $Al_xGa_{1-x}As$:Se ($x = 0.3$). The original energy spectra were taken near the Ga absorption K-edge ($V = 0$ V, $f = 5$ MHz). The insert shows an enhanced fraction of the capacitance signal together with a fit with the parameters according to the photocurrent signal.

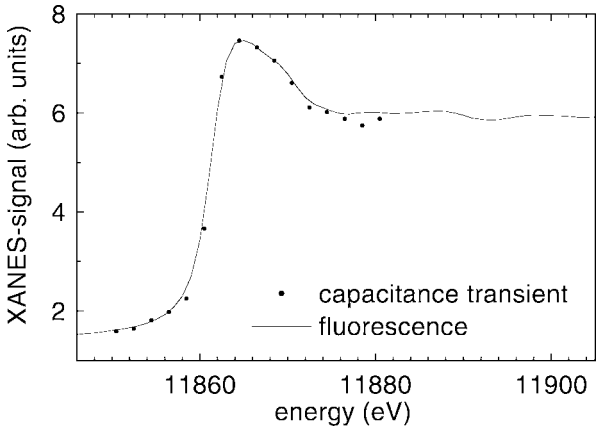

Fig. 3. Comparison of X-ray induced capacitance time constants with the fluorescence spectrum at the K-edge of As in bulk GaAS.

4.3. *X-ray induced capacitance transients*

A new way to measure XAFS oscillations arises from the detection of the time constant from capacitance transients as a function of X-ray energy (Fig. 3) [7]. The photon absorption at the defect is described by an optical cross section σ under the local photon flux ϕ at the defect which is simply related to a transition time constant τ by:

$$\tau = (\sigma \times \phi)^{-1}.$$

The absorption cross section of arsenic at the K-edge is $\mu = 2 \times 10^{-20}\,\mathrm{cm^2}$. The time constant for the trap ionization by 'site-selective' X-ray absorption (process (a)) can be estimated at HASYLAB to be

$$\tau = (\mu \times \phi)^{-1} \approx 5 \times 10^5\,\mathrm{s};$$

far beyond any experimental relevance.

The time constant of process (b) is related to the minority capture coefficient c_p from Shockley-Read-Hall statistics and is

given by:

$$\tau = \frac{q v_{drift}}{c_p j_{photo}}$$

with q denoting the elementary charge unit, v_{drift} the drift velocity inside the depletion layer, and j_{photo} the photocurrent density. With the measured photocurrent density $j \approx 1 \times 10^{-7}\,\mathrm{A\,cm^{-2}}$ and the capture coefficient for hole capture $c_p = 5.5 \times 10^{-8}\,\mathrm{cm^3\,s^{-1}}$ [3] one gets:

$\tau \approx 300\,\mathrm{s}$.

Thus, from the occurrence, amplitude or direction of a transient itself one can not deduce the underlying physical process. Only a calculation of the expected time constants according to the experimental conditions and the given specific defect parameters can clarify what physical process dominates.

5. Conclusions

Our measurements have shown that the trap ionization takes place significantly faster and can only be explained by hole capture from the photocurrent and not by direct 'site-selective' absorption processes. Thus, the capacitance EXAFS gives the same information as the measurement of the photocurrent – which is the absorption fine structure of the bulk material and not of the defects. From our analyses we find no evidence for a site-selectivity of capacitance EXAFS.

Acknowledgments

We acknowledge the stimulating discussions with R. Sielemann which initiated this study. A. W. R. Leitch, University of Port Elizabeth, SA supplied the AlGaAs samples and P. Gladkov prepared the contacts to the GaAs samples. Valuable and numerous discussions with D. Meyer on the EXAFS technique are acknowledged. The work was funded by the BMBF under contract 05KK10DA/2.

Abstract

The red color of ruby (α-Al_2O_3:Cr^{3+}) is assigned to transitions between 3d states of the chromium ion. A precise description of the structural and electronic environment of the Cr^{3+} ion in its slightly distorted octahedral site (C_3 symmetry) is needed to understand the cause of the color. We have analysed the Cr K-edge in α-Al_2O_3:Cr^{3+} with a reciprocal space approach that allows the computation of self-consistent spin polarized charge density for large unit cells, beyond the traditional "muffin-tin" approximation. Structural and electronic information is deduced from the calculation.

1. Introduction

The beautiful red color of ruby (α-Al_2O_3:Cr^{3+}) results from chromium impurities, that substitute for aluminum atoms in the structure. To understand the cause of the color, it is necessary to have a precise description of the local environment around the coloring atom. The positions of UV-VIS absorption bands indeed depend on the chemical bonding between the coloring atom and its nearest neighbors [1, 2, 3]. X-ray absorption spectroscopy is a powerful structural and electronic probe of matter. However, structural determination by Extended X-ray Absorption Fine Structure (EXAFS) is difficult in that case due to the low chromium concentration [4]. The XANES signal (X-ray Absorption Near Edge Structure), including the pre-edge, presents larger features, and contains structural and electronic information up to the medium range order. However, its interpretation is not straightforward and requires sophisticated simulation tools. In this paper, we show what kind of information it is possible to extract from the analysis of the angular dependence of the XANES spectrum at the Cr K-edge of α-Al_2O_3:Cr^{3+}, using a recently developed full potential scheme [5].

The crystal structure of α-Al_2O_3 belongs to the space group $R\bar{3}2/c$ or D^6_{3d} [6]. Therefore, in the electric dipole approximation, the absorption cross section of such a material depends on the angle θ between the C_3 axis and the polarization of X-rays [7]. The ionic radius of chromium atoms is larger than the ionic radius of aluminum atoms ($r_{Cr^{3+}} = 0.615$ Å and $r_{Al^{3+}} = 0.535$ Å in an octahedral site [8]). A modification of the chromium site in α-Al_2O_3:Cr^{3+} compared with the one of aluminum in α-Al_2O_3 is expected.

This article is divided into three parts. In the first part, we recall the main aspects of the calculation method. In the second part, we detail the structural information extracted from the XANES analysis. Electronic information is also given from the analysis of pre-edge features. In the third part, the results are discussed.

2. Calculation of the Cr K-edge XANES spectrum

Since the calculation method is detailed in a recent article [5] and in these proceedings [9], we just recall the main aspects of this reciprocal-space non "muffin-tin" approach. The scheme is implemented in an *ab initio* code [10] based on the Density Functional Theory (DFT) within the Local Density Approximation (LDA) that computes the spin polarized charge density self-consistently. The absorption cross section is computed in the electric dipole (E1) and quadrupole (E2) approximation. It is then possible to calculate the XANES signal on large supercells, and to take into account the 1*s* core hole effect on the absorption atom. In fig. 1, the calculation is compared to the experimental spectrum registered on the ID12A beam line (European Synchrotron Radiation Facility). The spectrum has been recorded on a single crystal and a reliable method has been applied to remove diffraction peaks [4]. The experimental layout is described in the following. All measurements have been made with the direction of the $\hat{k}$ X-ray wave vector ($[10\bar{1}]$ in the rhombohedral lattice) perpendicular to the surface of the sample, where the C_3 axis ([111]) and the polarization vector lie.

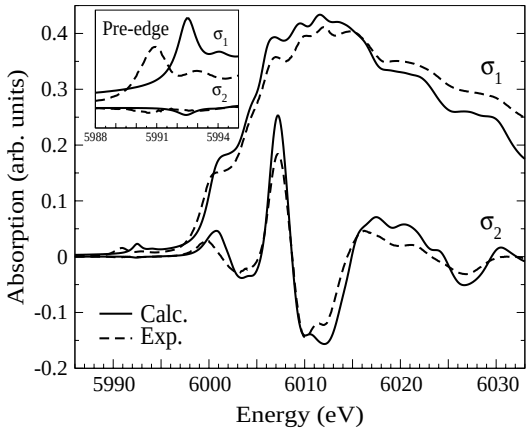

Fig. 1. Calculated (bold line) and experimental (dashed line) σ_1 and σ_2 spectra at the Cr K-edge in α-Al_2O_3-Cr^{3+}.

When $\theta = 0$ (resp. $\pi/2$), the absorption cross section measured is $\sigma_\parallel$ (resp. $\sigma_\perp$). In the electric dipole approximation, the angular mean $\sigma_1 = \frac{2\sigma_\perp + \sigma_\parallel}{3}$ is the isotropic absorption cross section, while $\sigma_2 = \sigma_\parallel - \sigma_\perp$ is the dichroic cross section.

The calculation is carried out on a rhombohedral $2 \times 2 \times 2$ supercell, resulting from an *ab initio* Car Parrinello energy minimization [11], and containing 1 chromium atom, 31 aluminum atoms and 48 oxygen atoms [4]. The calculation is carried out in two steps. First, charge density is computed using Troullier Martins potentials [12]. The electronic configuration of the chromium atom is $1s^1 2s^2 2p^6 3s^2 3p^6 3d^3$. The 1s, 2s, 2p are core states and the core radii of 3s, 3p, and 3d valence states are 0.53 Å, 0.90 Å, and 0.90 Å respectively. The charge density is computed on one *k*-point, with a 64 Ryd energy cut-off. The

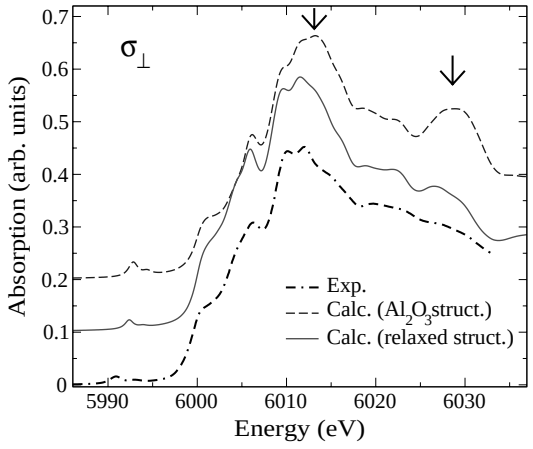

Fig. 2. Comparison of the SCF FP calculation on two different structural models. In the unrelaxed structure, the chromium atom substitutes exactly for an aluminum atom. The relaxed structure is given by an *ab initio* Car Parrinello code.

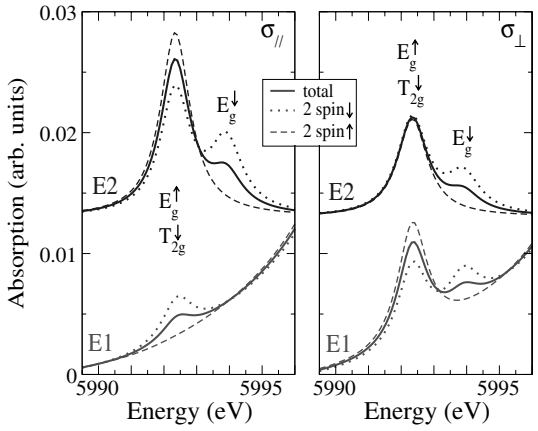

Fig. 3. Zoom on the pre-edge features of $\sigma_{\parallel}$ (left) and $\sigma_{\perp}$ (right) absorption cross sections in Al_2O_3:Cr^{3+}. The full lines are the calculated spectrum in the electric dipole (E1) and electric quadrupole (E2) approximation. The dotted lines are the spin down component and the dashed line are the spin up component of the signals.

XANES calculation is made in a second step. The cross section is computed on a 32 k-point grid.

3. XANES interpretation

3.1. *Structural information*

The XANES $\sigma_{\perp}$ cross section has been calculated on two different structural models (fig. 2). In the first one, atoms have the same position as in α-Al_2O_3 but one aluminum atom has been replaced by one chromium atom. The second structural model is given by an *ab initio* energy minimization [4]. The two calculated spectra reproduce the experimental spectrum reasonably well. However, the two features around 6010 eV on the experimental spectrum are not given by the calculation performed on the non relaxed structure. Moreover, this computed signal displays a large feature around 6030 eV, that does not appear in the experiment. The calculated spectrum obtained with the relaxed stucture is in good agreement with the experiment, it is then validated.

3.2. *Electronic information*

The pre-edge features contain useful information on the electronic structure around the probed atom. The electronic configuration of the absorbing atom in its ground state is [Ar]$3d^3$. It lies in a slightly distorted octahedral site. The asymmetry of the site can be evaluated by the parameter $2\frac{d_{Cr-O_1}-d_{Cr-O_2}}{d_{Cr-O_1}+d_{Cr-O_2}}$, whose value is 2.5%. The pre-edge features are made from a sum of electric quadrupole $1s \rightarrow 3d$ transitions, and of electric dipole $1s \rightarrow p$ transitions. Since the chromium site is not centrosymmetric, the p states are present at the pre-edge through 3d – p hybridization. The electric dipole and electric quadrupole contributions to the absorption cross section in the pre-edge region are represented in fig. 3. The contributions of spin up and spin down are detailed. The interpretation of the features is possible through group theory in the monoelectronic approach, using the character tables of the C_3, C_{3v} and O_h symmetry groups from [3]. The irreducible representations (irrep) of transitions, given by $\Gamma_f \otimes \Gamma_{\mathcal{O}} \otimes \Gamma_i$ depends on the symmetries $\Gamma_{\mathcal{O}}$ of the transition operator $\mathcal{O}$ and on the ones (Γ_f) of the final state (p or d) since the initial state (Γ_i) is totally symmetric. Allowed transitions belongs to the totally symmetric irrep. Although the symmetry of the Cr site in α-Al_2O_3 is C_3, it is allowed to treat it as if it is C_{3v} because there is no spin orbit coupling in the calculation. It is interesting to know what becomes the C_{3v} irrep in O_h symmetry. The p orbitals ($t_{1u}(O_h)$ irrep) are split into two irreps, that are $A_1(C_{3v})$ for the $p_{\parallel C_3}$ states and $E(C_{3v})$ for the $p_{\perp C_3}$ states. Concerning d states, the $e_g(O_h)$ irrep becomes $E(C_{3v})$ and the $t_{2g}(O_h)$ irrep is split into $A_1(C_{3v})$ and $E(C_{3v})$.

According to the experimental layout described before, the wave vector $\hat{k}$ stays perpendicular to the C_3 axis. In the case of pure electric quadrupole transitions ($1s \rightarrow 3d$), $\mathcal{O} = \hat{\varepsilon}{\cdot}r\hat{k}{\cdot}r$ belongs to the $E(C_{3v})$ irrep, for all angles θ between the C_3 axis and the X-ray polarization $\hat{\varepsilon}$ ($\hat{k} \perp C_3$ axis). Permitted transitions happen toward states belonging to the $E(C_{3v})$ irrep. These states are the corresponding $e_g(O_h)$ and $t_{2g}(O_h)$ in O_h symmetry. Since the $t_{2g}^{\uparrow}(O_h)$ are full, the transition toward $e_g^{\uparrow}(O_h)$ is the single transition permitted for spin up states. For spin down states, transitions toward $t_{2g}^{\downarrow}(O_h)$ and $e_g^{\downarrow}(O_h)$ are permitted. In the case of electric dipole transitions ($1s \rightarrow p$), the irrep of $\mathcal{O} = \hat{\varepsilon} \cdot r$ depends on the angle θ. If $\hat{\varepsilon}$ is parallel to the C_3 axis, then $\mathcal{O}_{\parallel} = \hat{\varepsilon}_{\parallel} \cdot r$ belongs to $A_1(C_{3v})$. The transition toward $A_1(C_{3v})$ is the single permitted transition. It corresponds to the $p_{\parallel C_3}$ states. These states cannot hybridize with $E(C_{3v})$ states, because they have not the same symmetry. There is no $p_{\parallel C_3}$-$e_g(O_h)$ hybridization. Given that $t_{2g}^{\uparrow}(O_h)$ states are full, no transition is allowed for spin up states. One transition toward $t_{2g}^{\downarrow}(O_h)$ is allowed for spin down states. If $\hat{\varepsilon}$ is perpendicular to the C_3 axis, then $\mathcal{O}_{\perp} = \hat{\varepsilon}_{\perp} \cdot r$ belongs to $E(C_{3v})$. The transition toward $E(C_{3v})$ symmetry states are the single permitted transitions. It corresponds to the $p_{\perp C_3}$ states in C_3 symmetry. Hybridization with both $e_g(O_h)$ and $t_{2g}(O_h)$ states are possible. For spin up states, the transitions occurs toward $e_g^{\uparrow}(O_h)$ and for spin down states, the transitions are toward both $e_g^{\downarrow}(O_h)$ and $t_{2g}^{\downarrow}(O_h)$ states.

From the calculation, we deduce that the $e_g^{\uparrow}(O_h)$ states lie about at the same energy as the $t_{2g}^{\downarrow}(O_h)$ states. Moreover, it is possible to deduce the energy difference between the $e_g^{\downarrow}(O_h)$ and the $t_{2g}^{\downarrow}(O_h)$ states by the energy difference of the first two features, which are 1.4 eV (resp. 2.0 eV) for the calculated (resp. experimental) spectrum. The difference between these two values may be linked to the DFT approach.

4. Discussion

Our main goal is to show that it is possible to extract precise information from XANES, thanks to an efficient self consistent (SCF) full potential (FP) code.

From fig. 1, the SCF FP calculation is in good agreement with the experimental spectrum. The calculation reproduces well the positions and the intensities of the features. A good adequacy between the calculated and the experimental spectrum is needed to succeed in extracting information from XANES spectra. It is obtained only by both a full potential and a self consistent approach. Indeed, a comparison on the shape of the potential used has been made between two SCF calculations in the electric dipole approximation: the above FP SCF method and a SCF "muffin-tin" calculation. The SCF "muffin-tin" calculation was made in real space on a system containing 102 atoms, within the full multiple scattering approach using the `feff8` code [13]. We have also analyzed the influence of the self consistency on two FP calculations in the electric dipole approximation. The FP non-SCF calculation is made in real space on a system containing 102 atoms, within the finite difference full potential approach (`fdmnes` code) [14]. The electronic density is described by the superposition of the neutral atoms. In the case of a SCF non-FP or FP non-SCF calculation, the shape of the calculated spectrum is not so good. In particular, for such calculations, the differences between the spectra calculated with the relaxed or the unrelaxed structure are as large as the differences between the calculated and the experimental spectra. The validation of any structural model is then impossible with FP non-SCF or SCF non-FP methods. It should be noticed that in the case of Al_2O_3:Cr^{3+}, the two structural models are very close, since they are different only by the positions of the neighboring atoms of the chromium atom. The Cr-O and Cr-Al distances deduced from the validation of the relaxed structure by the SCF FP method have already been discussed in [4].

The presence of the 1s core hole is needed to obtain a good agreement between the calculation and the experimental spectrum. In particular, the positions of the pre and near edge features are shifted towards lower energies due to the presence of the 1s core hole. But even with the 1s core hole, the positions of the calculated pre and near edge features are displaced with respect to experiment. This may be due to the approximations that are made in the DFT-LDA calculation. Excited states are usually rather badly described by DFT calculations. Multielectronic interactions are not taken into account by the effective potential. Localized states like the core hole or the Cr 3d orbitals are present in the calculation within the LDA approximation.

Pre-edge features measure the density of localized empty states (3d and hybridized p – 3d states). They contain information on the electronic structure of Al_2O_3:Cr^{3+}, particularly on 3d orbitals, that are involved in the absorption process that causes the color. From the calculation, it is possible to separate the contributions from each spin, and from electric dipole and electric quadrupole transitions. The pre-edge is composed of a large contribution of electric quadrupole transitions, compared to electric dipole ones. In fact, the chromium site is not centrosymmetric, but the asymmetry from a pure octahedral site is small (2.5%). Electric dipole transitions are then rather weak, corresponding to a weak p-d mixing.

The crystal field extracted from XANES should be compared carefully with results from other spectroscopies, because it has not the same signification in all cases. The value from XANES is 2.0 eV, while it is 1.8 eV from X-ray magnetic circular dichroism ($2p^63d^3 \rightarrow 2p^53d^4$ transitions) [15], and 2.23 eV from UV-VIS spectroscopy (d-d transitions) [16].

5. Conclusion

We have calculated the Cr K-edge XANES spectrum though an efficient calculation scheme. The XANES structural interpretation offers an alternative to the EXAFS analysis and the electronic structure interpretation provides useful information to clarify the origin of color in ruby. Such a kind of XANES interpretation will be applied to the study of other impurities in α-Al_2O_3, particularly in blue sapphires (α-Al_2O_3:Fe-Ti), to show the role of charge transfer in the cause of the color.

Acknowledgments

Abstract

L XAFS spectra of polycrystalline Fe and Cr films are investigated by EXAFS and TEY (Total Electron Yield) techniques. A new method of obtaining local structure information from overlapping *L* XAFS spectra for 3d metals is proposed. Tikhonov regularization method of solving ill-posed problem is used. In contrast to the conventional methods (Fourier transformation and fitting procedures) this method does not demand any model assumption and any special procedure of deconvolution of L_1 –, L_2 –, L_3 – contributions. The parameters obtained from *L* XAFS spectra of polycrystalline Fe and Cr films (interatomic distance and coordination number for the first and the second coordination shells) agree with the expected crystallographic values. Up to now the regularization method was applied only to nonoverlapping XAFS spectra.

1. Introduction

If the photon energy is high enough to excite an electron from an atomic core to the continuum, an edge-jump is found in the X-ray absorption coefficient. The excitation thresholds K, L_1, L_2, L_3 correspond to the transition of $1s_{1/2} \rightarrow \varepsilon p, 2s_{1/2} \rightarrow \varepsilon p, 2p_{1/2} \rightarrow \varepsilon s, \varepsilon d, 2p_{3/2} \rightarrow \varepsilon s, \varepsilon d$. The special feature of *L* spectra of 3d metals is overlapping. Fig. 1 shows model *L* spectra (total one and separate contributions) for pure Fe calculated by FEFF8 [1].

We propose a new method of obtaining local structure information from the overlapping *L* XAFS spectra for 3d metals using Tikhonov's method of solving ill-posed problem [2]. Up to now this method was applied to nonoverlapping EXAFS spectra [3, 4]. Recently a special procedure of deconvolution L_2 –, L_3 – contributions [5] was used for obtaining local structure information.

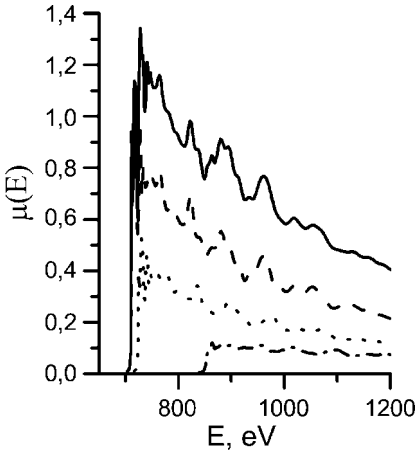

Fig. 1. FEFF8 simulation of *L* spectra (the total one (solid line) and the separate contributions: L_3 (dash line), L_2 (dot line) and L_1 (dash dot line)) for pure Fe.

2. Mathematical algorithm

For one component systems the atomic distribution is described by the pair correlation function (PCF) $g(r)$ which may be written as

$$g(r) = \frac{1}{4\pi\rho_0} \sum_l \frac{N_l}{r_l^2 \sigma_l \sqrt{2\pi}} \exp\left(-\frac{(r-r_l)^2}{2\sigma_l^2}\right). \quad (1)$$

Here ρ_0 is atomic density, N_l is coordination number for the l shell, σ_l is Debye–Waller factor for the l shell, r_l is position of the l shell. The normalized oscillating part of the EXAFS signal $\chi(k)$ for the K – spectrum is described as

$$\chi(k) = 4\pi\rho_0 \int_0^\infty R(k) \frac{f(k,r)}{k} \exp\left(\frac{-2r}{\lambda(k)}\right) \times \sin(2kr + 2\delta(k) + \varphi(k,r)) g(r) \mathrm{d}r. \quad (2)$$

Here $R(k)$ is reduction factor, $f(k,r)$ is a backscattering amplitude module, $\lambda(k)$ is the mean free path of a photoelectron, $\delta(k)$ is central atom phase shift and $\varphi(k,r)$ is a backscattering phase. All values are calculated by FEFF8 [1].

Using the dispersion laws for L_3, L_2, L_1 spectra one may conclude that *L* spectra have the same *E* space but different *k* spaces (namely, k_1, k_2, k_3). The laws for connection of k_1, k_2, k_3 spaces is found as:

$$k_2 = f(k_3) = \sqrt{k_3^2 + (E_3 - E_2)/a},$$
$$k_1 = h(k_3) = \sqrt{k_3^2 + (E_3 - E_1)/a}, \quad (3)$$

where E_3, E_2, E_1 are energies of L_3, L_2, L_1 edges, $a = \hbar^2 k^2/(2m) = 3.81$. Now the equation for the sum of L_1, L_2, L_3 EXAFS spectra in unified k_3 space may be written as [6]:

$$\chi_{sum}(k_3) = W_{L3}\chi_{L3}(k_3) + W_{L2}\chi_{L2}(k_2 = f(k_3)) + W_{L1}\chi_{L1}(k_1 = h(k_3)), \quad (4)$$

where W_{L3}, W_{L2}, W_{L1} are weight coefficients used to account the contributions of each edge and calculated by FEFF8 [1].

For *L* spectra the radial matrix elements are given by M_{01} for $l = 1 \rightarrow l = 0$ transitions and M_{21} for $l = 1 \rightarrow l = 2$ transitions. As shown in [7] for elements with $Z \geq 20$ the ratio M_{01}/M_{21}

is nearly independent of k, and the $p \to s$ contributions are practically unobservable, as $p \to d$ transitions are favored by a factor of 50. This means that all M_{01} contributions in the integral equation can be neglected and hence the L spectra can be analyzed in the same way as is done for the K spectra.

The integral equation for overlapping L spectra has the form:

$$\chi(k_3) = 4\pi\rho_0 \int_0^\infty \mathrm{d}r\ g(r) \times \left\{ W_{l1} \frac{f_1(k_1,r)}{k_1} \exp\left(\frac{-2r}{\lambda_1(k_1)}\right) \sin(2k_1 r + 2\delta_1(k_1) + \varphi_1(k_1,r)) + W_{l2} \frac{f_2(k_2,r)}{k_2} \exp\left(\frac{-2r}{\lambda_2(k_2)}\right) \sin(2k_2 r + 2\delta_2(k_2) + \varphi_2(k_2,r)) + W_{l3} \frac{f_3(k_3,r)}{k_3} \exp\left(\frac{-2r}{\lambda_3(k_3)}\right) \sin(2k_3 r + 2\delta_3(k_3) + \varphi_3(k_3,r)) \right\}. \quad (5)$$

If we compare Eq. (2) for Kspectra and Eq. (5) for L spectra we can see that in the last case we have the integral Fredholm equation with more complex kernel than in the first one. For L spectra it is possible to use the regularization method without any modification. Details of solving the EXAFS ill-posed problem may be found in [2–4]. For multicomponent systems the theory is easy to generalize. It is possible to apply this approach not only for overlapping L spectra but also for overlapping K-L spectra (for example, in the oxides Fe_3O_4, Cr_2O_3).

3. Experimental details

Two different techniques of experiment were used in this article – EXAFS in transmission mode and Total Electron Yield (TEY) technique.

TEY experiments were performed at room temperature using the facility of the RGBL beamline of BESSY II. The samples were polycrystalline Fe and Cr films. Fe film of thickness ∼300 Å was evaporated under UHV conditions onto W(110) substrate and the measurements were performed immediately after deposition. Cr film of thickness ∼300–400 Å was evaporated under UHV conditions onto MgO(100) substrate at the Institute of Metal Physics, RAS.

The low temperature (70 K) EXAFS measurements were carried out in transmission mode at the U4B beamline of the National Synchrotron Light Source (NSLS) located at Brookhaven National Laboratory (BNL, USA). The sample was polycrystalline Fe film. This film with thickness of 500 Å was evaporated under UHV conditions onto ∼1 μm thick semitransparent parylene $(C_8H_8)_n$ substrate (100). To prevent the film from oxidising an additional Al cap layer was deposited on the film.

For obtaining $\chi(k)$ functions for Fe and Cr films from raw experimental data we use the conventional procedure [8]. We normalise the experimental spectrum on sum of L_3, L_2, L_1 edge jumps, but we do not remove L_1 edge jump from the experimental $\chi(k)$ because the value of this jump in comparing with the common jump is approximately 0.1 (see Fig. 1). It validates by the fact that there is no jump at $k \sim 6\,\text{Å}^{-1}$ in the experimental spectra in contrast with the model simulation at the temperature 70 K (Fig. 2).

4. Discussion

Fig. 2 shows experimental $\chi(k)$ functions for Fe and Cr films obtained from TEY measurements and for Fe film obtained from EXAFS measurements in transmission mode. The extraction of the $\chi(k)$ functions from raw data was used [3, 4]. TEY $\chi(k)$ functions were rather noisy due to low statistics so these curves were smoothed. All curves are compared with the model functions calculated by FEFF8 [1].

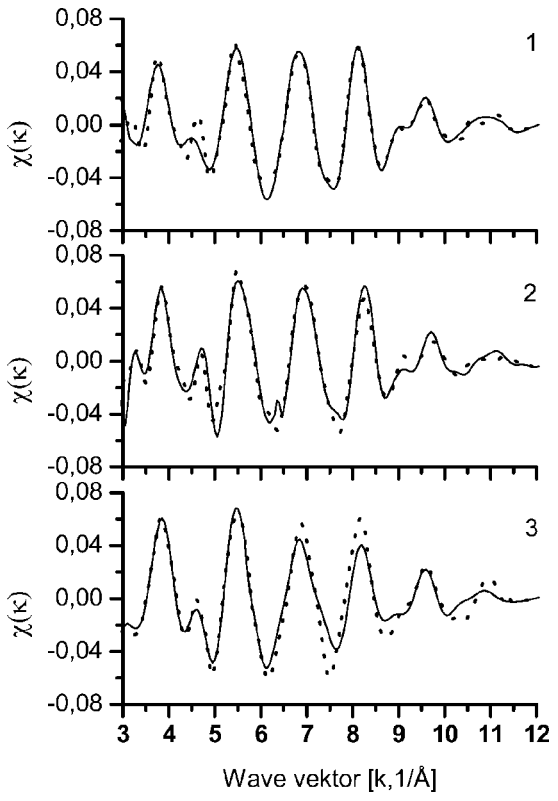

Fig. 2. Experimental EXAFS and TEY $\chi(k)$ spectra (dot line) in comparison with simulated functions by FEFF8 (solid lines) (1 – TEY spectra of Fe at 300 K, 2 – EXAFS spectra of Fe at 70 K, 3 – TEY spectra of Cr at 300 K).

Applying the regularization method described [2–4], one can find the solutions which are shown on Fig. 3. The obtained results

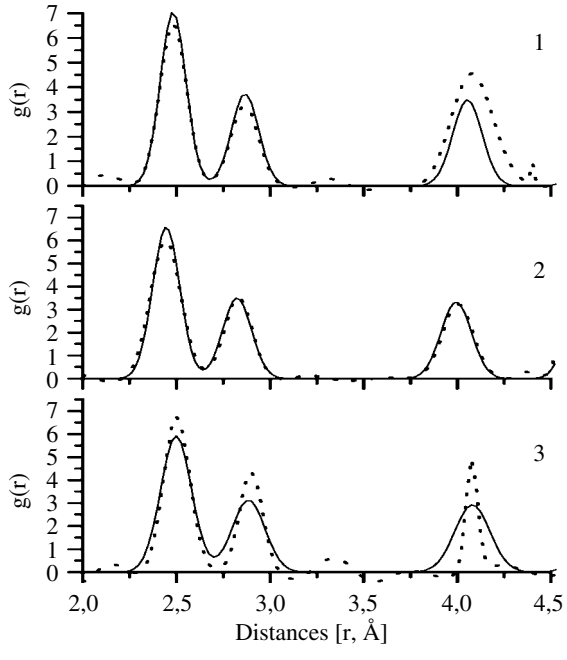

Fig. 3. Model PCF (solid line) and obtained (dot line) solution (1 – Fe at 300 K, 2 – Fe at 70 K, 3 – Cr at 300 K).

Table I. *Comparison of the model and experimental values obtained for the first and second shells of crystalline Fe and Cr (interatomic distance r and nearest neighbors coordination number N).*

		1st coordination shell		2nd coordination shell	
Edge	Type of experiment	r, Å	N, at.	r, Å	N, at.
Fe	Model 300 K	2.483	8.00	2.867	6.00
	TEY	2.482	7.87	2.865	5.38
	Model 70 K	2.446	8.00	2.824	6.00
	EXAFS	2.443	8.12	2.832	5.84
Cr	Model 300 K	2.499	8.00	2.885	6.00
	TEY	2.501	7.85	2.899	5.90

are compared with model PCF functions calculated on the basis of the well known crystallographic data.

The following main characteristics of the peaks for the function $g(r)$ have been selected: interatomic distance r and the nearest neighbors' coordination number N. These values were estimated according to the Gauss functions approximating the peaks of the solution and presented in Table I.

As it can be seen the main characteristics of the first and the second shells for crystalline Fe and Cr correspond to the crystallographic table values. There is a very high resolution in real space r with comparing the Fourier transformation. On the curve of Fourier transformation it is impossible to distinguish the first and the second shells of BCC lattice.

It is necessary to note that during the solution of the inverse problem (2) the contribution of photoelectron multiple scattering on the nearest neighbours were not accounted. It seems than simultaneous solving of three L spectra made the problem more stable.

5. Conclusion

The proposed new method of obtaining local structure information from overlapping XAFS spectra for 3d metals shows its efficiency. In contrast to the conventional methods (Fourier transformation and fitting procedures) this method does not demand any model assumption and any special procedure of deconvolution of L_1 –, L_2 –, L_3 – contributions and has a high resolution in real space r. Obtained parameters – interatomic distance, coordination number for the first and the second coordination shells agree well with the expected crystallographic values.

Abstract

In many cases X-ray absorption spectra measured in transmission mode are degraded by an inhomogeneity in thickness of the samples. As a result, the EXAFS amplitude is decreased and information about the coordination numbers is distorted. To avoid this influence, it is necessary to prepare a homogeneous sample. But, for powder samples, thick inhomogeneous foils, and sputtered films this is not possible. Absorption spectra on these samples should be corrected for the thickness inhomogeneity effect.

To correct an absorption spectrum it is necessary to know the sample thickness distribution function. We propose a method of solving an integral equation for a distribution function as an inverse problem. We use and compare the experimental pre-edge absorption behaviour with the theoretical Victoreen function. We apply the Tikhonov regularization algorithm to determine the distribution function. Model calculations are carried out to check the reproducibility of the calculations. This method is applied to preliminary procession of X-ray absorption spectra for high quality foils of crystalline Cu, crystalline Cu powder samples, and an inhomogeneous foil of ordered $Ni_{50}Mn_{50}$ alloy. We estimate the thickness inhomogeneity effect on the coordination numbers in the cases before and after correcting the spectra.

1. Introduction

The thickness effect, which is caused by leakage of radiation accompanying the absorption process, has been discussed earlier [1–11]. The samples for experiment in transmission mode need to be uniform [8], but it is difficult to prepare an uniform sample from powders, for example. For inhomogeneous samples, the EXAFS amplitude is decreased.

An integral equation for the sample thickness distribution function was written by L. Ottaviano *et al*. [9]. They proposed a sample preparation technique, suitable for X-ray absorption measurements of liquid and supercooled metals and determined experimentally the size distribution of metal droplets by means of an optical microscope. This distribution was described within the framework of a log-normal model of thickness distribution. A special procedure for correcting the raw data due to the inhomogeneity of the thickness was applied. Bausk *et al*. [10] proposed to correct the XAFS amplitude by constructing a correcting function using pre-edge data without restoring the thickness distribution.

In a previous paper [11] the idea to correct XAFS amplitude using pre-edge data [10] was adopted and a simple model describing the influence of thickness inhomogeneity on the edge step, the amplitude of EXAFS oscillations and the asymptotic behavior of absorption spectra was proposed. The asymptotic behavior was used in order to find some parameters of the model and to reconstruct the true absorption coefficient.

In the present paper we propose to solve an integral equation for the sample thickness distribution function. The problem is reduced to a system of linear equations by the regularization method. We present the sample thickness distribution functions and the correction of the effects related to the thickness inhomogeneity for crystalline Cu foils, powder samples of Cu and a thick inhomogeneous foil of $Ni_{50}Mn_{50}$.

2. A short description of the mathematical algorithm

A sample inhomogeneity can be characterized by the thickness distribution function $\alpha(x)$ [9, 10]. For discrete thickness it equals the ratio of sample area with thickness x_i to full area of sample, or $\alpha_i = S_i/S$, where $S = \Sigma S_i$.

For X-ray absorption we have an integral equation [9]:

$$e^{-\mu'(E)} = \int e^{-\mu(E)x}\alpha(x)\,dx, \tag{1}$$

where $\mu'(E)$ is the measured absorption of the sample and $\mu(E)$ is the true absorption of the sample.

Rewrite this equation in symbolic form:

$$U = A\alpha. \tag{2}$$

In discrete approximation eq. (1) represents a system of linear algebraic equations.

To solve the problem (1), we use the pre-edge asymptotic behavior of X-ray absorption. The slope of this curve is very weak. That is why the matrix A is ill conditioned and the problem is unstable. We replace the exact equation (2) in discrete form by the approximated one and obtain the so called Tikhonov solution using the regularization method [11]:

$$\alpha = (A + B)^{-1}U. \tag{3}$$

The average thickness $\langle x\rangle$ is defined as

$$\langle x\rangle = \int x\alpha(x)\,dx. \tag{4}$$

From the obtained $\alpha(x)$ and $\langle x\rangle$, we find the reconstructed spectrum for a homogeneous sample with thickness $\langle x\rangle$ using the iterative procedure:

$$\mu_l(E)\langle x\rangle = \mu'(E) + \ln\int e^{-\mu_{l-1}(E)(x-\langle x\rangle)}\alpha(x)\,dx \tag{5}$$

where l is the iteration number, $\mu'(E)$ is the initial experimental spectrum. At $l = 1$ we use an atomic absorption function $\mu_V(E)$ [12] as $\mu_{l=1}(E)$. Less than 10 iterations are required. Details of the mathematical algorithm will be published elsewhere.

3. Experimental details and results of spectra correction

To be able to evaluate the results of our method, we choose: two crystalline Cu foils with different thickness; two Cu powder samples; and a crystalline inhomogeneous foil $Ni_{50}Mn_{50}$.

3.1. *Crystalline Cu foils*

The first sample of crystalline Cu was prepared by EXAFS Materials Company (Danville, USA) with thickness 7 μm. The Cu K-edge of the X-ray absorption spectrum was collected in transmission mode at room temperature. The measurements were performed at the Rossendorf Beamline (ROBL) at the European Synchrotron Radiation Facility (ESRF) using a Si(111) double-crystal monochromator in fixed-exit mode [13]. In addition, a blank run of the Cu K-edge spectrum was made in order to determine the apparatus function by measuring the absorption spectrum without any sample. These measurements should be performed before and after measurement of the Cu spectrum without changing amplification. If the apparatus function is changed, it is necessary to repeat the measurements. This procedure was realized for all samples studies in this paper. The blank run is important because we use pre-edge asymptotic behavior for determination of the sample thickness distribution function. Fig. 1 shows the absorption Cu spectra before and after removing the apparatus function.

The second sample of crystalline Cu was prepared by polishing the foil to a nominal thickness of 5 μm. The Cu K-edge X-ray absorption spectrum was collected in transmission mode at room temperature at the PNC-CAT beamline, 20-BM at the Advanced Photon Source (APS) using a Si(111) double-crystal monochromator in fixed-exit mode [14].

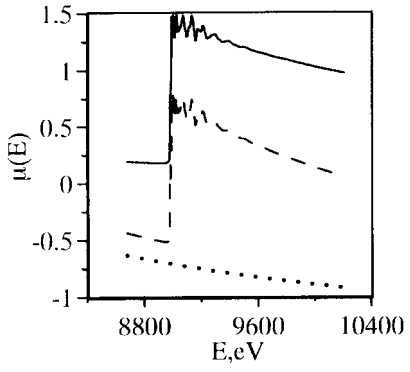

Fig. 1. Absorption data for Cu foil. Dotted line – blank run, dashed line – raw absorption spectra, solid line – absorption spectra after blank run removed.

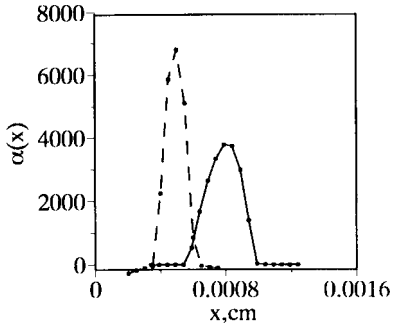

Fig. 2. Thickness distribution functions for homogeneous Cu foils. Solid line – distribution function for first foil sample ($\langle x\rangle = 7.2$ μm), dashed line – for second foil sample ($\langle x\rangle = 5.2$ μm).

Table I. *Coordination numbers for homogeneous Cu foils.*

	First foil sample		Second foil sample	
Model	Before correction	After correction	Before correction	After correction
12.00	11.97	12.01	11.96	12.05

The distribution function for both crystalline Cu foils (Fig. 2) have narrow symmetric peaks with the average thickness 7.2 μm (the first sample) and 5.2 μm (the second one). With these functions we have reconstructed the true signal, obtained the EXAFS spectrum and compared it with the initial EXAFS spectrum (before correction). We did not find any thickness effect and consider these samples to be good.

The first coordination numbers are listed in Table I. We conclude: the thickness inhomogeneity effect does not distort the EXAFS–spectra for homogeneous foils.

3.2. *Crystalline Cu powder samples*

The Cu particle size was 3.25–4.5 μm. The powder was spread onto Kapton tape in inert gas in a glove box and oxidation was minimized by covering with another layer of Kapton. The number of layers of Cu/Kapton was changed to produce the jumps 0.5 (1 layer) and 1.0 (3 layers).

The Cu K-edge X-ray absorption spectrum was collected in transmission mode at room temperature at the PNC-CAT beamline 20-BM at the APS.

The most interesting feature of these spectra before correction is the $\chi(E)$ function of 1 layer of Cu particles is almost identical to that for 3 layers. Significant differences occur only in the 10 eV interval above the first inflection point in $\mu'(E)$. We find this surprising because the effective sample thicknesses differ by a factor of 3.

Naively, one would have expected the effect of pinholes to cause a much greater distortion for 1 layer than for 3 layers. The thickness distributions $\alpha(x)$ obtained (Fig. 3) confirm that increasing the number of layers reduces the fraction of sample with thickness approaching zero. But the 3-layer sample is not homogeneous and has a wide asymmetric distribution function.

Fig. 4 shows EXAFS spectra for the first powder sample before (solid line) and after (dashed line) correction for the thickness inhomogeneity effect.

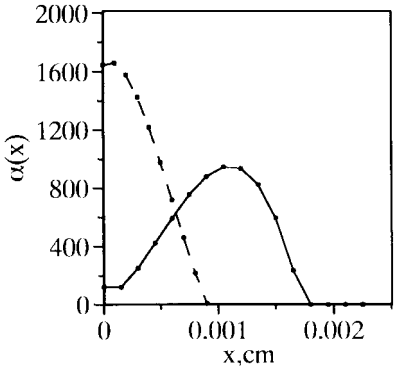

Fig. 3. Thickness distribution functions from Cu powder samples. Dashed line is the distribution function for 1 layer ($\langle x\rangle = 3.0$ μm) and the solid line is for 3 layers ($\langle x\rangle = 9.8$ μm).

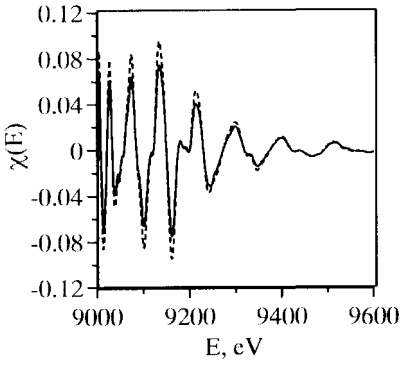

Fig. 4. EXAFS spectra from the first powder sample before (solid line) and after (dash line) correction on the thickness inhomogeneity effect.

Table II. *Coordination numbers for inhomogeneous Cu powder samples.*

	First power sample		Second power sample	
Model	Before correction	After correction	Before correction	After correction
12.00	8.86	12.05	8.75	12.01

Coordination numbers from EXAFS–spectra before and after correction are presented in Table II.

3.3. *Thick foils of $Ni_{50}Mn_{50}$ alloys*

The foil of the ordered $Ni_{0.50}Mn_{0.50}$ sample was prepared from a massive piece by polishing to a nominal thickness of 20 μm. The Ni and Mn K-edge absorption spectra of ordered $Ni_{0.50}Mn_{0.50}$ alloy were recorded in transmission mode at the PNC-CAT beamline 20-ID, APS [14]. A Si(111) double crystal monochromator was used (65% tune at 200 eV above each K-edge absorption edge). The storage ring was operated at 7.0 GeV and ring current was 65–100 mA.

We determined the thickness distribution function using only the Mn pre-edge. In this case the fluorescence effect is absent and the distribution function obtained for the Mn edge can be used for the Ni edge. The thick foil of the ordered $Ni_{50}Mn_{50}$ has a very asymmetric distribution with a small amount of pinholds (Fig. 5). The average thickness calculated for the sample of ordered $Ni_{50}Mn_{50}$ alloy is $\langle x \rangle = 23.1$ μm.

Coordination numbers for $Ni_{50}Mn_{50}$ alloy before and after correction are presented in Table III.

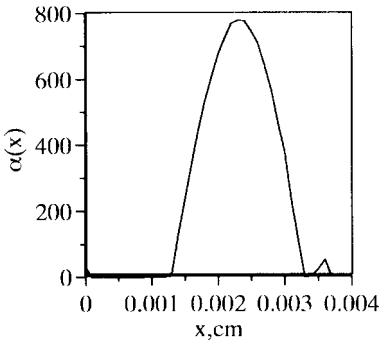

Fig. 5. Thickness distribution function for $Ni_{50}Mn_{50}$ alloy.

Table III. *Coordination numbers for first shell of $Ni_{50}Mn_{50}$ ordered alloy with and without the correction for the thickness inhomogeneity effect.*

	Ni–Ni	Ni–Mn	Mn–Ni	Mn–Mn
Before correction	0.17	7.06	6.98	−0.14
After correction	−0.14	8.16	8.16	−0.17
Model	0.00	8.00	8.00	0.00

Abstract

We propose the chemical matched EXAFS regularization method through the numerical analysis of Mn K-edge EXAFS data for $La_{1-x}Ca_xMnO_3$ specimens. A relatively narrow k-space window ($k_{max} - k_{min} = 6\,Å^{-1}$) has been used to compute the Mn-O pair distribution function in the specific r-space range of 1.8–2.2 Å. Results show that the resolution in r-space is greatly improved in the pair distribution functions of the Mn-O bond. EXAFS data of specimens with double shell pair distributions were hardly analyzed by the conventional method because they are not resolved in the Fourier transform. A preliminary test of the EXAFS regularization method shows that this is very effective method to study the double shell distribution due to the Jahn Teller effect. The test was performed on $La_{1-x}Ca_xMnO_3$ at $x = 0.2$ and 0.3.

1. Introduction

Extended X-ray absorption fine structure (EXAFS) analysis [1] gives useful information on the local structure of solid atoms. However, the method fails to analyze the double-shell configuration in which the distribution of the first and the second nearest neighbor atoms are partially overlapped.

Recently, this situation appears in a practical application of the analysis of colossal magnetic resistance (CMR) materials. Mn ions in $La_{1-x}Ca_xMnO_3$ have three different bond distances, $R = 1.91$, 1.97 and 2.12 Å. It has been reported that manganese-oxide perovskites (e.g. La-A-MnO_3 where A = Ca, Sr, Pr, etc.) have the strong electron-lattice coupling effect and their structural features are known as the Jahn Teller distortion of Mn^{3+} ion [2, 3]. The conventional EXAFS has hardly explained this phenomenon.

As one method to overcome the limitation of the conventional EXAFS, a regularization method has been proposed. The regularization method uses matrix inversion instead of Fourier transform to extract r-space information such as the pair distribution function. Therefore, the method is free from the requirements of the large k- and r-space window in Fourier and inverse Fourier transforms, respectively. The details of this method are described in next section.

2. EXAFS regularization method

In previous work [4], simulation has shown that the regularization method is more flexible and useful to seek the r-space information directly from the pair distribution function (PDF). The EXAFS equation can be expressed by:

$$\chi(k) = \frac{NS_0^2(k)}{k} \int_0^\infty \frac{g(r)}{r^2} F(k,r)\, \mathrm{e}^{-2r/\lambda(k)} \sin(2kr + \varphi(k,r))\, \mathrm{d}r \tag{1}$$

where $g(r)$ is the pair distribution function, N is the coordination number, k is the photoelectron wave vector, $S_0^2(k)$ is the many-electron overlap factor, $\lambda(k)$ is the mean free path, r is the interatomic distance, $F(k,r)$ is the effective backscattering amplitude, and $\varphi(k,r)$ is the phase shift due to the atomic potentials.

Spectrum $\chi(k)$ is obtained from experimental data of $\mu(E)$, by specifying E_0 position and applying the proper background subtraction. The first-shell filtered spectrum $\chi_1(k)$ is extracted properly by the procedure of the Fourier and inverse Fourier transform of $\chi(k)$.

The EXAFS inversion problem implies how accurately $g(r)$ can be computed from $\chi_1(k)$. In a linear system, we can define the χ-vector as $\chi = \mathrm{A}^* g$, where A is an $(m \times n)$ matrix, and g is a column vector, i.e. PDF. More specifically, A is an r-to-k transformation matrix defined with chemical matching to the Mn-O shell in terms of r-dependent functions computed by theoretical FEFF code. Here, the solution for g is obtained by solving the "ill-posed" mathematical problem.

The resultant g in vector form can be determined by the following algebraic equation:

$$\left(\sum_m A^*_{mn} A_{mn} + \tau(\alpha + 2\gamma S^n) I + \beta \sum_m B^{mn} \right) g^n = \sum_m A^*_{mn} \chi^m \tag{2}$$

where $\tau = \Delta r / \Delta k$. Δr and Δk are the step sizes in the vectorized g^n and χ^m, respectively. S^n and B^{mn}-matrices are described in previous works [4, 5]. In this regularization method, the optimal values of the regularization parameter α, the smoothness parameter β and the positivity parameter γ are obtained by minimizing $\|\chi - A^* g\|^2$, and simultaneously $g(r)$ is rendered as smooth as possible.

In this study, both the chemical matched EXAFS regularization method and the improvement of r-space resolution are pursued. We selected the Mn-O bond configurations for $La_{1-x}Ca_xMnO_3$ specimens to make a comparison test between the data analysis result and the structural interpretation related to materials essence.

To test the r-space resolution for Mn-O distances, $\chi(k)$-spectra were confined in a relatively narrow k-range window, $[k_{min}, k_{max}]$, where $k_{max} - k_{min} = 6\,Å^{-1}$. In a general EXAFS fitting procedure, the number of independent variables is given by $N_{idp} = 1 + 2(k_{max} - k_{min})(R_{max} - R_{min})/\pi$. To investigate the closely spaced double-shell distances in 1.8–2.2 Å in PDF (apparently, 1–2 Å in FT), the general fitting algorithm requires that $N_{inp} > 6$. Moreover, the summation and the separation of the typical Gauss distribution are only applicable with a relatively small

*e-mail: dsyang@chungbuk.ac.kr

Debye-Waller factor and its cumulant expansion terms. Hence, unless the effective k-range is extended, the PDF interpretation is hardly solved by the general EXAFS fitting procedures such as FEFFIT or other kinds.

3. Results and Discussion

The EXAFS regularization program is coded with a fixed number of data points and a fixed data interval (Δk) in this work. The window size of the k-region selection was not adjustable, but the window positioning from the $k_{\min}$-position (the significant limit in the lower k region) was selectable. In our preliminary test with the specimens $La_{1-x}Ca_xMnO_3$ ($x = 0.2$ and 0.3), we gave an arbitrary variation in choosing an $k_{\min}$-position around 3.9 Å, which is the significant knot position of $\chi_1(k)$, filtered Mn-O spectrum by FT and inverse FT with parameters; $k_1 = 2.9\,\text{Å}^{-1}$, $k_2 = 12.0\,\text{Å}^{-1}$, $dk_1 = dk_2 = 0.6\,\text{Å}^{-1}$ (for the Hanning window), $k$weight = 3 for FT, and $r_1 = 0.95$ Å, $r_2 = 1.90$ Å, $dr_1 = dr_2 = 0.1$ Å for inverse FT. When the $k_{\min}$-position is chosen at a typical knot (3.9 Å), the computed PDF represents a relatively stable feature, but not irregularly valued into a negative background level. It is also necessary to tune the E_0-position between the experimental data and the theoretical FEFF calculation. Though our experience of combined k_1 and E_0 adjustment, we specify the best minimum condition, namely the typical regularization condition, by choosing $k_{\min} = 3.9\,\text{Å}^{-1}$ and $E_0 = 6548$ eV. ($E_0 = 6539$ eV was calibrated using Mn metal foil.) Thus, the k-range selection is $[3.9 \sim 9.9]\ \text{Å}^{-1}$. This typical regularization condition is useful for finding realistic PDF representations, corresponding to the typical window function with the starting $k_{\min}$-position as a knot-point reference.

By choosing this typical regularization condition, the PDF results are plotted in Fig. 1, illustrating the PDF characteristics on the two different specimens; (a) $La_{0.7}Ca_{0.3}MnO_3$ and (b) $La_{0.8}Ca_{0.2}MnO_3$, respectively. As demonstrated in Fig. 1, our typical regularization condition is very convincing because the derivative PDF feature with respect to the $k_{\min}$-variable illustrates the remarkably minimum variation characters at the k_1-knot.

First of all, it should be pointed out that the regularization method improves the r-space resolution significantly. The first-shell |FT| peak regime which is not displayed in this figure is broadly covering [1.0, 2.0] in k-space, and each peak is not separated. On the other hand, in part (b) of Fig. 1, the typical PDF (solid line) is an obvious feature to observe that there are at least two separable shells which are even merged or distributed in crossover resolution. In contrast, in part (a) of Fig. 1, the typical PDF (solid line) also represents the asymmetric PDF caused by two different merged shells. In both cases, Mn-O distances are attributed to the static or dynamic broadening of shell distributions due to the Jahn Teller effect [2, 3].

In summary, our preliminary test evaluating the chemical matched EXAFS regularization method and its application to the Mn-O bond characteristics associated with the Jahn Teller effect was successful enough to highlight that the r-space resolution can be improved significantly.

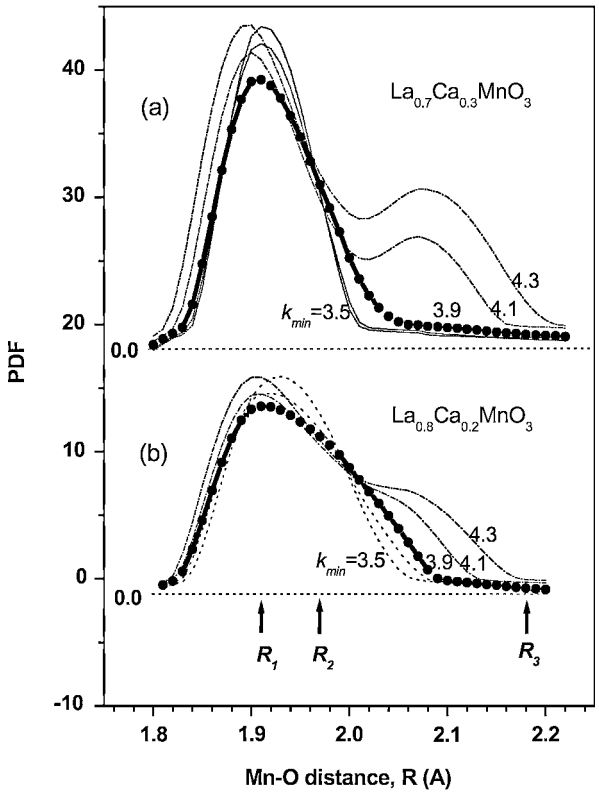

Fig. 1. Mn-O pair distribution function computed by the chemical matched regularization method. Comparisons are made for two specimens: (a) $La_{0.7}Ca_{0.3}MnO_3$ and (b) $La_{0.8}Ca_{0.2}MnO_3$. The typical regularization condition is given with k-range windowing from $k_{\min} = 3.9$ (at a knot-point reference). The $k_{\min}$-dependent variations are shown with dotted-line PDF curves, denoted by $k_{\min}$-value individually. Two regularized PDF plots with a shift of base line indicate a good r-space resolution for the case of double-shell crossover feature. The PDF as a function of r-space is compared with arrow-marked Mn-O distances, $R_1 = 1.91$ Å, $R_2 = 1.97$ Å and $R_3 = 2.18$ Å, as computed from the crystalline group *pbnm* of $LaMnO_3$.

Acknowledgments

Authors thank Dr. Alexander Ulyanov and Dr. Tae Young Koo who provided the samples and valuable discussions on $La_{0.7}Ca_{0.3}MnO_3$ and $La_{0.8}Ca_{0.2}MnO_3$, respectively. This work was partially supported by the Korean Research Foundation Grant (KRF-2001-005-D20010). Measurements at PLS were supported through the "X-ray-particle-beam Nano-characterization program" by the MOST and POSTECH foundation.

Abstract

Extended X-ray absorption fine-structure (EXAFS) data collected in the fluorescence mode are susceptible to an apparent amplitude reduction due to the self-absorption of the fluorescing photon by the sample before it reaches a detector. Previous treatments have made the simplifying assumption that the effect of the EXAFS on the correction term is negligible, and that the samples are in the thick limit. We present a nearly exact treatment that can be applied for any sample thickness or concentration, and retains the EXAFS oscillations in the correction term.

Under ideal circumstances, such as a very dilute sample, the photoelectric part of the X-ray absorption coefficient, μ, is proportional to the number of fluorescence photons escaping the sample. However, in extended X-ray absorption fine-structure spectroscopy (EXAFS), the mean absorption depth changes with the energy of the incident photon, E, which changes the probability that the fluorescence photon will be reabsorbed by the sample. This self-absorption causes a reduction in the measured EXAFS oscillations, χ_{exp}, from the true χ, and hence needs to be included in any subsequent analysis.

Previous treatments [1–3] to correct for the self-absorption effect account for the change in depth due to the absorption edge and due to the smooth decrease in μ that follows, for instance, a Victoreen formula, and have been shown to be quite effective in certain limits. These treatments typically make two important assumptions. First, the so-called "thick limit" is used to eliminate the dependence on the actual sample thickness, limiting the applicability to thick, concentrated samples, such as single crystals. One exception is the work of Tan, Budnick and Heald [2], which makes a number of other assumptions to estimate the correction to the amplitude reduction factor, ${S_0}^2$, and to the Debye-Waller factors, σ^2's, rather than correcting the data in a model-independent way. A second assumption is that, in order to make the correction factor analytical, at one point in the calculation, the true absorption coefficients for the absorbing species and the whole sample are replaced with their average values; in other words, the modulating effect of χ on the correction factor is taken as very small. Below, we present a treatment that, with only one assumption that is nearly exact for all cases we have measured, corrects fluorescence EXAFS data directly in k-space for any concentration or thickness. This correction is demonstrated for a copper foil that is about one absorption-length thick, and is therefore not in the thick limit.

Figure 1 shows the geometry used in this calculation. The fluorescence yield at the point of absorption is proportional to the X-ray intensity I at that point and the fluorescence efficiency. The intensity I at a depth y is

$$I = I_0 \mathrm{e}^{-\mu(E)y}.$$

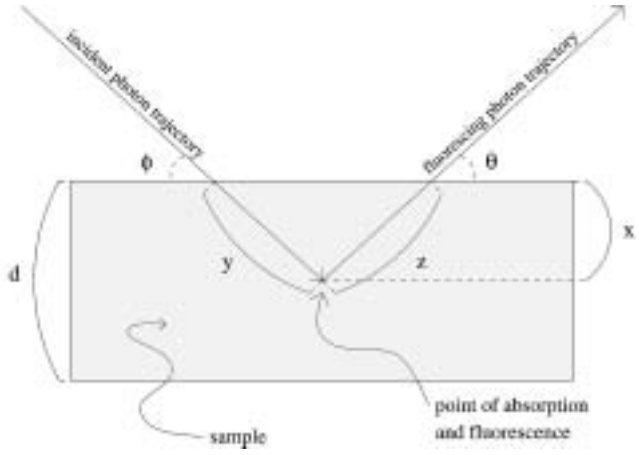

Fig. 1. Geometry used in calculating self-absorption correction in EXAFS.

The fluorescence photon then has to escape. The fluorescence flux from this point in the sample is then

$$I_f = I_0 \mathrm{e}^{-\mu(E)y} \mathrm{e}^{-\mu(E_f)z} \epsilon_a(E) \mu_a(E),$$

where $\mu_a(E)$ is the absorption due to the given core excitation of the absorbing atom, $\mu(E)$ is the total absorption, $\epsilon_a(E)$ is the fluorescence efficiency per unit solid angle, E is the incident beam energy, E_f is the energy of the fluorescing photon, and we're assuming that all the measured fluorescence is coming from the desired process (eg. Cu K_α, any other counts can be subtracted off).This equation is only true at a particular y and z, so we must integrate

$$\mathrm{d}I_f = I_0 \epsilon_a \mu_a \mathrm{e}^{-(\mu_T y + \mu_f z)} \, \mathrm{d}y.$$

Here the energy dependences are implicit and we have used $\mu_T = \mu(E)$ and $\mu_f = \mu(E_f)$. The variables z and y are dependent via $y \sin\phi = z \sin\theta = x$. Changing variables, we obtain

$$\mathrm{d}I_f = I_0 \epsilon_a \mu_a \frac{1}{\sin\phi} \mathrm{e}^{-(\frac{\mu_T}{\sin\phi} + \frac{\mu_f}{\sin\theta})x} \, \mathrm{d}x,$$

$$I_f = I_0 \epsilon_a \mu_a \frac{1}{\sin\phi} \int_0^d \mathrm{e}^{-(\frac{\mu_T}{\sin\phi} + \frac{\mu_f}{\sin\theta})x} \, \mathrm{d}x,$$

$$I_f = \frac{I_0 \epsilon_a \mu_a}{\mu_T + g\mu_f} \left[1 - \mathrm{e}^{-(\frac{\mu_T}{\sin\phi} + \frac{\mu_f}{\sin\theta})d}\right], \tag{1}$$

where $g \equiv \sin\phi / \sin\theta$. Eq. (1) describes the fluorescence in the direction given by θ. At this point one should integrate over the detector's solid angle. Ignoring this integral can affect the final obtained correction [4], especially for glancing-emergent

*Electronic address: chbooth@lbl.gov

angle experiments. However, for detector geometries where $\phi + \theta = 90^\circ$, we find the maximum error in g is on the order of $\sim$7% even for $\Delta\theta \approx 5^\circ$ at $\theta = 10^\circ$. For more severe geometries, the solid angle should considered, but for the following, we ignore this correction.

In EXAFS measurements, we want

$$\chi = \frac{\mu_a - \bar{\mu}_a}{\bar{\mu}_a},$$

but what we actually obtain experimentally is

$$\chi_{exp} = \frac{I_f - \bar{I}_f}{\bar{I}_f},$$

where $\bar{I}_f$ is the spline function fit to the data to simulate the "embedded atom" background fluorescence (roughly I_f without the EXAFS oscillations). Now make the following substitutions:

$$\mu_T = \bar{\mu}_T + \chi\bar{\mu}_a,$$

$$\mu_a = (\chi + 1)\bar{\mu}_a,$$

$$\mu_T - \bar{\mu}_T = \mu_a - \bar{\mu}_a.$$

These equations and Eq. (1) are then plugged into χ_{exp}:

$$1 + \chi_{exp} = \frac{\mu_a(\bar{\mu}_T + g\mu_f)[1 - \mathrm{e}^{-(\frac{\mu_T}{\sin\phi} + \frac{\mu_f}{\sin\theta})d}]}{\bar{\mu}_a(\mu_T + g\mu_f)[1 - \mathrm{e}^{-(\frac{\bar{\mu}_T}{\sin\phi} + \frac{\mu_f}{\sin\theta})d}]}.$$

Dividing by $1 + \chi$ and defining $\alpha \equiv \bar{\mu}_T + g\mu_f$, we get:

$$\frac{1 + \chi_{exp}}{1 + \chi} = \frac{[1 - \mathrm{e}^{-(\bar{\mu}_T + \chi\bar{\mu}_a + g\mu_f)\frac{d}{\sin\phi}}]\alpha}{(\alpha + \chi\bar{\mu}_a)[1 - \mathrm{e}^{-\frac{\alpha d}{\sin\phi}}]}.$$

Now χ_{exp} can be written in terms of the actual χ:

$$\chi_{exp} = \left[\frac{1 - \mathrm{e}^{-(\alpha + \chi\bar{\mu}_a)\frac{d}{\sin\phi}}}{1 - \mathrm{e}^{-\frac{\alpha d}{\sin\phi}}}\right]\left[\frac{\alpha(\chi + 1)}{\alpha + \chi\bar{\mu}_a}\right] - 1. \quad (2)$$

At this point in the calculation, the relation between χ and χ_{exp} is exact. However, we need χ in terms of χ_{exp}, and Eq. (2) is for χ_{exp} in terms of χ. In order to invert Eq. (2), we make a simple approximation. Assuming that

$$\frac{\chi\bar{\mu}_a d}{\sin\phi} \ll 1$$

we can say

$$1 - \mathrm{e}^{-(\alpha + \chi\bar{\mu}_a)\frac{d}{\sin\phi}} \sim 1 - \mathrm{e}^{-\frac{\alpha d}{\sin\phi}}\left(1 - \frac{\chi\bar{\mu}_a d}{\sin\phi}\right). \quad (3)$$

This approximation gets worse with large χ and $\bar{\mu}_a$. It also has a maximum for both ϕ and d, because of the $\mathrm{e}^{-(\alpha d)/(\sin\phi)}$ term. Plugging in some typical numbers from the Cu K-edge of $YBa_2Cu_3O_7$ ($\phi = 10^\circ$, $\bar{\mu}_T = 1284\,\mathrm{cm}^{-1}$, $\mu_F = 1115\,\mathrm{cm}^{-1}$, $\bar{\mu}_a = 462\,\mathrm{cm}^{-1}$ and $\chi = 0.5$) the maximum error is $\sim$0.7% at a thickness of $\sim$1.9 μm. Such a high value of χ does not actually occur in YBCO. Indeed, such a high χ is rare. In any case, various combinations of the above parameters can conspire to produce errors above 1%, so the approximation should be monitored when making the corrections outlined below.

With the above approximation, and defining the following quantities:

$$\beta = \frac{\bar{\mu}_a d\alpha}{\sin\phi}\mathrm{e}^{-\frac{\alpha d}{\sin\phi}}, \quad \gamma = 1 - \mathrm{e}^{-\frac{\alpha d}{\sin\phi}},$$

Eq. (2) is reduced to a quadratic equation in χ and we can finally write the full correction formula:

$$\chi = \frac{-[\gamma(\alpha - \bar{\mu}_a(\chi_{exp} + 1)) + \beta] + \sqrt{[\gamma(\alpha - \bar{\mu}_a(\chi_{exp} + 1)) + \beta]^2 + 4\alpha\beta\gamma\chi_{exp}}}{2\beta}, \quad (4)$$

where the sign of the square root was determined by taking the thick or thin limits. In the thick limit ($d \to \infty$), Eq. (4) gives:

$$\chi = \frac{\chi_{exp}}{1 - \frac{\bar{\mu}}{\alpha}\chi_{exp} - \frac{\bar{\mu}_a}{\alpha}},$$

which is the same as that calculated in Ref. [3] without the χ_{exp} term in the denominator. In the thin limit, it can be shown that Eq. (4) reduces to $\chi = \chi_{exp}$ as expected.

We performed an experiment on a copper foil to demonstrate the correction. Cu K-edge data were collected both in the transmission mode and in the fluorescence mode using a 32-element Canberra germanium detector on beam line 11-2 at the Stanford Synchrotron Radiation Laboratory (SSRL). The transmission data were checked for pinhole effects (found to be negligible) and the fluroscence data were corrected for dead time. The sample thickness was estimated to be 4.6 μm from the absorption step at the edge, and was oriented such that $\phi = 49.4 \pm 0.5^\circ$. The thickness is about 25% of the estimated thick-limit thickness. The data were reduced to k-space using the RSXAP analysis program REDUCE [5–7], which incorporate these corrections. Figure 2 shows the correction factor (χ/χ_{exp}) for these data. The error in the approximation in Eq. (3) exceeds 2% only below $\sim$1.6 Å^{-1}. The total correction in the thick limit is much larger (about 3 times the displayed correction). As shown in Fig. 3, the corrected fluorescence data in k-space are remarkably similar to the transmission data, despite the large magnitude of the correction.

Although only a copper foil is reported as an example, we have successfully applied this correction to a wide range of oxides and intermetallics, including single crystals and thin films [8–12]. The ability to correct for intermediate film thicknesses is, in fact, crucial for studying films thinner than $\sim$20 μm thick.

In summary, we have provided an improved self-absorption correction for EXAFS data that operates at any sample thickness

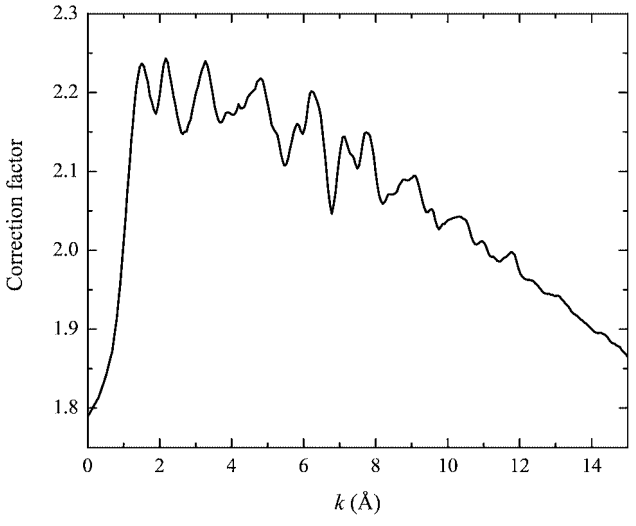

Fig. 2. Correction term χ/χ_{exp} given by Eq. (4) for Cu K-edge absorption data from a 4.6 μm-thick copper foil at $\phi = 49.4^\circ$.

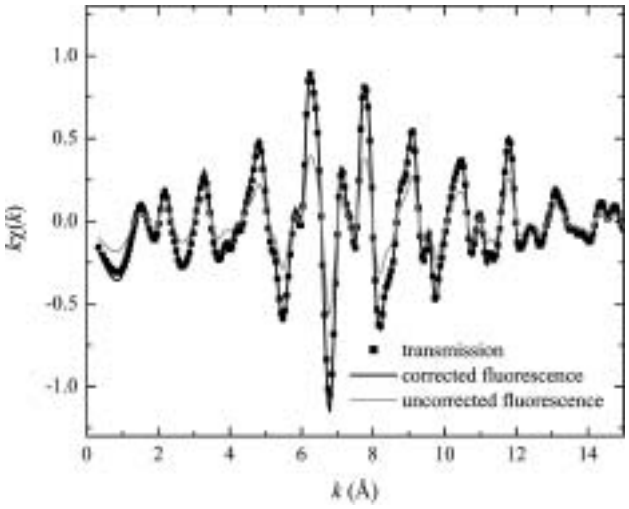

Fig. 3. Corrected EXAFS data in k-space for the copper foil data, compared to transmission data and uncorrected fluorescence data. Note that the corrected data are difficult to discern on top of the transmission data.

or concentration. Our example of a pure copper foil demonstrates both the accuracy of the correction and that, for concentrated samples, the correction can be surprisingly large. Moreover, for well-ordered materials, χ can have a surprisingly large effect.

Abstract

Today a lot of XAFS analysis software is available either free of charge, licensed or commercially. The list of the programs can be found on web sites (IXS web site display 35 programs and ESRF web site displays 23) and there are many XAFS analysis softwares not on such lists yet. We describe recent progress of the latest version of the REX2000 XAFS analysis package. The REX2000 run on MS-Windows family operating system, and is an entirely new package with user-friendly interface and simple operation. The package provides many classic DATA reduction methods for EXAFS and XANES. All the parameters needed for DATA analysis can be set on graphics windows as well as numerical input. The package also has FEFF interface for multiple scattering capability.

1. Introduction

The original version of Rigaku EXAFS analysis package (REX) was established in 1990. It ran on NEC's 16 bits personal computer PC-9800 series. The MS-DOS for PC-9800 is the Japan localized version. Neither the hardware nor the software were compatible with regular MS-DOS (or IBM-DOS). Therefore the program was modified shortly after the initial release so that it runs on IBM PC/AT compatible machines. The program was developed with collaboration of Prof. Kuroda's group (The University of Tokyo) and the data reduction algorithm was referred to their mainframe program EXAFS1 [1], but the source code was independent.

This program had been modified since then and eventually transferred to the Microsoft Windows platform in 2000. The windows version REX is named REX2000 and has presently been distributed in more than 80 sets.

2. EXAFS DATA reduction

REX2000 consists of 8 programs. They are named: "EXAFS", "Reference", "RATIO", "FEFF", "XANES", "Simulation", "multi-plot" and "DATA Editorial". The "EXAFS" program carries out ordinary EXAFS data reduction [2, 3, 4]. Several ways of data processing are provided in each step. For instance, linear to 6th order polynominal functions as well as ordinary Victoreen extrapolation (with and without constant) can be used for background subtraction. The EXAFS oscillation extraction method advocated by Cook and Sayers [5] is well implemented and successfully extracts the fine structure for most cases with default parameter sets (Fig. 1). The range or node point can be set either by clicking mouse pointer on the plotted data or by input energy values in the parameter window. After extracting the EXAFS oscillation, fast Fourier transformation is applied and the pair distribution function is obtained. Then non-linear least square curve fitting is performed to minimize the sum of the residuals, Δ;

$$\Delta = \sum (k^n \chi_{obs}(k) - k^n \chi_{calc}(k) / k^n \chi_{obs}(k))^2. \quad (1)$$

Up to 10 shells can be fitted at the same time. All the parameters and method used for the data reduction can be saved in a file and used for other data reductions to minimize uncertainty. The "Reference" program extracts the empirical backscattering amplitude and phase shift out of reference sample data for which the crystallographic structure is already known. Then those parameters are used for the fit and sometimes gives a more accurate result than using theoretical parameters.

FEFF [6, 7] developed by Professor Rehr's group is a program calculating XAFS spectra considering ab initio multiple scattering effects and is widely used in many XAFS analysis software. Although REX2000 employs theoretical tables calculated by McKale *et al*. [8] as default parameters for backscattering amplitude and phase shift, FEFF tables [9] can be alternatively used. Furthermore the parameters calculated by FEFF software can be used for a curve fit. There are two ways doing that. One is using chi.dat (one of output files of FEFF code) as measured data. The chi.dat is treated as reference data and empirical parameters are extracted in the same manner as the standard sample. The other way is using FEFFnnnn.dat. FEFFnnnn.dat is intermediate products of a FEFF calculation and it contains both backscattering amplitude and phase shift of a specific path. REX2000 can extract and use those parameters for a curve fit. One of the minor problems using FEFF stand-alone would be its interface. Because FEFF is FORTRAN program running on command line, it does not have a graphical user interface. REX2000 provides a graphical user interface for FEFF version 6, 7 and 8. The REX2000's FEFF dialog makes it easy for users to select many options just by clicking on a button. Making a model structure is another troublesome process for a FEFF calculation. A wizard style program to make crystallographic structure is available. An input file for atoms [10] can also obtained easily from the metal data file (CRYSTMET) according to the collaboration with the Tosh Information Systems Inc [11].

3. XANES analysis

The DATA reduction procedure for EXAFS is well established and standardized, but the DATA reduction of XANES spectra is not standardized yet because of the complexity of the phenomenon. REX2000 provides two DATA reduction tools, which are fairly popular for XANES analysis. One is spectrum fit and the other is peak deconvolution. An XANES spectrum of a mixture can be expressed as a linear sum of standard XANES spectra, the tools for background subtraction, normalization and linear least square fit of summed spectrum are provided. The most common numerical approach for quantitive analysis of XANES is to deconvolute the spectrum into Lorentzian functions and an arctangent function, which is the contribution of the continuum state [12]. REX2000 offers the tools for the deconvolution.

*e-mail: takey@rigaku.co.jp

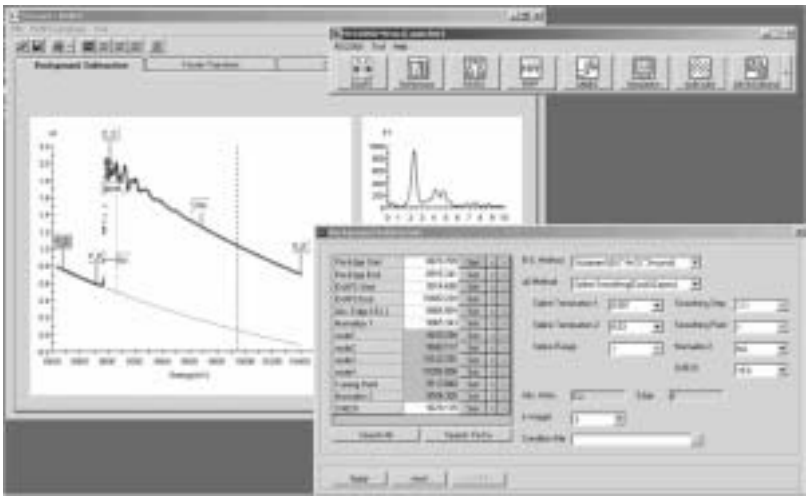

Fig. 1. EXAFS data reduction window.

4. Extra features

DATA conversion function is separated from the main program in order to cope with many different DATA format. The most recently added feature is multi-element Solid State Detector (SSD) DATA conversion with dead time correction. A nineteen-element SSD system for fluorescent XAFS experiments has been installed in the Photon Factory [13]. Although it is a powerful tool for characterization of very thin film and diluted system, summing up the output signals out of many elements is troublesome task. Moreover the output signals from the 19 elements are not always all usable. For instance, in the case of total reflection fluorescence XAFS, some elements are physically in a shadow region and only output background noise, and some elements might contain undesired diffraction peak(s). Summing up such signals spoils the DATA and can lead to incorrect conclusion. The REX2000 data conversion procedure for 19 elements SSD provides a visual interface to select the useful output, apply dead time correction if necessary and sum them up.

A procedure of error estimation for XAFS data analysis has been discussed for a long time, but no definite way of obtaining errors is established. Then we follow the recommendation of IXS Standards and Criteria Committee [14]. We assume the uncertainty of the j-th independent parameter P_j as

$$\mathrm{d}P_j = \sqrt{C_{jj}} \tag{2}$$

where C_{jj} is the j-th diagonal element of the covariance matrix used for the fit.

5. Conclusions

The latest version of REX2000 offers many useful features for XAFS analysis. Its intuitive interface helps simple analysis for a novice and a lot of options makes complicated analyses possible for an experienced user.

Abstract

The independent-electron approximation together with the final-state rule provides a well established method for calculating X-ray absorption spectra that takes into account both core-hole effects and inelastic losses. Recently a Bethe-Salpeter Equation approach based on Hedin's GW approximation that explicitly treats particle-hole excitations has been applied to the same problem. We discuss here the formal relationships between these approaches for deep-core X-ray spectra and show that they are similar, apart from differences in their practical implementations. Their similarity is illustrated with results from both theoretical approaches and compared with experiment. This comparison also suggests ways to improve both approaches.

1. Introduction

The question of how to treat the core-hole effects in X-ray absorption spectra (XAS) has long been unsettled. Within the independent-electron approximation, the core hole is often treated within the "final-state rule," (FSR) i.e., the one-electron Golden rule with final-state potentials calculated in the presence of a fully relaxed core hole. This approach provides a well established and efficient method for calculating X-ray absorption spectra and also includes electron damping effects by virtue of a complex electron self-energy [1]. More detailed treatments of the core-hole interaction require approximations that go beyond the independent-electron approximation. For example, a two-particle Bethe-Salpeter Equation (BSE) approach has recently been applied to XAS [2]. This approach explicitly treats particle-hole excitations and includes a self-energy based on Hedin's GW approximation (*GWA*) [3]. Simpler approximations have also been proposed. For example, one-electron methods that treat the core hole with various *ad hoc* approximations include the "$Z + 1$" [4], and "transition state" [5] approaches. Also, approximate methods that go beyond the independent electron model include time-dependent density-functional theory (TDDFT) [6–8]. In this paper, we discuss the formal relationships between these various approaches for calculations of deep core XAS. We show that the BSE for deep-core XAS and FSR are closely similar, apart from differences in their practical implementations. Their similarities help explain the numerical agreement often observed in calculations. Their formal differences rest largely in the treatments of local-field effects and exchange. These differences help explain why the effect of the core-hole varies from case to case, and also suggest how these approaches can be improved. Results from these theoretical approaches are compared with experimental near-edge spectra to illustrate these findings. We also discuss how additional many-body effects such as intrinsic losses and edge singularities can be included.

2. Final-State Rule

The final-state rule (FSR) was introduced by von Barth and Grossmann [9] for model, many-body treatments of XAS. The rule states that the X-ray absorption spectra $\mu'(\omega)$ is given to a good approximation by a one-electron Fermi Golden rule expression

$$\mu'(\omega) \sim \sum_f \left|\langle \psi'_f \,|d|\, \psi_i\rangle\right|^2 \delta_\Gamma(E_f - E_i - \hbar\omega), \tag{1}$$

where ψ'_f denotes a *final state* wave function calculated self-consistently in the presence of a static core hole with wave function ψ_i, and δ_Γ is a Lorentzian of with a width Γ determined by the core-hole lifetime. Here and elsewhere we use a prime to denote quantities calculated in the presence of a core hole. The matrix element involves the dipole-transition operator $d = \hat{\boldsymbol{\epsilon}} \cdot \vec{\boldsymbol{r}}$ coupling the electrons to the X-ray field.

Because of its computational efficiency, the FSR approach is often used in practical calculations [1, 10], and typically leads to good agreement with experiment for deep core-hole XAS. The FSR can be understood heuristically from the ΔSCF approximation in which the many-body final and initial states of the system are taken to be Slater determinants and non-orthogonality effects are ignored. Nevertheless, the validity of the FSR and other one-electron approaches has remained questionable, because many-body effects beyond the one-electron approximation are neglected. Indeed "failures" of the rule have sometimes been observed where core-hole effects are significantly suppressed [7].

Recently, however, the final-state rule has emerged as the leading term in a "quasi-boson model" for XAS [11]. This formulation encompasses a many-body treatment of X-ray absorption in terms of convolution of $\mu'(\omega)$ and an energy-dependent spectral function $A(\omega, \omega')$,

$$\mu(\omega) = \int \mathrm{d}\omega' A(\omega, \omega')\mu'(\omega). \tag{2}$$

The spectral function also includes satellite terms which account for inelastic intrinsic losses (e.g., multi-electron excitations) and interference effects beyond the quasiparticle approximation. The quasi-boson model also explains how edge-singularities can be incorporated in the theory [11]. The above convolution shows that the main effect of the satellite excitations is an additional broadening, which has been shown to be small near threshold.

Within the FSR a precise statement of the final state rule is given by a quasiparticle model that incorporates the core hole. That is, the the final states $|\psi'_f\rangle$ are scattering states which satisfy the Dyson equation,

$$h'\psi'_f = E_f\psi'_f, \tag{3}$$

$$h' = \frac{p^2}{2m} + V'_C + \Sigma'(E_f). \tag{4}$$

Here h' denotes the lossy quasiparticle final-state Hamiltonian for an excited state with energy E_f and a core-hole in state ψ_i.

V_C' is the final-state Coulomb potential, and $\Sigma'(E_f)$ is the complex self-energy operator, which is also primed in Eq. (4) to remind one that the self-energy should be evaluated in the core-excited state. In practice, the self-energy operator $\Sigma(E) \approx iGW$ is usually calculated within the GWA, where $G(E)$ is the one-particle Green's function and $W(\omega) = \epsilon^{-1}(\omega)v$ is the screened Coulomb interaction, $\epsilon^{-1}(\omega)$ being the inverse dielectric matrix, and $v = 1/|\vec{r} - \vec{r}'|$, the Coulomb interaction. Also, although the self-energy is formally a non-local operator, local-density approximations are often used in practice [12].

Thus calculations of X-ray absorption spectra within the FSR require the one-particle excited-state electronic structure and a final-state Coulomb potential $V_C' = V_C + \Delta V_C$. We have used V_C to represent the total Coulomb potential in the ground state, i.e., it has contributions from the ions as well as the electrons, and ΔV_C is the change in the Coulomb potential due to the core-hole, including screening by relaxation of the electrons.

Note that the quasiparticle Hamiltonian is non-Hermitian; this implies the existence of inelastic mean free paths $\lambda \approx p/|\mathrm{Im}\Sigma'(E)|$ which are typically between 5 Å and 20 Å. Moreover, there are systematic shifts in the spectral peak positions which affect the E-vs-p dispersion relation, $E_p = p^2/2m + |\mathrm{Re}\Sigma'(E_p)|$ and, concomitantly, the excitation spectra.

3. Bethe-Salpeter Equation

Another many-body approach for calculating XAS which explicitly treats particle-hole excitations is the Bethe-Salpeter equation (BSE). A practical approximation to the BSE based on the GWA has been derived from many-body perturbation theory [13], and has been implemented in various ways [2, 14, 15]. An important ingredient in the BSE is the quasiparticle approximation, with a self-energy based on GWA. In this approach the intrinsic and extrinsic losses are approximated by quasiparticle lifetimes, and dynamic interference effects and inelastic satellite excitations are ignored, an approximation which is reasonable close to an absorption edge. Here we follow the treatment of Soininen and Shirley [2] and adapt the discussion specifically for deep core-hole states. In their approach, the particle-hole basis states are represented as

$$\Phi(\vec{r},\vec{r}') = \sum_{ki} C_{ki}\phi_k(\vec{r})\frac{1}{N^{1/2}}\sum_{\vec{R}}\chi^*_{i,\vec{R}}(\vec{r}') \times \exp[-\mathrm{i}(\vec{k}-\vec{q})\cdot\vec{R}], \quad (5)$$

where e.g., in crystals, $k \equiv n\vec{k}$ denotes a band index and Bloch wave number of the final state, and i denotes the quantum numbers of the initial core level. Here $\phi_k(\vec{r})$ is a Bloch function and $\chi_{i,\vec{R}}(\vec{r}')$ is a core-level wave function in the unit cell associated with lattice vector $\vec{R}$. These quasiparticle states are, in principle, eigenfunctions of the GW Hamiltonian,

$$h = \frac{p^2}{2m} + V_C + \Sigma(E), \quad (6)$$

but ground-state wave functions can provide a good approximation in practice, and the excitation energies are corrected for self-energy effects. The electron and hole coordinates are respectively denoted by $\vec{r}$ and $\vec{r}'$. The vector $\vec{q}$ is the momentum of the excitation. This is the incident photon momentum in XAS, but modest revisions of the approaches discussed here allow one to study inelastic electron and X-ray scattering. N is the number of unit cells in the crystal, and the electron and hole wave functions in each pair state are properly normalized when integrated over the entire crystal. The excitation energies E_λ are the solutions of a coupled, electron-hole equation of motion,

$$H_{\mathrm{eff}}\Phi_\lambda = E_\lambda\Phi_\lambda, \quad (7)$$

$$H_{\mathrm{eff}} = \hat{H}_0 + \hat{V}_D + \hat{V}_X. \quad (8)$$

Here $\hat{H}_0$ denotes the Hamiltonian for the single-particle terms. The operator $\hat{V}_D$ accounts for the direct, screened electron-core hole attraction involving the screened Coulomb interaction $W(\omega)$. Usually the static limit $W(\omega = 0)$ is used in practice [2]. The corresponding exchange term $\hat{V}_X$ is unscreened. Instead of solving the eigenvalue problem of Eq. (7) it is usually easier to calculate the spectra in a continued fraction form as done for example in Ref. [2, 16]. There the matrix elements of H_{eff} are taken to be

$$\langle ki|H_{\mathrm{eff}}|k'i'\rangle = (E_k - E_i)\delta_{kk'}\delta_{ii'} + \langle k|V_D(i) + V_X(i)|k'\rangle\delta_{ii'}, \quad (9)$$

where $E_k = \epsilon_k + \Sigma(E_k)$ denotes the GWA quasiparticle energies.

Clearly static screening of a core-hole reduces its effect. Also the exchange term has an opposite sign from the direct term giving a further reduction. For these reasons the net effect of the core-hole can be substantially reduced. This explains why sometimes transition-state (i.e., calculations with 1/2 a core hole) or even "initial-state rule" (i.e., with the ground state Hamiltonian of the initial state with no hole) calculations are reasonable, especially in cases with strong screening.

The BSE is usually more computationally demanding than the FSR, due to the need for a much larger particle-hole basis and also a calculation of the inverse dielectric matrix ϵ^{-1}. However, the above formulation of the BSE is efficient for calculations in crystals with band-structure techniques, because a super-cell approach is not needed. Single-particle wave functions can be calculated to high accuracy, and self-energy effects can be included, including real shifts in band energies and lifetime damping effects.

The TDDFT approach for XAS is similar in several respects to the BSE [15]. For example, within TDDFT the term $\hat{V}_X$ is similar to that in the BSE. However, instead of $\hat{V}_D$, the analogous term in the TDDFT is the exchange-correlation kernel $f_{xc}(\omega)$, which in the local-density approximation is density-dependent and derived from the ground state exchange-correlation potential. Also the, particle-hole basis states are taken to be eigenstates of the ground-state density-functional Hamiltonian. For these reasons, the treatments of the screened core-hole interaction and inelastic losses are obscured in the TDDFT approach with local kernels.

4. Deep Core Level XAS

Let us now consider the XAS from a deep core level i that is static and structureless, e.g., in a K-shell of a sufficiently heavy atom. In the BSE with the approximations discussed above, the Golden rule for XAS can be expressed as a particle-hole resolvent,

$$\mu(\omega) = -\frac{1}{\pi}\mathrm{Im}\left\langle 0\left| d^\dagger \frac{1}{\omega - H_{\mathrm{eff}} + \mathrm{i}\Gamma} d\right| 0\right\rangle, \quad (10)$$

where d is the dipole operator, and where we have included the core-hole lifetime Γ. For a sufficiently deep core level, this yields

$$\mu(\omega) = -\frac{1}{\pi}\mathrm{Im}\sum_{kk'}\langle i\,|d^\dagger|\,k\rangle\left\langle ki\left|\frac{1}{\omega - H_{\mathrm{eff}} + \mathrm{i}\Gamma}\right|k'i\right\rangle\langle k'|d|i\rangle,$$

$$\approx -\frac{1}{\pi}\mathrm{Im}\sum_{kk'}M^*_{ik}\left\langle k\left|\frac{1}{\omega - h'_{\mathrm{eff}} + E_i + \mathrm{i}\Gamma}\right|k'\right\rangle M_{ik'}, \quad (11)$$

where $M_{ik'} = \langle k'|d|i\rangle$ is a one-particle matrix element, and h'_{eff} is an effective single-particle Hamiltonian derived from the BSE for a given core hole level i,

$$h'_{\mathrm{eff}} = h + V_D(i) + V_X(i). \quad (12)$$

Clearly h'_{eff} is analogous to the quasiparticle final state Hamiltonian h' in the FSR. In particular, the first term h is the quasiparticle Hamiltonian of Eq. (6) for single-particle excitations with $E = \omega + E_i$.

In the treatment of Soininen and Shirley the direct interaction $V_D(i)$ is calculated by static linear response, giving rise to the real-space potential,

$$V_D(\vec{r}) = \int \mathrm{d}^3r' W(\vec{r},\vec{r}';\omega = 0)$$

$$\times\ \frac{1}{N}\sum_{\vec{R}}|\chi^*_{i,\vec{R}}(\vec{r}')|^2\exp[-\mathrm{i}(\vec{k}-\vec{q})\cdot\vec{R}]$$

$$\equiv V_i(\vec{r}) + V_{\mathrm{ind}}(\vec{r}), \quad (13)$$

where $V_i(\vec{r})$ is the bare core-hole potential, and the induced potential from the valence electrons that screen the core hole is

$$V_{\mathrm{ind}}(\vec{r}) = \int \mathrm{d}^3r'[\epsilon^{-1}(\vec{r},\vec{r}';\omega = 0) - \delta(\vec{r}-\vec{r}')]V_i(\vec{r}'). \quad (14)$$

This is a good approximation, since the valence-electron screening is well described by linear response [2]. The corresponding exchange term involves the *unscreened* Coulomb matrix element

$$\langle k|V_X(i)|k'\rangle = \langle ki|v|ik'\rangle. \quad (15)$$

What above are (for simplicity) written as matrix elements of $V_D(i)$ and $V_X(i)$ between Bloch states are actually two-particle matrix elements between pair states in which the electron and core hole carry a net total crystal momentum of $\vec{q}$. Such a matrix element is equivalent to N times the matrix element for a Bloch wave scattered from a core-hole potential in each unit cell scaled by a factor of $1/N$. The factor $1/N$ arises because of normalization of the Bloch sum of atomic core-state wave functions in each pair state. The factor of N accounts for coherent summation over all units cells when computing the two-particle matrix element. This assumes that core-level wave functions on different sites are non-overlapping, which should be a very good approximation. Consequently, the effective matrix elements can be expressed as

$$\langle k|V_D(i)|k'\rangle = \int \mathrm{d}^3r\phi^*_k(\vec{r})V_D(i,\vec{\mathbf{0}};\vec{r})\phi_{k'}(\vec{r}),$$

$$\langle k|V_X(i)|k'\rangle = \int \mathrm{d}^3r\mathrm{d}^3r'\phi^*_k(\vec{r})V_X(i,\vec{\mathbf{0}};\vec{r},\vec{r}')\phi_{k'}(\vec{r}'). \quad (16)$$

Here $V_D(i,\vec{R} = \vec{\mathbf{0}};\vec{r})$ is the screened potential of a hole in core level i in the unit cell of the crystal associated with the origin $\vec{R} = \vec{\mathbf{0}}$. Choosing this cell eliminates the need to consider complex phases related to the core-hole crystal momentum in each pair state. Correspondingly, $V_X(i,\vec{R} = \vec{\mathbf{0}};\vec{r},\vec{r}')$ is the "Fock" exchange term for this potential. Finally, we note that we are only considering matrix elements that are diagonal in i.

5. Final-State Rule vs Bethe-Salpeter Equation

We now compare the FSR and BSE term by term, and find that they can be put in near one-to-one correspondence. The effective Hamiltonian h' for the quasiparticle (photoelectron) state in the FSR has three terms,

$$h' = \frac{p^2}{2m} + V'_C + \Sigma'$$

$$\equiv h + [V'_C - V_C] + \left[\Sigma' - \Sigma\right]. \quad (17)$$

Here h is the quasiparticle Hamiltonian of Eq. (6).

The screened core-hole potential appears in $V_D(i)$ in the BSE and analogously in $[V'_C - V_C]$ in the FSR. Within the FSR the bare core-hole potential is always accompanied by an induced screening potential in response to the core hole which is generated by the SCF loop,

$$V'_C(\vec{r}) - V_C(\vec{r}) \equiv V_i(\vec{r}) + \Delta V_{\mathrm{scf}}(\vec{r}). \quad (18)$$

Hence, these seemingly different expressions for the direct screened core-hole interaction are quantitatively similar,

$$\Delta V_{\mathrm{scf}}(\vec{r}) \approx V_{\mathrm{ind}}(\vec{r}). \quad (19)$$

This near equivalence largely explains the typical close numerical similarity in the results of the two methods for the Mg K edge of MgO (Fig. 1) and the O K edge of MgO (Fig. 2), both of which agree reasonably well with experiment.

The biggest formal differences between the BSE for deep core levels and the FSR lie in the treatments of the exchange term $V_X(i)$ in the BSE, and correspondingly the difference in self-energies $\Sigma' - \Sigma$ in the FSR. These terms are analogous physically, because the self-energy can be viewed as a dynamically screened exchange interaction, i.e.,

$$\Sigma(\omega) = \mathrm{i}G[v + (\epsilon^{-1}(\omega) - 1)v] = V_{ex} + \Sigma_C(\omega), \quad (20)$$

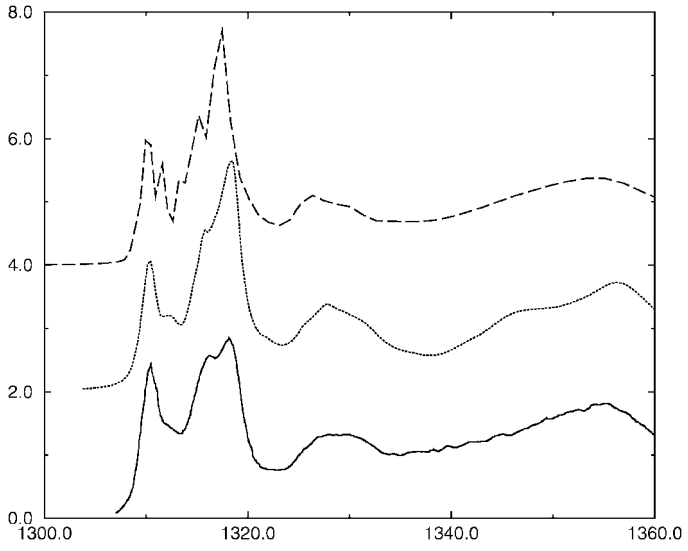

Fig. 1. Comparison of final-state rule (dashes) and Bethe-Salpeter equation (dots) calculations of XAS vs energy E in eV with experiment (solid) for the Mg K edge for MgO. The theoretical curves are shifted vertically for clarity.

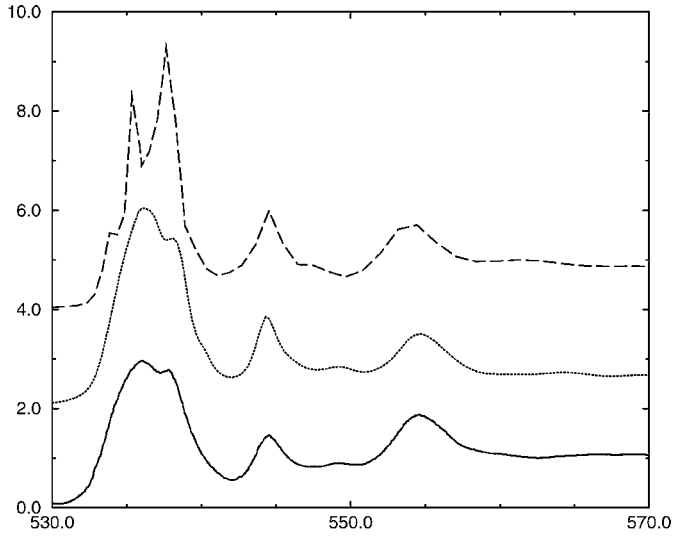

Fig. 2. Comparison of final-state rule (dashes) and Bethe-Salpeter equation (dots) calculations of XAS vs energy E in eV with experiment (solid) for the O K edge for MgO. The theoretical curves are shifted vertically for clarity.

where $V_{\rm ex}$ is the unscreened Fock exchange interaction

$$V_{\rm ex}(\vec{\boldsymbol{r}},\vec{\boldsymbol{r}}') = \sum_n^{occ} \frac{\langle\vec{\boldsymbol{r}}|n\rangle\langle n|\vec{\boldsymbol{r}}'\rangle}{|\vec{\boldsymbol{r}}-\vec{\boldsymbol{r}}'|}, \tag{21}$$

and $\Sigma_C(\omega)$ is the dynamic part of the self-energy. Now we can express the difference between the initial- and final-state self-energy operators as

$$\Sigma' - \Sigma = V_X(i) + \Delta V_{ex} + \Delta\Sigma_C, \tag{22}$$

where ΔV_{ex} represent the change in the exchange-operator due to the relaxation of the occupied states (excluding the core state) and $\Delta\Sigma_C$ is the change in Σ_C. If these last two terms can be neglected, the FSR and BSE approaches are rather similar. In particular, this is a good approximation below typical plasmon energies, where the quasiparticle corrections are small.

6. Discussion and Conclusions

We have shown that the BSE and FSR approaches for calculations of deep core XAS are formally similar. In particular they both incorporate GWA self-energies and their treatments of the screened core-hole are comparable. Apart from their formal similarities, however, these approaches differ in their practical implementations. For example, in the BSE approach described above, Σ and $V_X(i)$ are treated as non-local operators, while in typical applications of the FSR [10], the self-energy Σ (or Σ') is approximated using plasmon-pole, electron-gas self-energy models within a local-density approximation [12].

The difference in the treatment of the locality of the exchange operator V_X turns out to be crucial. It appears that the non-local treatment of V_X used in the BSE is generally preferable to the local exchange approximation used in the FSR. In particular, the non-local form naturally includes "local-field effects," namely the screening of the X-ray field which is particularly important for soft X-ray edges. This screening may be described formally by the random-phase approximation (RPA) bubble diagrams [6, 17]. Indeed, if the screened-core-hole interaction $\hat{V}_D$ were neglected, the BSE would be equivalent to the RPA. Screening by electrons other than resonantly excited core electrons would necessarily need to be included as well for a complete treatment. However, such screening is weak and has a weak energy dependence. However, in many cases the local-field corrections are small, especially for very deep-core XAS. For such cases, the present comparisons show that the FSR and BSE are expected to give similar results, consistent with numerical calculations.

Thus, we suggest that it may be preferable in calculations of deep core XAS to replace the FSR Hamiltonian h' with its deep-core BSE counterpart $h'_{\rm eff}$. This approach requires some additional computational effort to incorporate the non-local exchange matrix elements of $V_X(i)$. However, this can be facilitated with iterative techniques, a local-basis approach [7], and/or the use of atomic-structure calculations [2]. The most time-consuming part of this approach is still the calculation of the inverse dielectric matrix. However, this calculation can be avoided by calculating the screening of the core hole within the SCF loop using Eq. (18). The resulting FSR-like one-particle theory is defined self-consistently by the Hamiltonian

$$\begin{aligned} h'_{\rm scf} &= \frac{p^2}{2m} + V'_C + \Sigma(\omega) + V_X(i) \\ &= h + V_X(i) + \Delta V_{\rm scf}, \end{aligned} \tag{23}$$

and is thus simpler than the BSE for deep core levels. Moreover, since the quasi-particle corrections are small at low photoelectron energies (below the plasmon onset) one could use the ground state LDA (or Hartree-Fock) band energies (or Green's functions) in that regime.

The above approach can also be generalized to treat XAS from several nearly degenerate deep core levels, e.g., L-shell XAS. This leads to a coupled set of equations that mix the various levels i, similar to that discussed in Ref. [7]. For this case, the screening response to the core hole $\Delta V_{\rm scf}$ can also be calculated using the SCF loop instead of linear response.

On the other hand, all FSR-like theories are explicitly level dependent, and become impractical for valence band excitations. Moreover, an explicit calculation of the dielectric matrix makes it possible additionally to study the effects of energy dependence of V_D (i.e. dynamic screening of the core-hole), which has been argued to be important in some cases [7]. Finally, the inclusion of satellite inelastic losses interference terms can be included in the theory via a convolution, adapting the treatment of Ref. [11].

Acknowledgments

We respectfully acknowledge our indebtedness to Lars Hedin for discussions that led to this work. We also thank A. Ankudinov, G. Bertsch, S. Pantelides and L. Reining for useful comments. Abstract

The solid solutions $Cu_xAg_{1-x}GaS_2$ and $Cu_xAg_{1-x}InSe_2$ for $x = 0.5$ and their terminal compounds ($x = 0$; 1) have been investigated both theoretically and experimentally using X-ray emission and absorption spectroscopy. These solid solutions are advanced materials for the transformation of solar energy. The electron structure of these solutions and compounds was investigated using FEFF8 code. The calculated local densities of electron states and X-ray absorption spectra were compared with our experimental X-ray spectra and photoelectron curves taken from the literature. The good correspondence of the theory to the experiment guarantees the assumed interpretation of the results for the solid solutions $Cu_xAg_{1-x}GaS_2$ and $Cu_xAg_{1-x}InSe_2$. It was found that in these solid solutions "pushing apart" of d-states of Cu and Ag takes place, which can be explained by the splitting of p-states of the atoms C^{VI} and d-states of A^I-atom (Cu and Ag). Our calculations have proved and explained the nonlinear dependence of the energy gap E_g on x.

1. Introduction

The solid solutions $Cu_xAg_{1-x}GaS_2$ and $Cu_xAg_{1-x}InSe_2$ and their marginal compounds have interesting optical properties and nonlinear dependence of the energy gap E_g on x [1, 2]. It was shown [3, 4], that the doping of $CuInSe_2$ can change the type of conductivity of it. The compound $CuInSe_2$ can be used as sun-battery cell [5].

The electron energy structure (EES) of $CuInSe_2$ and the defect structure $CuIn_3Se_5$ have been investigated in the work of J. Jaffe and A. Zunger [6] and recently [7–9]. In work of Japanese authors [9] the LOPW-method was applied to calculate EES of $CuInSe_2$. It was shown that the great value of E_g in $CuIn_3Se_5$ was caused by p-d hybridization and by d-d mixing.

The compounds $CuGaS_2$ and $AgGaS_2$ and their solid solutions crystallize into the chalcopyrite structure with the space group I42d (D_{2d}^{12}) [10]. The solid solutions $Cu_xAg_{1-x}InS_2$ [1] and $Cu_xAg_{1-x}InSe_2$ [2] have the same crystalline structure. The lattice of chalcopyrite can be presented in the first approximation as a supersphalerite structure, which for $CuGaS_2$ can be derived from close-packed fcc lattice of sulfur atoms, the tetrahedral interatomic emptinesses being occupied by atoms of copper and gallium such that in the first atomic shell of sulfur atom there are two atoms of copper and two atoms of gallium. The tetragonal elementary cell of chalcopyrite is characterized by the parameters: $\boldsymbol{a}$ along axes X and Y and $\boldsymbol{c} \approx 2\boldsymbol{a}$ along axis Z. In contrast to sphalerite lattice the face-centred cation sublattice of chalcopyrite consists of two types of atoms, that results in the distortion of the tetrahedral surrounding of every anion (S or Se). This distortion is described by two parameters: by the difference between $\boldsymbol{c}$ and $2\boldsymbol{a}$ and by the parameter $\boldsymbol{u}$, which shows the shift of a cation along the space diagonal.

In the present work theoretical EES and X-ray absorption spectra of the solid solutions $Cu_{0.5}Ag_{0.5}GaS_2$ and $Cu_{0.5}Ag_{0.5}InSe_2$ and their marginal compounds were investigated using FEFF8 code. The calculated local partial electron densities of states (LPDOS) and X-ray absorption edges for the compounds were compared with X-ray emission and absorption spectra studied earlier [11] and taken from the literature [12–14]. One of the main purposes of this work was to prove theoretically the results of experiments [1, 2], a nonlinear dependence of the energy gap E_g on the concentration x of these solid solutions.

2. Method of calculations

The experimental values of the lattice parameters for compounds $CuGaS_2$, $AgGaS_2$ $CuInSe_2$ and $AgInSe_2$ were taken from review [15]. The crystallographic parameters for the solid solutions were determined according to Vegard's law as the averages of ones for the margin compounds.

To calculate EES and theoretical forms of X-ray absorption spectra the *ab initio* full multiple scattering method realized in FEFF8 code [16] was used. The self-consistent densities of electron states, electron density in real space and Fermi energy E_F were calculated. The calculations of the theoretical form of X-ray absorption edges were carried out taking into account the screened core hole and the broadening effect due to the X-ray spectrometer window width and to the core hole life-time. The LPDOS for every type of atom in the system were determined by calculations using the retarded Green function by integration in complex plane for a cluster centred at this type of atom. At the first stage of the calculations the self-consistent mt-potentials for a clusters of about 35 atoms were obtained. After that the full multiple scattering calculations were fulfilled, taking into account 87 atoms as centres of scattering and then all significant pathes were considered for 1000 atoms. To achieve the self-consistency for Fermi energy up to some-hundredths of eV less than 11 iterations were enough.

3. Results and discussion

The results of the calculations of LPDOS and X-ray absorption spectra are shown in figures 1–5. The superposition of the experimental and theoretical curves for the compounds were made the standard way [11]. The energy zero corresponds to the top of the valence band, which was found by the SK-emission band corrected (by deconvolution), taking into account the width of the K-level of sulfur and the spectrometer window width. As for the solid solutions, the superimposition of the LPDOS and the experiment curves were carried out in the following way: the energy positions of the peaks B and C of the corresponding XPS bands of the margin compounds $CuGaS_2$ and $AgGaS_2$ were put in coincidence with the maxima of Cu 3d-states and Ag 4d-states of the solid solution $Cu_{0.5}Ag_{0.5}GaS_2$ (Fig. 1). It reflects the fact

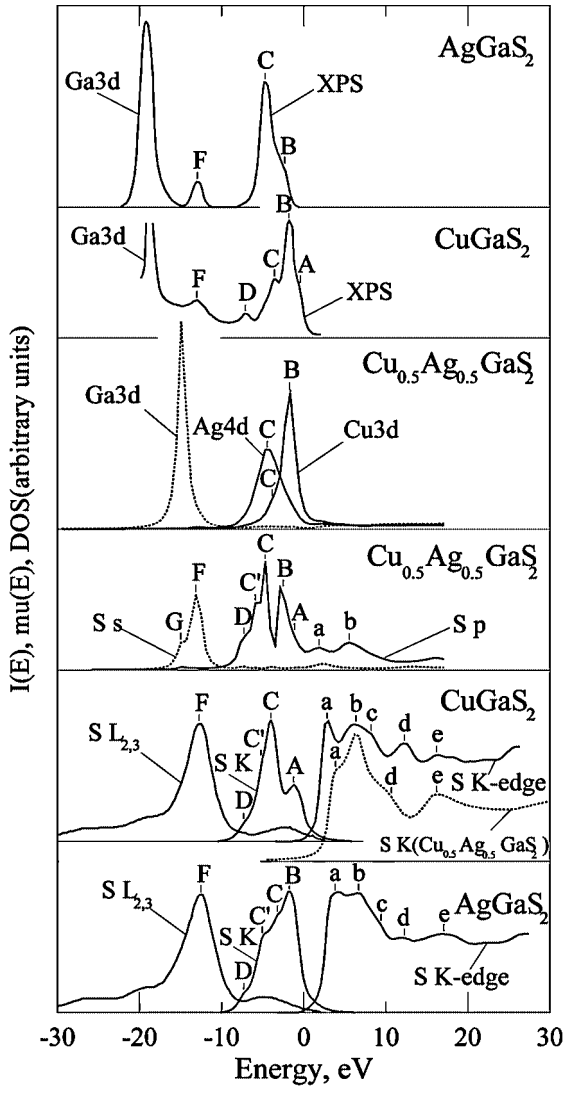

Fig. 1. The calculated densities of electron states in the solid solution $Cu_{0.5}Ag_{0.5}GaS_2$ in comparison with X-ray spectra of emission and absorption in the compounds $CuGaS_2$ and $AgGaS_2$, and also with XPS-spectra for $CuGaS_2$ and $AgGaS_2$ from the literature [12, 13]. The zero of the energy scale corresponds to the top of the valence band.

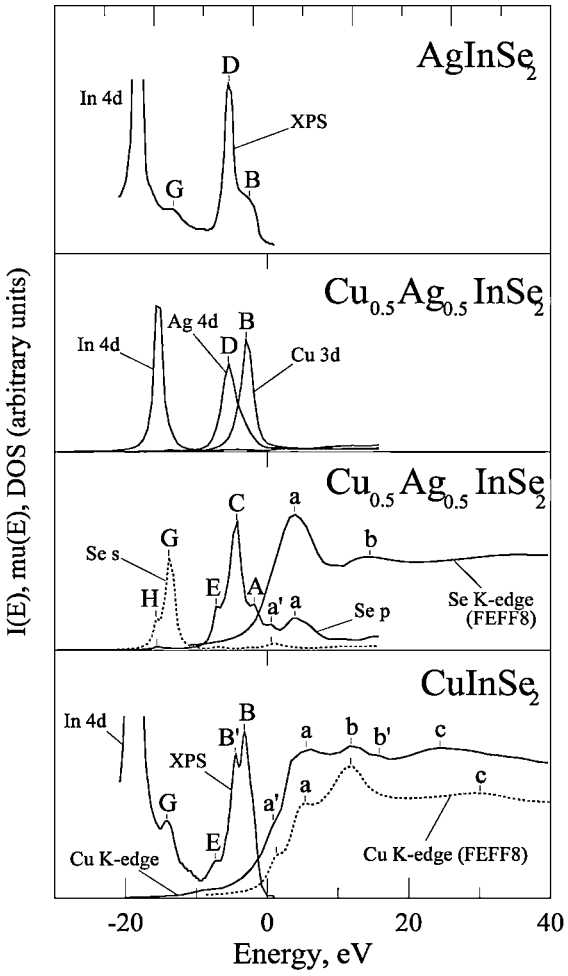

Fig. 2. The calculated density of electron states, X-ray K-absorption spectrum of Se in the solid solution $Cu_{0.5}Ag_{0.5}InSe_2$, and K-absorption edge of Cu in $CuInSe_2$ compared with taken from the literature: XPS-spectra in the compounds $CuInSe_2$ and $AgInSe_2$ [12] and K-abosrption spectrum of Cu in $CuInSe_2$ [14]. The energy zero corresponds to the top of the valence band.

that XPS bands of such metals represent the energy distribution of d-electrons mainly, because their cross-sections are greater than ones for s- and p-electrons. One can see in Fig. 1 the good correspondence of theory and experiment. The only exception is the energy position of 3d-states of Ga, their energy is about 3 eV less than for the XPS-spectrum.

In Fig. 2 the experimental XPS-spectra [12] for the compounds $AgInSe_2$ and $CuInSe_2$ and the X-ray CuK-absorption spectrum of $CuInSe_2$ are shown in comparison with the calculated LPDOS for s- and p-electrons of Se and d-electrons of Cu, Ag, and In in the solid solution $Cu_{0.5}Ag_{0.5}InSe_2$. Further, the form of the SeK-absorption edge was calculated for this solution and the theoretical CuK-absorption edge was obtained.

To be sure that our calculations are adequate we have compared (Fig. 3) the calculated LPDOS for $CuInSe_2$ with the experimental XPS spectrum [12] and X-ray emission $SeM_{4,5}$-spectrum. One can see, that the energy positions of all maxima of Cu d-states and Se p-states nearly coincide with the energy positions of the corresponding features of the experimental curves. It was found that 4p-states of Se are splitted in two subbands A and C, which is proven by the $SeM_{4,5}$-spectrum. The hybridizing interaction

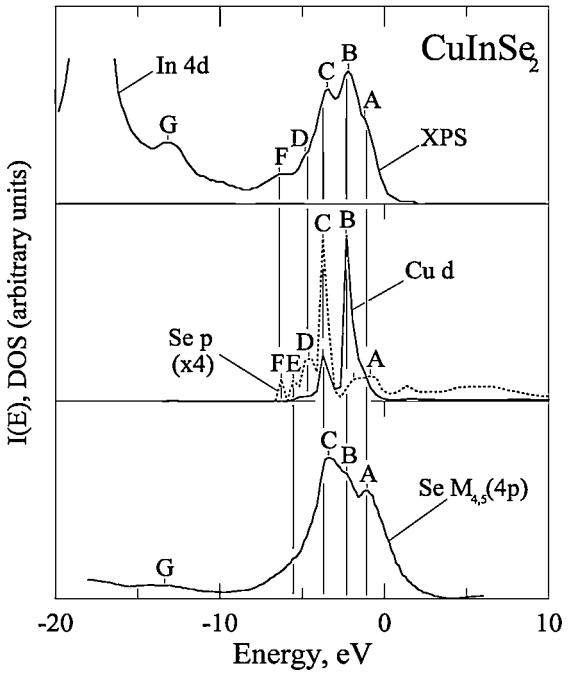

Fig. 3. The calculated densities of electron d-states of Cu and p-states of Se in $CuInSe_2$ compared with X-ray emission spectrum of Se $M_{4,5}$ and XPS-spectrum [12]. Zero energy is chosen at the top of the valence band.

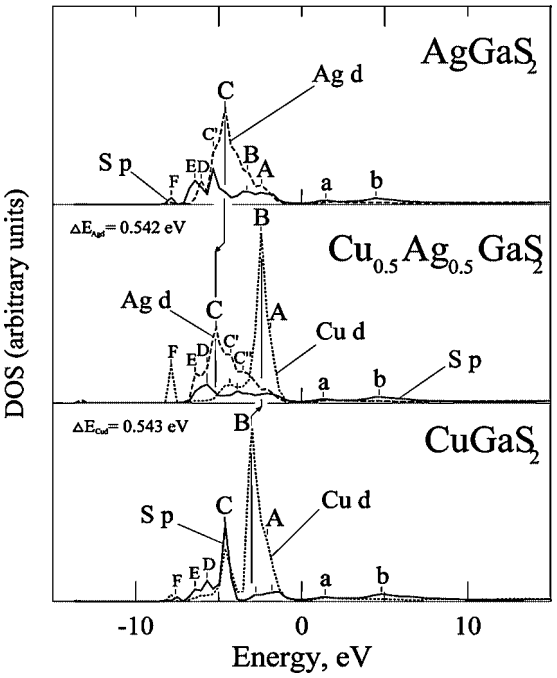

Fig. 4. Calculated electron densities of p-states of S (bold curves) and d-states of the noble metals (dashed curve for Ag and dotted curve for Cu) in compounds $AgGaS_2$ and $CuGaS_2$ and in the solid solution $Cu_{0.5}Ag_{0.5}GaS_2$ superposed by Fermi level.

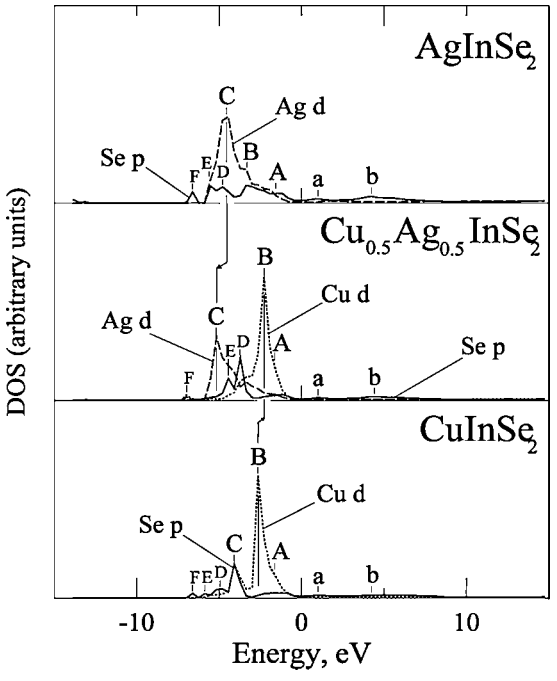

Fig. 5. Calculated electron densities of p-states of Se (bold curves) and d-states of the noble metals (dashed curve of Ag and dotted curve for Cu) in compounds $AgInSe_2$ and the solid solution $Cu_{0.5}Ag_{0.5}InSe_2$, superposed by the Fermi level.

brings a splitting of d-states of copper to subbands B and C also. These maxima of the theoretical curve correspond to peaks B and C of the XPS spectrum [12]. For such compounds one always observe in the upper part of the valence band a so-called d-s,p, resonance [17, 18], that leads to decreasing forbidden energy band width E_g. For $CuInSe_2$ it is the interaction of the p-states of Se with d-states of Cu, that results in the evident splitting of the p-band of Se to two maxima. From our previous investigations [11, 19] it follows, that the bottom of the conduction band in the compounds $A^IB^{III}C_2^{VI}$ form s-states of the metal B^{III} (Ga, In), which also decrease E_g compared to their isoelectronal analogues $A^{II}B^{VI}$.

For the solid solutions $Cu_{0.5}Ag_{0.5}GaS_2$ (Fig. 4) and $Cu_{0.5}Ag_{0.5}InSe_2$ (Fig. 5) the calculations of PLDOS show, that the d-states of the noble metals Cu and Ag are "pushed apart" comparing to the marginal compounds with increased energy distance between them by about 0.9 eV. This "pushing apart" of d-states of Cu and Ag and the energy positions of s-states of Ga and In atoms at the bottom of the conduction band can lead to a nonlinear change of E_g in the solid solutions. Following I. V. Bodnar *et al.* [2], we also suppose that the dependence $E_g(x)$ can be described by the formula $E_g(x) = ax^2 + bx + c$. The coefficient 'a' characterizes the non- linearity of this dependence. For the solution $Cu_xAg_{1-x}InS_2$ we found for this coefficient the value 0.088 eV. The empirical estimation [2] of 'a' for $T = 77$ K is 0.102 eV. However one has take into account that our calculations were carried out for $T = 0$ K. For the solution $Cu_xAg_{1-x}InSe_2$ we obtained $a = 0.18$ eV, that is twice that for the previous solution. So our theoretical investigation has proved the nonlinear dependence of $E_g(x)$ in correspondence with the experimental data.

Abstract

The Fe-O distances (R_1) and the number of nearest oxygen atoms (N_1), which coordinate Fe in Fe(II) and Fe(III) containing silicate glasses are determined by the method based on the Fourier-transform analysis of XANES performed for the short k-range and the subsequent fit of the extracted first shell's contribution. The scattering amplitudes for Fe-O pair, used for the fit, are calculated by the HF MT-potential with the neutral electronic configurations of atoms. The validity of this model for the different redox states of Fe in glasses and the accuracy of the determined R_1 and N_1 are analyzed applying the method to the Fe K-XANES of the references – Fe(II) and Fe(III) aqueous sulfate solutions. The modeling of the contribution of the Fe nearest oxygens to the Fe K-XANES of Fe(II)- and Fe(III)-rich silicate glasses, as well as in the series of glasses with the mixture of Fe(II) and Fe(III) states, performed through a single-shell fit and a subsequent two-shell fit, provides structural parameters for the oxygen-polyhedron around the ionized Fe^{2+} and Fe^{3+}-atoms and gives access to the estimates for the Fe^{2+}/Fe^{3+} ratio changes among all samples studied.

1. Introduction

The application of X-ray absorption spectroscopy (XAS) to determine the coordination environment of Fe in Fe-bearing silicate glasses, that suffered reduction or weathering, can provide important structural information, including 2D/3D micro mapping of Fe-O distances and Fe-coordination numbers, in addition to redox mapping. However, for a large number of these amorphous compounds, the application of XAS is often limited by the analysis of XANES. The very high resolution and poly-dimensional (2D mapping and 3D-tomography) XANES studies are benefiting highly from the recent development of micro-absorption methods on third generation sources. At the same time, the most current approaches of XANES analysis are based on indirect and qualitative information on the studied local structure estimated by comparing "unknowns" with model compounds. In this paper, the method proposed in [1, 2] is used to quantitatively determine Fe-O distances and coordination numbers for Fe in Fe(II)- and Fe(III)-bearing silicate glasses. This method, originally developed for crystalline minerals and glasses with low-Z atoms ($Z < 20$), is based on the Fourier-transform (FT) analysis of XANES within the short range of the photoelectron's wave numbers ($k = 0.2625^*(E - E_{MT})^{1/2}$, where E_{MT} is the interstitial potential for the compound studied), followed by a model of the contribution related to the first neighbours.

2. Determination of structural parameters for Fe coordination environment in the references Fe(II)- and Fe(III)-aqueous sulfate solutions

Analysis of the accuracy of metal-oxygen distances (R_1) and the number of nearest oxygen-atoms (N_1) of the first shell around the absorbing atom, determined by FT of XANES over the short k-interval $\sim 2.5\,\text{Å}^{-1}$ was performed in [1] for crystalline minerals and glasses consisting of low-Z atoms. To confirm the accuracy of R_1 and N_1 determination in the studied Fe-containing amorphous compounds, the method (including the accuracy of the scattering amplitudes and phase shifts calculated for the Fe-O pair) was validated using two Fe(II)- and Fe(III)-sulfate aqueous solutions (0.2 M), with pre-edge typical of regular 6-coordinated Fe(II,III) environments and with no medium-range order (MRO) contribution [3]. As was shown in [1, 2], the MRO-contribution can decrease (in contrast to the multiple-scattering (MS) term the accuracy of structural parameters obtained via FT and fit performed over the short k-interval. The XANES-simulations for the model crystals and their glass equivalents [1, 4, 5] reveal that for the studied crystalline compounds the first main edge crest features in their XANES are often strongly affected by the MRO- and MS-terms. At the same time, these simulations for glasses reveal that the fine structure at higher energies, after the first main edge crest features in XANES, is formed dominantly by the oxygen-polyhedron around the absorbing atom, due to the increasing diffusion for the second and more distant shells. According to this result the effect of the MRO-term in the studied Fe-containing silicate glasses can be minimized by the choosing adequately the corresponding k-interval for the FT. Therefore, for the Fe(II)- and Fe(III)-silicate glasses, as well as for the used references Fe(II) and Fe(III)-aqueous sulfate solutions, the FT was applied to the $\chi(k)$ over the short range of the wave numbers k: 3.9–5.8 Å^{-1}. This k-range excludes the main edge crest features (at $k < 3.9\,\text{Å}^{-1}$) and the small value of k_{max} makes it even more pertinent for disordered compounds. The $\chi(k)$ was extracted from the experimental Fe K-XANES spectra by the equation:

$$\chi(k) = \sigma^{exper}(k)/\sigma_{at}(k) - 1 \quad (1)$$

and the factorised "atomic" part of the absorption cross-section σ_{at}, obtained from the experimental Fe-XANES by the procedure proposed in [1]. The photoelectron phase shifts and scattering amplitudes were calculated by Hartree-Fock (HF) MT-potential [6], generated using the electronic configurations: $Fe(1s^1 2s^2 \ldots 3d^7 4s^2)$ – for the absorbing atom and $O(1s^2 2s^2 2p^4)$ – for the neighboring oxygens, which provides the value of $E_{MT} = 7092.7$ eV for the compounds studied. The photoelectron extrinsic

*e-mail: bugaev@rnd.runnet.ru

losses, core hole width and experimental energy resolution were accounted for by $\exp(-0.2625(\Gamma_{\text{exper}} + \Gamma_{\text{h}} + \Gamma_{\text{el}})2R/k)$, where Γ_{exper} is the energy parameter (eV) for the experimental resolution, Γ_{h} and Γ_{el} are the energy widths of the core hole and the excited electron states respectively. This exponential can also be rewritten as $\exp(-2R/\lambda_{\text{eff}})$ with the effective mean free path λ_{eff} for the photoelectron, given by:

$$1/\lambda_{\text{eff}} = 0.2625\ (\Gamma_{\text{exper}} + \Gamma_{\text{h}})/k + 1/\lambda_{\text{el}}. \quad (2)$$

The Γ_{h} and the photoelectron mean free path length $\lambda_{\text{el}}(k) = k/(0.2625\,\Gamma_{\text{el}})$ for Fe containing compounds were taken from [7]. The FT of the $\chi(k)$ extracted from the experimental Fe K-XANES and the three-parameters (N_1, R_1, σ^2) fit in R-space (0.3–2.5 Å) of the first oxygen shell's peak in $|F(R)|$ were performed under the constant reduction factor $S_0{}^2 = 0.8$, using FEFFIT [8].

The agreement between the determined structural parameters for Fe-environment in Fe(II)-solution with the available structural information [3] appears to be similar to that for the crystalline minerals consisting of low-Z atoms [1]. This accuracy suggests that the fit for the $\chi(k)$, extracted by the $E_{\text{MT}} = 7092.7$ eV of the used HF MT-potential, can be performed without any additional energy shift (i.e. under the parameter $E_0 = 0$ eV for the FEFFIT model). This conclusion justifies the adequacy of the HF MT-potential based on the neutral electronic configurations of atoms for the FT-analysis of the Fe(II)-rich compounds.

However, the same comparison for the model Fe(III)-sulfate solution reveals that to obtain sufficient accuracy for the Fe-O distance by the same scattering amplitudes and phase shifts as for the Fe^{2+} state and by the E_{MT} of the used HF MT-potential, the energy shift $E_0 = 2$ eV is needed for the FEFFIT model. The last conclusion is justified by the results on the scattering phase shifts parameterization [9], which showed that for the different charge states of atom, the logarithmic derivatives of the photoelectron wave functions at the MT-radius (used for the phase shifts calculation) are only shifted in the energy scale, without the change of their shapes.

3. Fe-coordination environment in Fe(II)- and Fe(III)-silicate glasses

The results of the FT-analysis for the reference solutions permit us to apply the method to a set of silicate glasses of float composition (molar composition $\sim Ca_1Na_1Al_1Si_4O_{11}$) doped with 1 wt.% Fe, quenched from their respective melts equilibrated at different oxygen fugacities and characterized using Fe K pre-edge information at the Fe K-edge [10]. Two end-members were isolated from that series, which contains more than 99 atom% of iron, as Fe(II) and Fe(III) respectively [10]. In Fig. 1, the FT for the experimental Fe K-XANES in Fe(II)-rich glass and in Fe(III)-rich glass are compared with the corresponding single-shell models, performed with $S_0{}^2 = 0.8$ and $\Lambda_{\text{eff}}(k)$ obtained by (2). The determined structural parameters of the models for the Fe(II)-rich glass are: $N_1 = 5.1$, $R_1 = 2.0$ Å and for the Fe(III)-rich glass: $N_1 = 4.5$, $R_1 = 1.92$ Å, under approximately the same $\sigma^2 = 0.005$ Å^2 as for the Ti-containing glasses [5].

The Fe(II)- and Fe(III)-rich silicate glasses were treated as the boundary samples for the series of eight silicate glasses (named further as Sample1, Sample2, ..., Sample8) which contain the mixture of Fe^{2+} and Fe^{3+} states with the concentration (C) of Fe^{2+}, decreased along this row. The analysis of the asymmetry of the first shell's peak (nearest oxygens contribution) in $|F(R)|$ performed via the two-shell fit gives access to the estimate for the

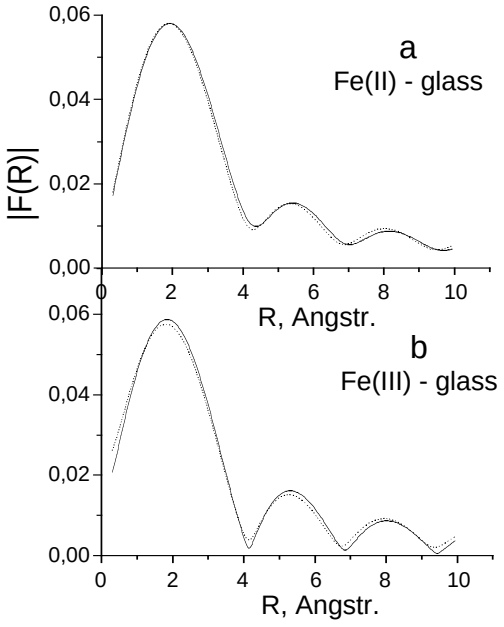

Fig. 1. $|F(R)|$ for Fe(II)-bearing (a) and Fe(III)-bearing (b) silicate glasses: solid curves – the FT of the $\chi(k)$ extracted from the Fe K-XANES and dashed curves – the results of the single-shell fit.

change of the ratio Fe^{2+}/Fe^{3+} among all the samples studied, in assumption that the anharmonicity effects in atomic motion are negligible. For this purpose, the possible concentrations of the two mixed Fe-states with different oxygen-coordinations can be estimated by the two-shells fit. This fit is based on the assumption that each shell (which contains $N_{1,j}$ atoms at $R_{1,j}$ distance, $j = 1, 2$ is the shell's number) represents the different type of oxygen-coordination environment of corresponding Fe-state. In this case, the fitting function $\chi(k)$ can be constructed by FEFFIT as follows:

$$\chi(k) = C\chi_{1,1}(k) + (1 - C)\chi_{1,2}(k) \quad (3)$$

where $\chi_{1,1}(k)$ – is the contribution of the first shell – oxygen polyhedron for Fe^{2+} environment, with $N_{1,1} = 5.1$ atoms at $R_{1,1} = 2.0$ Å (as was determined for the Fe(II)-rich glass); C – the concentration of the Fe^{2+}-states; $\chi_{1,2}(k)$ – is the contribution of the second shell – oxygen polyhedron for Fe^{3+} environment with $N_{1,2} = 4.5$ atoms at $R_{1,1} = 1.92$ Å (as was determined for the Fe(III)-rich glass). Then, a two-shell fit was performed considering the fixed $N_{1,1}$, $R_{1,1}$ and $N_{1,2}$, $R_{1,2}$, but with a "single-shell" value of $\sigma^2 = 0.005$ Å^2 (as for Fe(II), Fe(III)-rich glasses) and with the concentration C allowed to vary. According to the results for the used references Fe(II)- and Fe(III)-aqueous sulfate solutions, the fit was performed by the same set of HF scattering amplitudes and phase shifts both for the $\chi_{1,1}(k)$ and $\chi_{1,2}(k)$ using, however, the constant energy shift $E_0 = 2$ eV for $\chi_{1,2}(k)$ within the FEFFIT model. This scheme of the two-shell fit was tested for the boundary Fe(II)- and Fe(III)-rich glasses. The results of the fit for the other eight silicate glasses (Samples 1–8) give the values of concentrations C for Fe^{2+} in them. These C values are presented in Table I in comparison with the corresponding concentrations obtained via the chemical method (using ferrous ortophenantroline after glass dissolution under inert atmosphere). As can be seen, the values of concentrations for Fe^{2+} determined by Fe K-XANES correlate reasonably with the chemically obtained C values and show the nonmonotonous decrease of the Fe^{2+}/Fe^{3+} ratio along the studied row of glasses, from Fe(II)- to Fe(III)-rich silicate glass.

Table I. *Concentrations of Fe^{2+} in the series of glasses with the mixture of Fe^{2+} and Fe^{3+} states, obtained by Fe K-XANES and by the chemical method.*

Glasses with the mixture of Fe^{2+}, Fe^{3+} states	Concentration C (%) of Fe^{2+}	
	Fe K-XANES	Chem. method
Sample1	96.0	96
Sample2	71.0	69
Sample3	60.8	62
Sample4	45.4	45
Sample5	33.0	27
Sample6	21.9	26
Sample7	18.5	22
Sample8	9.0	9

For the Fe-bearing glasses, the obtained structural information is in agreement with pre-edge, Mössbauer, optical properties and molecular dynamics studies on these glasses [10] as well as circular dichroism experiments in similar glasses [11]. From these models, one can now use a similar approach for 2D/3D micro mapping of Fe-O distances and/or Fe-coordination number in glass samples.

Abstract

In the room-temperature EXAFS spectrum of Rb in the Rb/K alloy, the sharp spectral features due to double photoexcitation are plainly visible from 40 eV above the K edge. The weak and short structural signal is attributed to the strong thermal disorder. A unique atomic absorption background of the Rb atoms in the solid alloy is extracted and compared to the pure atomic absorption, measured on the monatomic Rb vapor, as a direct test of the practical transferability of experimentally determined atomic absorption backgrounds.

1. Introduction

It is well known in X-ray absorption spectrometry that the EXAFS region above an absorption edge hosts, beside the structural signal, also one or more groups of small sharp features, the multielectron excitations [1–3]. These, together with their extended tails, comprise the so-called atomic absorption background (AAB), characteristic of the target atom but only weakly depending on its environment. In the standard EXAFS analysis, the AAB is approximated by a spline background, constructed from the Fourier components of the absorption signal with periods below the range of possible neighbor distances. This may be adequate for samples with a strong structural signal. For weakly ordered or amorphous substances, however, the structural signal and AAB may be of comparable amplitude with widely overlapping harmonic components so that Fourier separation is not feasible and the analysis can only proceed with a directly determined AAB, exploiting its transferability for a given atomic species [4, 5].

The scarce data on the directly determined AAB come either from experiments on monatomic elemental samples or from the reverse analysis where the structural signal can be removed from the absorption spectrum with sufficient accuracy. The first and the only exact approach provided AABs of alkaline metals [6–9] and Zn [10], Cd [11] and Hg [12], if the data on noble gases could be momentarily put aside for the evident lack of interest from EXAFS practitioners. The second approach is more generally applicable, its early examples may be found in comparative studies using reference standards [3, 13–15].

Absorption spectra of inter-alkaline alloys open another path to AAB, seemingly related to both approaches. The Cs L edge absorption of a Cs/Na alloy at room temperature shows virtually no structural signal [16, 17]. Its atomic character is suggested after comparison with the purely atomic absorption of the adjacent noble gas Xe [18]. In the same way, the Rb K-edge absorption measured on a thin layer of the Rb/K or Rb/Na alloy is almost EXAFS-free, surprisingly similar to the absorption spectrum of the monatomic Rb vapor [6, 8]. In the present study, the absorption of the Rb/K alloy with atomic ratio 1 : 6 is measured at several temperature points between 80 K and room temperature with the aim to establish the temperature dependence of the crystalline order, i.e. to decide whether the absence of the structural signal is caused merely by the thermal disorder or by formation of a specific highly disordered phase.

2. Experiment

The alloys of Rb and Cs with the lighter homologues K and Na in different mixing ratios were prepared by melting together and homogenizing appropriate amounts of the constituent elements under the bath of paraffine oil. A speck of the solid alloy was placed between kapton foils with a drop of the oil, squeezed between carbon platelets in a special container and inserted into the cryostat. The absorption measurement was performed at the BM29 beamline of the European Synchrotron Radiation Facility (ESRF), Grenoble, with a two-crystal Si(311) monochromator with a resolution of ∼0.5 eV at the Rb K edge (15200 eV). The high flux of monochromatic beam and remote vision system of the station with a TV camera and a fluorescent screen was crucial for the success of the experiment, allowing to choose a small patch of homogeneous transmission on the sample.

3. Results and discussion

In view of the weak structural signal of the alloy, the standard spline construction of the absorption background is precluded. Instead, the available AAB, measured on Rb vapor [6, 8], is applied. A similar procedure has been used before for Br and Rb compounds [5] and in the extraction of AAB of 4p elements [15]:

- the data in the pre-edge region are modeled by a sum of a linear function and an arctan profile of the edge: after subtraction of the linear part, the K-shell Rb contribution remains (Fig. 1),
- the K-shell absorption is normalized by a Victoreen fit of the above-edge region beyond 500 eV (i.e. beyond the last visible MPE feature),
- a similarly prepared absorption spectrum of the Rb vapor (cf. insert in Fig. 1) is subtracted, whereby the non-structural contributions are removed,
- the remaining structural signal is transformed into $\chi(k)$ by conversion from E-space to k-space.

In a FEFF model [19, 20] potassium and rubidium are placed as closest neighbors at respective contact distances ($R_{\text{Rb-K}} = 4.72$ Å, $R_{\text{Rb-Rb}} = 4.96$ Å) [21]. The perfect agreement of the model and experiment is shown in Fig. 2 for the 80 K spectrum

where both neighbor shells are well defined, with $N_K = 7.4 \pm 0.7$ and $N_{Rb} = 2.0 \pm 0.5$. In all other spectra, only the potassium shell is statistically significant: with increasing temperature the EXAFS signal wanes and the weakly populated second shell is drowned in noise. For that reason, a single-shell model is applied to all spectra (Table I). Neglecting the second shell, though, has an unwanted side effect: its vestiges shift the first-neighbor distance (r_1) upwards. Since the second-shell signal wanes with temperature faster than the first-shell signal, r_1 spuriously shows a slight decrease with temperature.

The parameters of the model show a good consistency: the number of neighbors is steady within the error bars, and the Debye-Waller factor grows steadily (practically linearly) with temperature, as expected. It is worth noting that $\sigma^2 = 0.03$ Å^2 at

Table I. *Parameters of the single-shell model of Rb neighborhood in the Rb/K alloy: shell radius correction ($R_1 = 4.72$ Å), the number of K atom neighbors and the Debye-Waller factor. Parameter errors (in parentheses) are given in units of the last decimal place. The N_1 value at 293 K is fixed to stabilize the fit.*

Best fit parameters	Rb/K sample temp. (K)				
	80	130	180	250	293
ΔR_1 (Å)	−0.108(4)	−0.124(4)	−0.131(5)	−0.138(5)	−0.149(6)
N_1	7.5(4)	7.7(5)	8.1(7)	7.2(7)	[8]
σ_1^2 (Å^2)	0.032(3)	0.050(4)	0.069(5)	0.077(5)	0.094(8)

the low-temperature end means a strong suppression of the signal and that value triples within the observed temperature range. The dramatic decrease of the structural signal is thus a purely kinetic effect: no order-disorder phase transition is involved. The large σ^2 value usually affects the accuracy of the other shell parameters: if only one or two oscillations are evident before the interference pattern is suppressed by the thermal motion, the amplitude and phase of the Fourier component cannot be determined with good precision. In the Rb/K alloy, however, the large interatomic distance means a short period of the EXAFS oscillation. Even if the 80 K signal vanishes by ∼100 eV above the edge, it completes ∼6 cycles and its parameters can be read with sufficient precision.

With the calculated structural signals the atomic absorption background can now be reconstructed. The k-space model signal of FEFFIT [19] is transformed back to the energy space and subtracted from the respective Rb K-shell contribution spectrum of Fig. 1. What remains is the atomic absorption background – but this time specifically the background of the metallic Rb in the alloy. Except for the 80 K spectrum, where the AAB still shows some vestiges of the higher harmonics of the structural signal, the resulting AABs are identical. In Fig. 3, this AAB is compared to the K-edge absorption of the Rb vapor. The difference is minute – the linewidth of the MPE features in the Rb/K AAB is somewhat larger. The [1s4p] peak at 26 eV above the edge is slightly broader and the miniature edges of the 4s and 3d coexcitations at 50 and 130 eV, respectively, are more extended. The additional width can be attributed to the band structure of available final states in the conducting alloy.

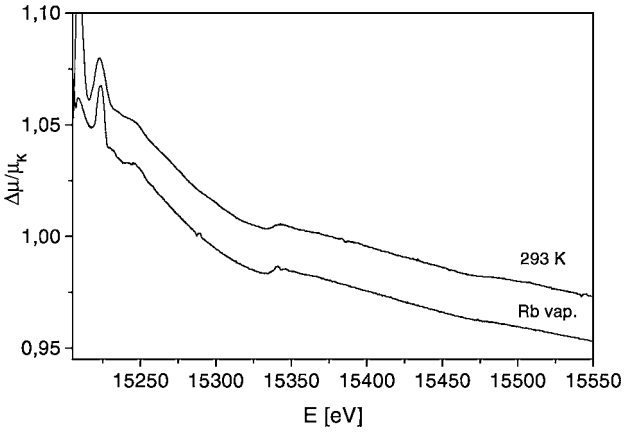

Fig. 3. The comparison of the Rb AAB extracted from the Rb/K alloy spectrum at room temperature, and the atomic absorption on Rb vapor. The signals are vertically displaced by 0.02 for clarity. The artifact on the Rb vapor spectrum at ∼15290 eV is a monochromator glitch.

4. Conclusion

The temperature dependence of the Debye-Waller factor shows that the EXAFS signal in the Rb/K alloy is suppressed by the thermal disorder and no specific disordered phase needs to be invoked.

The comparison of the recovered AAB and the Rb vapor absorption exhibits only minute differences in the linewidth and thus proves the transferability of the AABs for the purpose of practical EXAFS analysis.

Abstract

The continuous Cauchy wavelet transform (CCWT) is applied to the analysis of XAFS spectra. Thanks to that method, XANES and EXAFS signals can be visualized in three-dimensions: the wavevector (k), the interatomic distance uncorrected for phase-shifts (R') and the CCWT modulus (corresponding to the continuous decomposition of the amplitude terms). Applied to EXAFS spectra, the CCWT analysis provides straightforward qualitative information related to the k-range of each "R'-EXAFS" contribution. Such information is particularly useful to perform next nearest-neighbors identification, despite the presence of spectral artifacts such as multiple-scattering features, multi-electronic excitations or noise. When applied to XANES spectra, the CCWT analysis helps highly to measure the "spectral limit" between XANES and EXAFS regions, as well as the energy range required to model properly next-nearest neighbors. To further illustrate the potential of CCWT analyses applied to XAFS spectra, we present examples related to: (1) a XANES spectrum collected at the Ti K-edge for titanite ($CaTiSiO_5$); (2) an experimental Au L_{III}-edge EXAFS spectrum for gold sorbed on goethite (FeO(OH)).

1. Introduction

X-ray absorption fine structure (XAFS) spectroscopy (including XANES and EXAFS regions) is a powerful tool for investigating the short-, and medium range environment around a selected absorbing atom in structurally complex materials like ceramics, glasses and solutions. However, the experimental signals can often be complex to analyze due to the overlapping of several contributions such as single-scattering (SS), multiple-scattering (MS), multi-electronic excitations and various constructive and destructive interferences among next-nearest neighbor contributions. Usually, Fourier transform (FT) methods are used to obtain a frequency decomposition of the normalized EXAFS signal. FT analyses only provide a one-dimensional decomposition in the R'-space (interatomic distances uncorrected for phase-shifts) of the data processed in k-space (wavevector). Alternatively, we present here a continuous wavelet transform approach [1], providing a two-dimensional representation of the analyzed signal (e.g., a "time-frequency" correlation). More particularly, we use the continuous Cauchy wavelet transform (CCWT), which was recently proven to be successful for analyzing EXAFS signals in a two-dimensional (k, R')-space [2]; the third dimension (i.e., the CCWT modulus) representing the amplitude terms to within a wavelet-defined constant. Details on the theory of the method and the choice of the Cauchy "mother-wavelet" are explained in [2] and [3]. In this study, we present new applications of the CCWT theory.

2. Application to XANES and EXAFS spectra for complex materials

Figure 1 shows a CCWT modulus (2D and 3D), calculated between 0.2 and 6.0 Å, for the Ti K-edge XANES spectrum of crystalline titanite ($CaTiSiO_5$; data from [4]). The XANES spectrum was previously converted into k-space, and normalized using cubic splines, like for an EXAFS spectrum. Thanks to the (k, R') decomposition, the CCWT modulus clearly distinguish the "XANES" region (coming essentially from first-neighbors MS events near 3.5 Å), from the "EXAFS" region (where the SS events from distant neighbors dominate, e.g., near 1.5 Å). Note that the FT analysis only provides an average magnitude between both regions and underestimates drastically the signal in the "XANES" region. This example shows the particular interest of a (k, R')

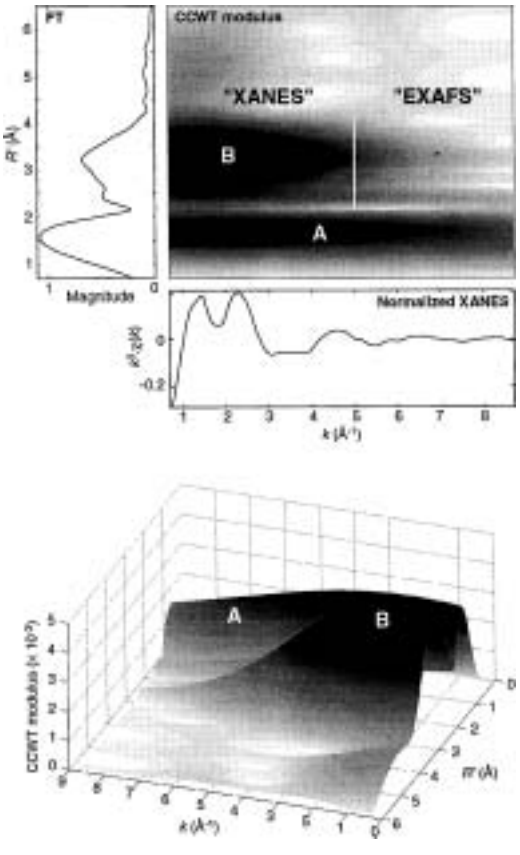

Fig. 1. CCWT analysis for a Ti K-edge XANES spectrum of titanite, (up) 2D modulus; (down) 3D modulus. Note that on the FT magnitude, the intensity of "B" is averaged over the k-range 0–9 $Å^{-1}$, whereas its intensity is higher than "A" (i.e., first neighbors contribution) in the low k-region (see "XANES" on the CCWT modulus).

*e-mail: farges@univ-mlv.fr

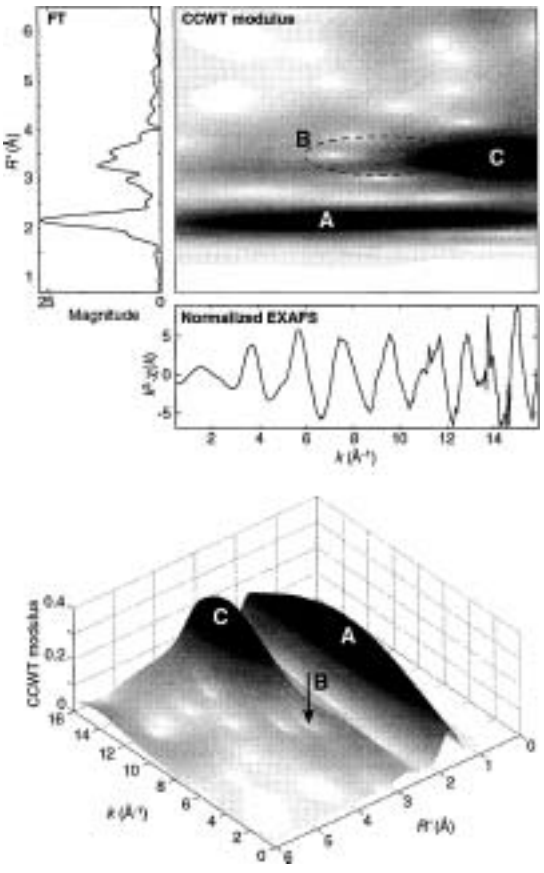

Fig. 2. CCWT analysis for a Au L_{III}-edge EXAFS spectrum of gold sorbed on goethite, (up) 2D modulus; (down) 3D modulus. Note the destructive interference "B" between the MS from the oxygen first neighbors, and the SS from the iron second neighbors. Note also that collecting data up to 16 $Å^{-1}$ is required to model robustly the Au-Fe pairs.

representation, as compared to a direct space representation (R') provided by conventional FT analyses.

Figure 2 shows the analysis (2D and 3D CCWT modulus) of an experimental Au L_{III}-edge k^3-weighted EXAFS spectrum, collected for gold sorbed on a goethite (FeOOH); data from [5]. The CCWT modulus, calculated between 0.2 and 6.0 Å, shows a second neighbors contribution (ridge C) occurring for high k-values, which suggests the presence of "heavy" atoms (i.e., high atomic number) in that coordination shell [2]. However, based on other evidence (see [5] for details), Au atoms cannot be located in the next-nearest environment around gold. Consequently, the CCWT modulus highlights an important destructive interaction (see region B) between, at least, two EXAFS contributions. Based on a detailed analysis of the EXAFS spectrum [5], the first contribution is related to "Au–O" MS events, whereas the other one is related to Au–Fe SS events. Also, the CCWT analysis shows the importance, in that specific case, to collect data up to 16 $Å^{-1}$ in order to get significant contributions from the distant Fe atoms.

3. Conclusions

The continuous Cauchy wavelet analysis is a useful tool to better understand the various contributions that compose an XANES and EXAFS spectrum. The code requires only a minimum number of pre-defined parameters (Cauchy order and number of steps, usually both set to 200). Its simplicity of use makes it quite powerful, especially for non-expert users. Our code can be freely downloaded from http://www.univ-mlv.fr/~farges/wav/. This code is a script that runs under Matlab, which was positively tested in Windows and MacOS platforms (both 9 and X).

Abstract

Pre-edge features in the Ni K-edge X-ray absorption near-edge structure (XANES) spectrum of Ni monoxide (NiO) in octahedral coordination, were investigated. By comparing experimental data with dipolar and quadrupolar cross-section calculations in the framework of the full multiple-scattering theory we assign the first pre-edge peak to a direct quadrupolar transitions from the 1s core state to the 3d molecular orbitals of the central atom (due to the more effective attraction of the core hole). The intensity of quadrupolar transition is almost equal to the dipolar pre-edge structure, at higher energy, due to the hybridization between the p-orbitals of the central atom with the higher-shell metal octahedral orbitals, that reflects the density of states derived by the medium range order of the system.

1. Introduction

X-ray absorption fine structure (XAFS) is a unique probe to determine local atomic structure as well electronic information in many systems, e.g., in biology, chemistry, geophysics, metallurgy, or materials science [1, 2]. Over the past three decades this technique has made great progress by providing high precision information. In fact, the success of the XAFS technique must be attributed, in large part to the advance of the theory, which allows a reliable quantitative structural information. So far systematical theoretical analyses of X-ray absorption spectroscopies in 3d TM compounds have not been conclusive and most of the interpretations and general understanding of the X-ray-absorption near edge structure (XANES), in particular at the pre-edge, remains an open and controversial problem [3–9].

It is well known that various properties of these transition-metal oxides are correlated to the geometrical structure around the transition-metal sites [10, 11]. Therefore a quantitative understanding of the transition features in the spectra is a prerequisite to a full investigation of the atomic environment around the photoabsorber as well as the electronic structure of metal-ligand atoms. In this work we present a detailed theoretical analysis of experimental XANES data at the K edge of the Ni for the NiO system.

2. Experiment and Calculation

XANES spectrum at the Ni K edge was measured in transmission mode using a Si(111) double crystal monochromator at the X-ray absorption station (beam line 4W1B) of the Beijing Synchrotron Radiation Facility (BSRF). The storage ring was working at the typical energy of 2.2 GeV with an electron current of about 100 mA. To suppress higher harmonics, a detuning of 30% was performed between the monochromator crystals. The spectrum was stored at steps of 0.5 eV and at the energy resolution of ∼1.5 eV. NiO samples of fine powders were achieved spreading powders on two pieces of a Kapton tape.

The calculations were carried out using the one-electron full multiple-scattering theory [12–14] and the Mattheiss prescription [15] to construct the cluster electronic density and the Coulomb part of the potential (by superposition of neutral atomic charge densities obtained from the Clementi-Roetti tables [16]), and the screened $Z + 1$ approximation (final state rule) [17] for simulating the charge relaxation around the core hole. The energy-dependent real Hedin-Lundqvist exchange potentials was used, followed by a Lorentzian convolution (∼2.9 eV consistent with the core hole life time and the experimental resolution) to account for inelastic losses of the photoelectron in the final state and the core hole width. We have chosen the muffin-tin radii allowing a 10% overlap between contiguous spheres to simulate the atomic bonds [18, 19].

3. Results and Discussion

Nickel K-edge experimental XANES spectrum of NiO is shown in Fig. 1 (upper curve). It displays several main features labeled (A1, A2, B and C) in good agreement with other published work

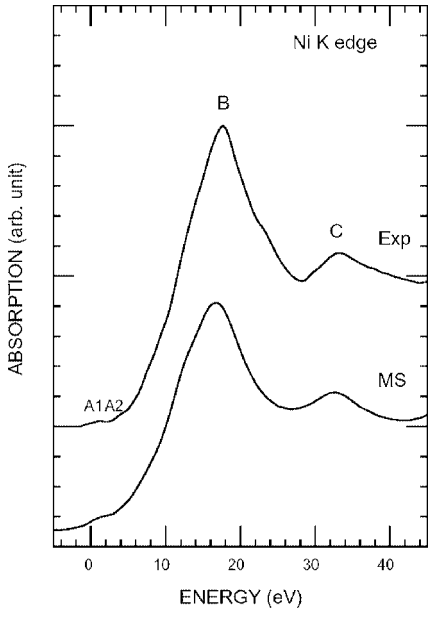

Fig. 1. The experimental and the multiple-scattering calculation of the XANES spectra at the Ni K edge of the NiO system.

*Corresponding author: E-mail: wuzy@ihep.ac.cn and/or wuziyu@lnf.infn.it

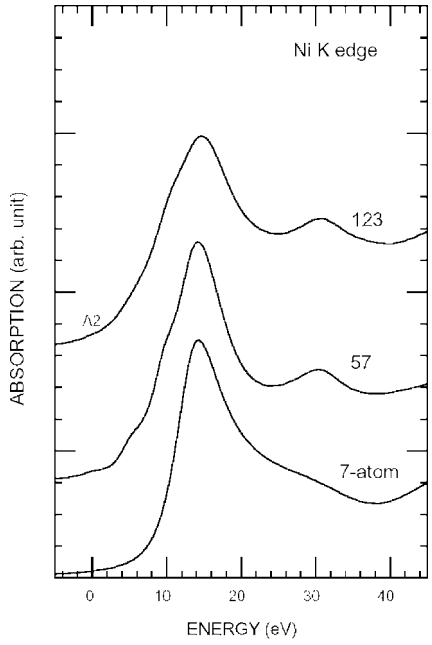

Fig. 2. Theoretical dipolar XANES spectra at the Ni K edge in NiO, as a function of the cluster size (7, 57 and 123 atoms).

[20]. Actually, we may divide the spectrum in three regions:

(I) the first region (labeled A) named the "pre-edge" region. For NiO, in this region two components (not resolved very well), A_1 and A_2 of approximately equal intensity, separated by about 1.3 eV appear;
(II) the second region, around the maximum of the cross section, that presents a strong feature labeled B;
(III) the third region, that extends up to about 20 eV from the edge contains the broad peak labeled C.

The comparison in Fig. 1 reveals a good agreement between the calculated (bottom curve) and experimental Ni K-edge XANES spectra for the NiO. The calculation takes into account all multiple-scattering paths in a rather big cluster (123 atoms) but do not allow us to assign a particular shell of neighbors to each feature. To clarify this point, we have to perform MS calculations adding consecutive Ni and O shells around the emitter atom.

NiO has a cubic structure with a lattice constant $a_0 = 4.16$ Å [21]. The coordinating oxygen octahedron around the nickel atom is perfect with a bond length of Ni-O of 2.08 Å. In Fig. 2, we present computations of the Ni K-edge XANES spectra for NiO by using a fully relaxed final state potential obtained within the $Z + 1$ approximation [17] for different cluster sizes (7, 57, and 123 atoms) up to the convergence. The last one contains all atoms within 7 Å from the photoabsorber (i.e., the Ni) taken as the center of the cluster. For a minimal cluster composed just of a Ni as the central atom (emitter) and six nearest neighbors (O atoms), the calculated absorption spectrum shows the main peak B and a broad peak C which correspond to transition to the Ni p-like final states. In MS calculations, from the point of view of the scattering, the second shell (six oxygen atoms) is necessary to reproduce the quite strong peak B as well as the broad peak C. So, these features arise from scattering within the first oxygen atomic shell. This behavior is the demonstration of the relatively strong backscattering of the O^{2+} ions [22].

Increasing the cluster, up to the fourth shell of Ni and oxygen atoms, the pre-peak A_2 appears. The reason for this is rather clear. Higher coordination neighbors (the next-nearest Ni shell plus surrounding oxygen atoms) are necessary to construct the appropriately hybridized 3d-like molecular orbitals around each Ni atom in the cluster which are made up of 3d metal orbitals and 2p oxygen orbitals. The 57-atom cluster in fact already includes enough oxygen around Ni to form octahedra whose orbitals mix with the 4p states of the central atom. Furthermore, these neighboring octahedra strongly interact with each other and cause molecular orbitals to overlap, forming extended energy bands and modifying their energy position.

All features observed in the experimental spectrum, except the pre-edge A_1, are reasonably well reproduced in the last large cluster calculation (123 atoms), not only in term of relative intensities but also in energy separations. This points out that a 123-atom cluster is sufficient to describe bulk properties and that the pre-peak is, at the same time, very sensitive to the "medium-range" order of the solid. They might therefore be used to extract information on this range. Furthermore, the peak A_2 comes from dipole transition based on theoretical MS simulation of absorption cross sections.

Since in transition-metal compounds the empty 3d-derived states normally lie at lower energies than the empty 4p-like states, significant quadrupole transitions are mostly to occur mainly in the pre-edge region. In order to shed light on the type of transition involved and identify the origin of spectral feature A_1, we present theoretical simulation, based on one-electron full multiple scattering theory, the unpolarized quadrupole absorption cross sections based on the following equations:

$$\sigma^{Q}(\omega) = 4\pi^2(\alpha\hbar\omega)^3 \frac{1}{240} \frac{2l_0+1}{2l+1} \sum_{lm} \mathrm{Im}\tau^{00}_{lm,lm}(M^q_{l_0 l})^2(l_0 020 \mid l0)^2.$$

As usual in MS theory, $\tau^{00}_{lm,lm}$ is the scattering path operator calculated at the photoabsorbing site for angular momentum lm, the imaginary part of which is proportional to the site and lm projected density of state of the system, $M^q_{l_0 l}$ is the radial matrix element of the quadrupole operator between the core state and the l component of the final state wavefunction, l_0 is the angular momentum of the initial core state and $(l_0 0 l_t 0 \mid l0)$ is a Clebsh-Gordan coefficient. We use atomic units (au) for lengths and Rydberg units for energy so that the cross section is expressed in $(\mathrm{au})^2$.

In Fig. 3 the contribution of the quadrupole allowed absorption is presented by the solid line (bottom curves) and compared with the dipole allowed absorption dot line (bottom curves), before the convolution, for the 123-atom cluster. As can be recognized, the quadrupolar spectrum is almost featureless except for a pronounced pre-edge peak A_1 lying at the lower energy about 1.3 eV than the dipole allowed pre-edge structure A_2, with the similar intensity. The agreement between the experiment and theoretical simulations is much better by taking into account both contributions of dipole and quadrupole as shown in Fig. 3, curves (b) and (c), indicating that the first prepeak in the Ni K-edge XANES spectrum of NiO is a purely quadrupole one.

4. Conclusion

In conclusion, we have studied experimentally and theoretically for the first time the pre-edge features in the X-ray absorption spectrum of NiO at the Ni K edge in octahedral coordination. By comparison of the dipolar and quadrupolar cross sections calculated in the framework of ab initio full MS theory we claim that the lowest feature in energy is purely quadrupolar in

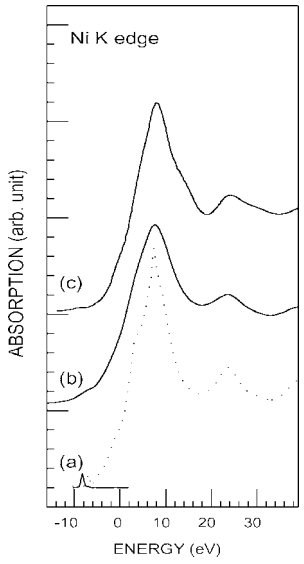

Fig. 3. The curves (a) are the multiple scattering quadrupolar (solid line) and dipolar (dot line) calculations of the XANES spectra of the Ni K edge in NiO, using a 123-atom cluster. Curve (b) is the convoluted sum of the dipolar and quadrupolar contributions while the experimental data are curve (c).

character followed by dipolar transition due to the medium range order of the system (a mixing of p orbitals of absorbing atom with 3d orbitals of higher-neighbouring metal octahedra). A good agreement between experimental data and theoretical ones has been achieved indicating that a purely quadrupole nature of the preedge was established in a positive way.

We stress here that the comparison is precise and may be extended to other 3d TM compounds and more complex systems.

Abstract

This report describes an effort to include three-dimensional interactive molecular graphics into the main APEX program, a free, open source, cross platform data analysis package for X-Ray Absorption Fine Structure (XAFS) data analysis. The latest version of APEX (2.7.3) based on a native TCL/TK tab-notebook style graphical user interface includes among others, user-friendly interactive two-dimensional graphics under BLT, an extension of TCL/TK with advanced printing capabilities; generic format conversion from ASCII to University of Washington binary-type files; new TCL routines for data handling; XMU corrections and multiple scattering fitting. Based on Virtual Rendering System (VRS), the 3-D version reads and displays molecular structures for various file formats allowing object rotation, translation and atoms selection for determining interatomic distances and angles. The most important feature of 3D APEX is the interaction with the FEFF program: scattering paths are displayed, selected and are used to generate appropriate $\chi(k)$ XAFS spectra. 3D APEX is the only program that offers three-dimensional graphics and in its current form is suitable for routine data analysis and training. At this time the 3D APEX add-on is only available for Windows PC. Addition of more advanced methods of data analysis are planned.

1. Introduction

The first version of Analysis Program for EXAFS (APEX) [1, 2] provided one of the first open-source cross platform graphical user interface (GUI) interfaces to EXAFS analysis programs. Early APEX versions included standard methods based on University of Washington (UW/NRL) Fortran codes for XAFS data reduction and analysis. Subsequently support for automated background subtraction and multiple scattering fitting via AUTOBK [3] and FEFFIT [4] programs was added, and two-dimensional (2D) interactive graphics was dramatically improved. Here we report additional enhancements including three-dimensional (3D) interactive graphics for simplifying manipulation of FEFF multiple scattering path files.

The main GUI for APEX 1.0/2.0 versions was written in TCL/TK [5, 6] programming language, which runs on a wide variety of the operating systems like Linux, Silicon Graphics IRIX version 6.5 and above, Apple operating systems MacOS9, MacOSX, and PC compatibles under Windows 98 and above. The 2D interactive graphics was written in BLT [7], an extension of TCL/TK that is available on all of the above mentioned platforms except the obsolete Mac OS 9.

APEX development was based on the perceived need for a cross platform XAFS data analysis package that runs without emulation on different operating systems, was easy for novices, but also useful for experts. Starting with a proven code base (UW/NRL), incrementally removing its limitations, and adding more advanced features has led to a well acceptable package. Recently we have improved the functionality of the main APEX GUI card using a native TCL tab-notebook style GUI. Writing code on native TCL ensures cross-platform compatibility and easy access to bug-fixing problems. The reading and writing to and from UW binary platform-dependent files, and most of the old UW FORTRAN based utilities are now written under native TCL, thus improving integration of the executables with the GUI cards. Improvements to the base code include adding advanced printing capabilities based on the interactive BLT graphics, adding contextual balloon style help, generating unique symbolic keys for input/output UW files using TCL, adding an XMU correction program and calculating X-Ray absorption and scattering cross sections directly from a graphical periodic table. The main APEX code (version 2.7.3) runs under Linux, IRIX and WinPC. Porting the main package to Mac OS X is underway.

During APEX development other excellent cross-platform packages like ATHENA [8] also have been developed. Between the various packages the basic needs we perceived have been addressed. We therefore we decided to add newer, more advanced capabilities to the APEX package: the inclusion of 3-D interactive graphics that could interact with the FEFF [9] program.

This 3-D OPENGL library-type window is using the Interactive Virtual Rendering System (VRS, iVRS [10]), a cross-platform C++ type application programming interface (API) that can be called as an external package from TCL/TK and provides full access to all 3D features of the VRS system. Using iVRS, complex interactive scenes can be rendered and integrated with the TK toolkit. The 3D-APEX reads and displays molecular structures in various formats allowing the user to rotate, and zoom the structure but also to determine graphically interatomic distances and angles. If a FEFF input file is read together with the corresponding scattering paths file, these paths are interactively displayed and can be selected for further analysis.

Current limitations of the main APEX program is that the Random Data File format (RDF) UW file format upon which it is based are platform dependent e.g. a Linux UW file will not be directly usable in a WinPC type environment unless its is first converted to ASCII. A new cross-platform standard file format (e.g. Hierarchical Data Format (HDF) or XML) is required for future use in APEX, and this is planned. 3D-APEX is currently available for WinPC, and ports to Linux, Mac OS X, IRIX, and other Unix derivatives are planned. Official versions of APEX 2.7.3 and 3D-APEX are available at the APEX [11], Bio-CAT [12] home pages and mirror sites.

2. Discussion

The 3D-APEX window is incorporated into the main APEX package and directly linked under APEX FEFF card. For WinPC

*e-mail: dimakis@biocat2.phys.iit.edu

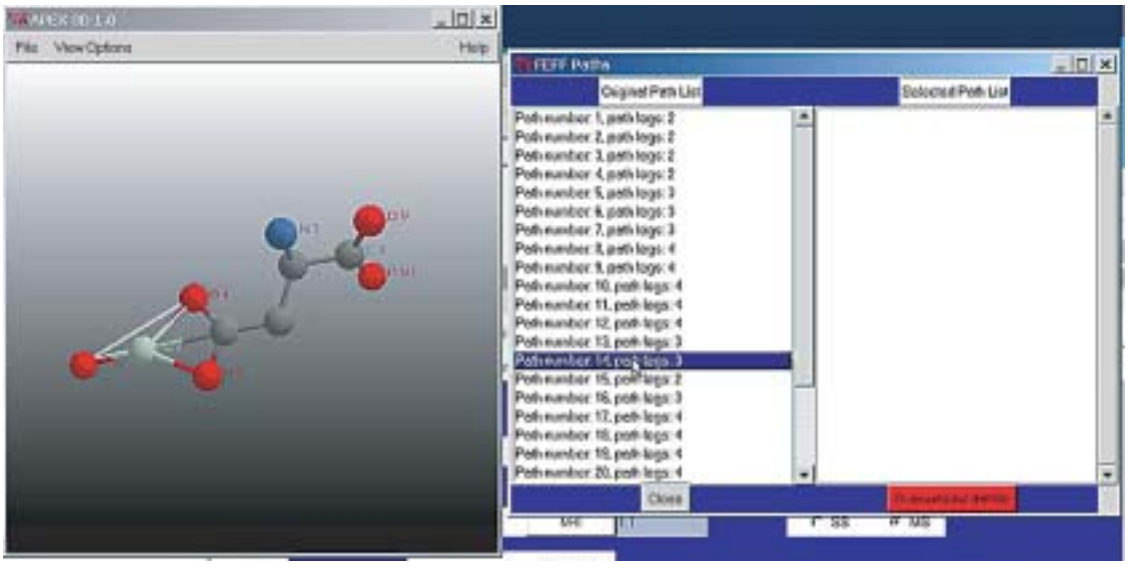

Fig. 1. Screenshot of 3D APEX window displaying Zn-Aspartic acid structure using *feff.inp* file format. The listbox on the right can be used to select FEFF generated scattering paths and overwrite the FEFF *list.dat* file for $\chi(k)$ calculation.

versions a new button appears on the FEFF card prompting the user to launch the 3D-window. A *feff.inp* file that either has been loaded into APEX or created from the package itself is read and its corresponding molecular structure is displayed. Atoms appear as colored solid spheres and these colors are defined in the periodic table card. The user can display atoms and bonds (default value) or atoms only. Although 3D-APEX has no particular information about the corresponding molecular orbitals of the displayed structure, interatomic bonds are drawn based on interatomic distance and covalent radius. The user can also define and remove labels i.e. select atoms and display their corresponding interatomic distance/angle in the main window. Background color is user selectable and subsequent versions of the 3D window will also permit user-selectable atom colors.

The most important feature of the 3D-APEX is its ability to read and display FEFF single- and multiple-scattering paths for a given molecular structure. Paths are read from FEFF *paths.dat* file and entered in a TK listbox. Selecting a particular path from the paths listbox will automatically render it in the 3D-window (Fig. 1) with its "legs" to appear as grayed cylinders. The program ensures that paths "legs" will not overlap with the interatomic bonds if the later are also present in the display. After visualizing a particular path the user may choose to keep it by copying it into another adjacent listbox. Selected copied paths in the later listbox will be used for to generate $\chi(k)$ XAFS spectra by writing out the corresponding FEFF *list.dat* file. The 3D-window also offers printing capabilities: *any* rendered graphics in the 3D canvas window can be exported into JPEG file type format (Fig. 2) for either printing or used elsewhere.

Besides the 3D graphics this latest APEX 2.7.3 offers much more than just incremental improvements. A screenshot of the BLT graphics with the printing dialog is shown in Fig. 3. The small canvas picture in the printing dialog is a direct copy of the main graphics canvas: the user may scale the graphics by resizing the small picture, print it in grayscale/color and landscape/normal page formats. Two dimensional graphics can also be exported as either GIF, PostScript or PDF file formats with the help of ghostscript program that is included in APEX package.

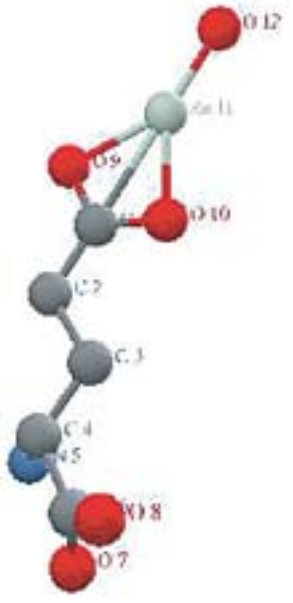

Fig. 2. Zn-Glutamic Acid structure as exported in JPEG format by 3D-APEX. The structure was in xyz-format.

Many users rarely read help manuals. Whenever they encounter a difficulty they try to experiment before they think about reading the help manual. Therefore we have included an interactive balloon type help system in addition to the local and internet help that previous APEX versions offered. Positioning the mouse over a label a balloon help text appears dialog box provide brief description about a label or a menu.

Future plans on the 3D-APEX include adding stereo capabilities, allowing the user to drag-and-drop atoms and include pre-built libraries of organic structures like amino acid residues. For the main package, designing a new type of RDF file (possibly XML or HDF) that will replace the platform specific UW format files, bundling FEFF6, incorporating the new interactive IFEFFIT, add extensions to RDF reconstruction by regularization, and adding automatic edge-energy selection are some of the near future improvements. FEFF7 and higher versions are separately

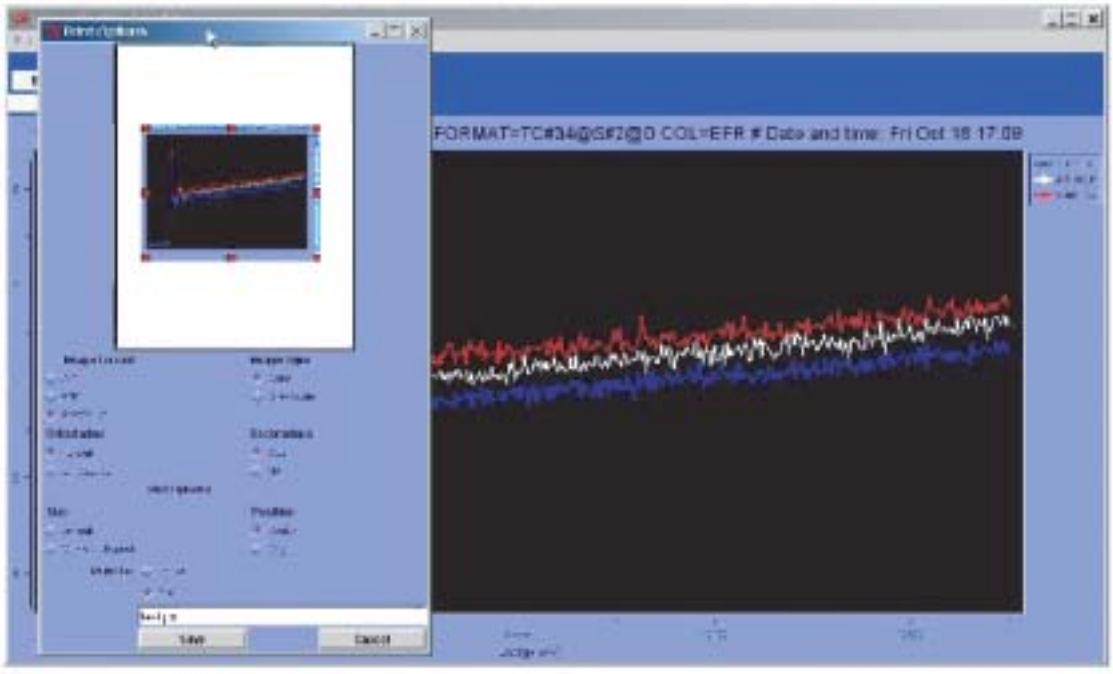

Fig. 3. Advanced Printing option for the BLT interactive graphics. The file output can be scaled, plotted in color/grayscale and exported in PostScript, GIF, and PDF file formats.

licensed and are not part of the APEX package, and must be obtained from the FEFF project.

3. Conclusion

The 3D version of APEX is an open-source XAFS data analysis package that offers support for multiple complementary algorithms for data reduction and analysis (UW/NRL, AUTOBK/FEFFIT), a friendly graphical user interface, advanced presentation-quality plotting and printing capabilities, direct interaction with FEFF, display of 3D molecular structures from FEFF path files, and graphically selection of single and multiple scattering paths for generating $\chi(k)$ XAFS. Our near-future tasks are to port these 3D capabilities into other operating systems like Linux, Mac OSX and IRIX. More advanced and automated data analysis routines in a cross-platform native TCL language are underway.

Abstract

Electronic decay of synchrotron-radiation-excited VUV-resonances in the KCl and CsCl molecules is studied. Despite the similarity of the two compounds, qualitatively different resonant modifications of the valence electron spectra are observed and are investigated by modelling nuclear dynamics including the lifetime vibrational interference. The modelling predicts a much shorter lifetime of the resonances in KCl than in CsCl, which is confirmed by ion yield measurements as due to the opening of a spectator-type decay channel in KCl.

1. Introduction

Alkali halide molecules have a strongly ionic bond, where one outer shell electron from the alkali atom is transferred to the halide side. With the absence of shared electrons, the electronic transitions in alkali halides are typically studied as transitions in either the alkali$^+$ or halide$^-$ ion. Studying the products of the subsequent molecular dissociation allows one to identify the electronic transition channels. Previously, dissociation following the VUV-excitations in KCl and CsCl has been studied in Refs. [1] and [2], where the existence of inter-ionic electronic decay channels was found.

In the present work, the electron emission spectra at the VUV-resonances in KCl and CsCl are compared. At the resonances, the valence photoelectron spectra can be enhanced by an autoionization channel. This contribution can strongly modify the observed lineshapes, being a sensitive indicator of the lifetime of the excited state [2]. Our aim is to study the crucial role of the lifetime in decay and to arrive at a consistent interpretation of the absorption, electronic decay and dissociation processes, particularly taking into account the fact that very different fragmentation patterns were observed for these molecules [1, 2].

2. Experimental

The experiments were performed on the bending magnet beamline BL52 [3] at the MAX–I storage ring in Lund, Sweden. The synchrotron radiation is monochromatized by a normal incidence monochromator and focused to the experiment with a toroidal refocusing mirror. Photon energy calibration was done measuring simultaneously the Ar 3p photolines with the first and second order radiation from the monochromator. The experimental set-up consists of a Scienta SES-100 electron energy analyzer mounted in the same vacuum system with a Wiley-McLaren type of ion TOF spectrometer [4]. A resistively heated oven was used to produce molecular vapour of the solid KCl and CsCl. The temperatures needed to generate the 10^{-2} mbar vapour pressure inside the stainless steel crucible were in the range of 800–900 K for both of the molecules. All electron spectra were measured at the magic angle (54.7°) relative to the electric field vector of the linearly polarized light. The binding energy calibration of the measurements was obtained from the simultaneous measurement of Ar 3p photolines [5] and the studied valence photoelectron spectrum. In the ion yield measurements the fluctuations and the photon energy dependency of the incident photon flux were accounted for using the GaAsP photodiode mounted behind the interaction volume.

3. Results and Discussion

3.1. *Photoabsorption*

The photon energy range of the total ion yield (TIY) spectra of Fig. 1 represents photoabsorption by the outermost shells of the alkali and halide ions. In the TIY spectrum of CsCl [Fig. 1(a)], a resonant structure appears between 12 and 18 eV and in the TIY spectrum of KCl [Fig. 1(b)], four resonances appear at 18–24 eV. Assuming a fully ionic bond, these resonances are assigned to the Rydberg excitations in the metal end of the molecule, i.e. $3p \rightarrow nd$ in K^+ [1] and $5p \rightarrow nd$ in Cs^+ [2].

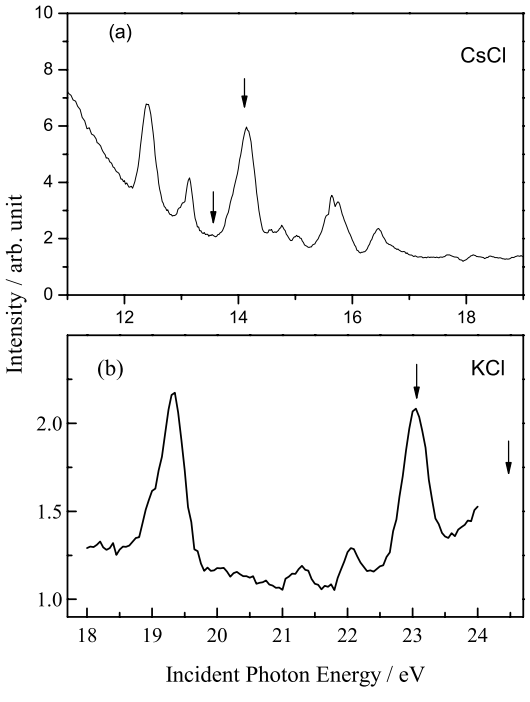

Fig. 1. Total ion yield (TIY) spectra of CsCl [2] and KCl [2]. The arrows refer to the photon energies of the photoelectron spectra of Fig. 2.

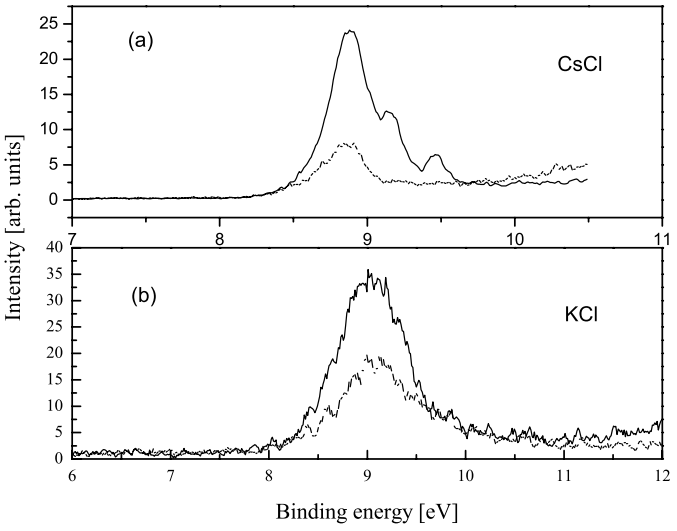

Fig. 2. Valence photoelectron spectra of the CsCl and KCl molecules. (a) CsCl, measured at a resonant [2] (14.2 eV, solid) and nonresonant photon energy (13.5 eV, dashed); (b) KCl, measured at a resonant (23.0 eV, solid) and nonresonant (24.5, dashed) energy.

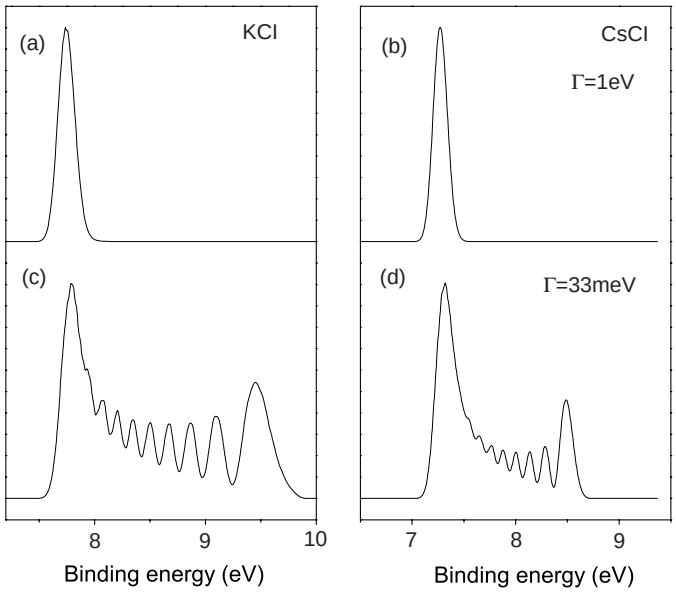

Fig. 3. The modelled electron decay spectra of KCl and CsCl. The upper spectra correspond the case where the electronic decay is fast compared to the nuclear motion; the lower spectra present the case where the timescales are similar.

3.2. *Electron spectra*

In order to study the nature of the decay of the excited states in the KCl and CsCl molecules, the valence photoelectron spectra corresponding the photoionization of the $3p$ orbital in Cl^- in our ionic model were measured at a resonant and, for reference, at a non-resonant photon energy (Fig. 2). Comparing the resonant and non-resonant spectra of KCl, about twofold intensity enhancement is seen, but the lineshape remains unaffected. The spectra of CsCl would be expected to behave similarly, since both molecules are ionically bonded and the resonances have a similar Rydberg character, but as seen in Fig. 2, remarkable differences occur. The nonresonant spectrum of CsCl [Fig. 2(a)] consists of a single peak with a width of 0.4 eV (FWHM), similarly to KCl. However, in the spectrum measured at a resonance, a clear triple-peak structure is seen in addition to the intensity enhancement by a factor of 3.6. The intensity increase at resonant photon energy in both of the molecules shows that the decay includes the inter-ionic participator-type Auger transition (autoionization) channel $A^*Cl(A^+mp^5nd, Cl^-3p^6) \rightarrow ACl^+(A^+mp^6, Cl^0 3p^5) + e^-$, where $A = K(m = 3)$ or $A = Cs$ $(m = 5)$. The final state of the autoionization is the same as for direct Cl $3p$ photoionization, after which the KCl (CsCl) molecule consists of Cl^0 and K^+ (Cs^+).

3.3. *Modelling*

The electronic decay in molecules is affected by the vibrational motion. In order to study its influence on the electron spectra, the electronic decay and nuclear relaxation processes were modelled. The modelling for CsCl is described in detail in Ref. [2] and the same procedure was followed for KCl. Briefly, the potential energy curves (PECs), vibrational wavefunctions and energy levels were calculated and the electronic transitions between the PECs were examined. The PECs for CsCl (Ref. [2]) and KCl have similar properties – the ionic state is dissociative or very weakly bound due to the lack of Coulomb attraction between the Cl^0 and Cs^+, but the excited state is more strongly bound, having a shorter equilibrium distance than the ground state.

If the nuclear wavepacket has sufficient time to evolve after photoabsorption, the excited state can be properly represented by time-independent vibrational eigenfunctions. Then, since relatively high vibrational levels are excited, the probability density has two main maxima at the classical turning points (CTPs) and the electronic decay spectra shows two main peaks at the binding energies of the final ionic states, corresponding to the vertical transitions from the excited state at the CTPs. However, if the lifetime is comparable or much shorter than the vibrational period, the time-independent eigenfunctions and Franck-Condon factors alone are unsufficient to describe the system, but interference terms must be included [6–8], modifying the electron emission lineshape.

By comparing the simulations (Fig. 3) to the experimental valence photoelectron spectra (Fig. 2), it can be concluded that in KCl the period of vibrational motion is much longer than the electronic lifetime of the excited state, while in CsCl they are comparable.

KCl: Since the period of the vibrational motion is much longer than the electronic lifetime, electronic decay only happens at the outer CTP of the excited state. The transitions at the inner CTP are completely suppressed by the interference terms and the resulting electron spectrum (a) in Fig. 3 is identical in shape with the nonresonant photoelectron spectrum, as observed [Fig. 2(b)]. The resonance only enhances the photoionization cross-section.

CsCl: In this case, the wavepacket has a significant probability to reach the inner CTP. The interference suppression of the second peak is therefore incomplete and it appears in the spectrum (d), corresponding to the new structures seen in the experiment [Fig. 2(a)]. Although the agreement between the modelling and experiment is only qualitative (the reasons are discussed in Ref. [2]), it is the appearance of any significant new structure as such that indicates a considerably longer excited state lifetime.

The model thus predicts that in addition to the decay by autoionization, which is present in both of the studied molecules, in KCl there must exist an additional, faster decay channel following the resonant exitation, shortening the lifetime.

3.4. *Partial yields*

In order to search for the differences in the decay channels that could account for the predicted large differences in the resonant state lifetimes between KCl and CsCl molecules, partial ion yields

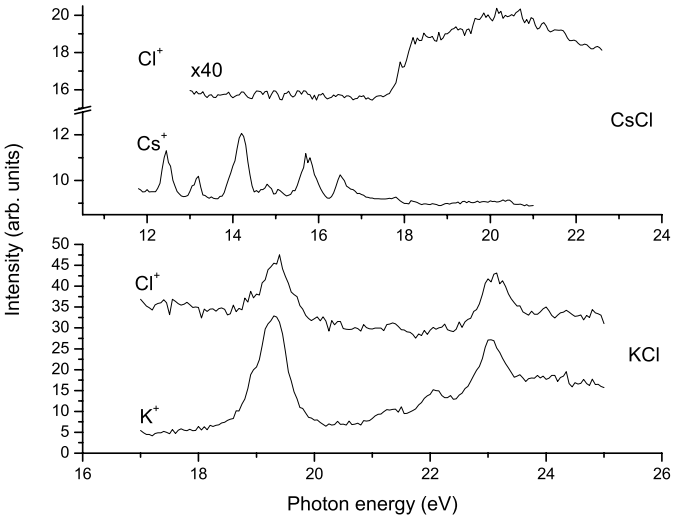

Fig. 4. The partial ion yield spectra of CsCl [2] and KCl [1].

in the energy regions of the resonances were studied. Figure 4 presents the partial yields of the $K^+(Cs^+)$ and Cl^+ of KCl (CsCl). It can be seen that in KCl the yield of both fragments follow the absorbtion pattern, but in CsCl only the amount of Cs^+ ions resonates, following the TIY-spectrum [Fig. 1(a)]. The autoionization process that contributes to the valence electron spectra produces only the metal ions. Positive chlorine ions can only be produced if the excited electron remains as a spectator electron while the vacancy is filled by a Cl^- $(3p)$ electrons and another one is emitted. So the two decay channels for KCl are autoionization $[K^*Cl(K^+3p^5nd,\ Cl^-3p^6) \rightarrow KCl^+(K^+3p^6,\ Cl^03p^5) + e^-]$ and spectator decay $[K^*Cl(K^+3p^5nd,\ Cl^-3p^6) \rightarrow KCl^+(K^03p^6nd, Cl^+3p^4) + e^-]$, whereas in CsCl only autoionization $[Cs^*Cl(Cs^+5p^5nd, Cl^-3p^6) \rightarrow CsCl^+(Cs^+5p^6, Cl^03p^5) + e^-]$ takes place. The spectator-type transition is usually very rapid, which explains the differences in the resonant state lifetimes. The absence of the spectator transitions in CsCl can be explained by taking into account that the binding energy of the electron experiencing the initial excitation in K^+ is larger than in the Cs^+ [2] and the energy released by filling the vacancy is sufficient to eject the other Cl^- $3p$ electron only in the former case.

4. Conclusions

The electronic decay of the VUV-excited resonaces, studied using electron spectroscopy, exhibits a very different character in molecular KCl and CsCl. Both cases were modelled including the lifetime intererence effects and the lifetime of the excited state in KCl was predicted to be much shorter than in CsCl. This conclusion was verified by studying the partial ion yield spectra, where in addition to the inter-ionic participator transition in both of the studied molecules, spectator Auger transitions appear only in KCl. The model was thus found to correctly predict the lifetime of the excited state based on the structure of the electon emission spectra. The lifetime dependency and lineshape modifications appear to be exceptionally strong in alkali halides and likely in other ionic compounds also.

Acknowledgments

This work has been financially supported by the Vilho, Yrjö and Kalle Väisälä Foundation, the Research Council of the Academy of Finland and the EU – Access to Research Infrastructure action of the Improving Human Potential Programme. We are gratefull to V. Kisand, E. Nõmmiste and V. Pennanen for their help in acquiring the data. The kind assistance of the MAX-lab staff is also akcnowledged.

Abstract

Extended X-ray absorption fine structure data evaluation usually begins with the Fourier transform of the spectrum. We suggest the wavelet transform as a complement to the Fourier transform. While the Fourier transform analyzes the distances to the backscattering atoms, wavelet transform additionally reveals the wavenumber dependence of the scattering. Thus wavelet analysis can differentiate between heavier and lighter backscattering atoms, even if they are almost equidistant from the central atom. First the method of operation and the advantage of the wavelet analysis will be demonstrated by simple models. Then it is applied to the interpretation of extended X-ray absorption fine structure spectra concerning the complexation of Uranium(VI) with the carboxylic groups acetic-, formic-, and glycolic acid. The wavelet transform analysis suggests clearly for the system Uranium-formic acid both, U-U and U-C-C, structural elements. In contrast to the clear separation of different scattering paths by wavelet transform, Fourier transform analysis was not able to resolve the two different backscattering processes.

1. Introduction

Since the pioneering works of Stern, Lytle and Sayers [1–4] to the theory and data evaluation of extended X-ray absorption fine structure (EXAFS) spectra the data analysis begins with the discussion of the Fourier transform (FT) of the (k^3-weighted) EXAFS spectra. This first qualitative approximation to the determination of the searched physical parameters enables us to estimate how many co-ordination shells at which distances are entered by the EXAFS spectrum.

The theoretical basis for the quantitative analysis of the spectrum is the EXAFS equation:

$$\chi(k) = S_0^2 \sum_{i=1}^{n} \frac{N_i}{R_i^2} \frac{F_i(k,R)}{k} \mathrm{e}^{\frac{-2R_i}{\lambda}} \mathrm{e}^{-2\sigma_i^2 k^2} \sin(2kR_i + \Psi), \qquad (1)$$

where $\chi(k)$ is the measured EXAFS spectrum, k is the electron wave vector, $S_0^2(k)$ is the amplitude reduction factor, N_i is the number of atoms in the i-th coordination sphere, R_i is the average radial distance to the i-th coordination sphere, $F_i(k,R)$ is the backscattering amplitude, $\lambda(k)$ is the mean free path, σ_i^2 is the Debye Waller factor, and $\Psi(k,R)$ is the sum of the phases of the central- and backscattering atoms.

Usually, the amplitudes, phases and mean free paths were calculated by the FEFF8 code [5]. Several possible fitting programs like e.g. EXAFSPAC [6] exist for the data processing and the determining of the radial distances, coordination numbers and Debye Waller factors.

A complete summary of the standard EXAFS theory and data evaluation one finds by Teo [7].

Complementing the conventional Fourier transform analysis, the wavelet transform (WT) is able to extract more information from the k-dependence of the absorption signals. While the FT analyzes the distances of the backscattering atoms, WT reveals additionally at which energies, that is, at which wavenumbers k, the backscattering takes place. Thus wavelet analysis can differentiate between heavier and lighter backscattering atoms, even if they are at the same distance from the central atom.

Originally, wavelets were used for image and data compression, and wavelet data analysis forms a powerful tool for the evaluation of various complex time-frequency signals, see e.g. the textbooks [8–10]. The essential advantage of the WT is the fact that the time-frequency window is flexible and does in fact adapt in such way that there is always about the same number of periods of the frequency analyzed in the time window.

The disadvantage of the Fourier transformation is the following property. If the signal changes on one time moment, changes the Fourier transformation everywhere. However, if one use not infinitely expanded periodic oscillations, but located wave trains (wavelets) for the integral transformation, then one may analyze the frequencies in each place by dilatation and translation of the wavelets. Wavelets are a wide and flexible class (the function class l^2) of window functions $\psi(t)$ with zero mean:

$$\int_{-\infty}^{+\infty} \psi(t)\,\mathrm{d}t = 0. \qquad (2)$$

In the following the Morlet-wavelet [11] is chosen. First of all its structure is "similar" to an EXAFS signal. That is, the wavelet consists of a slowly varying amplitude term and a fast oscillating phase term. Secondly the formal mathematical description of the wavelet analysis should be in this introductory article in analogy to the Fourier analysis. The Morlet wavelet is obtained by taking a complex sine wave, and by localizing it with a Gaussian (bell-shaped) envelope (see figure 1).

The WT is a window operation like a windowed FT. The kernel of the WT is obtained by translation (parameter b) and scaling (parameter a) of the chosen basis "mother" wavelet. The WT of a

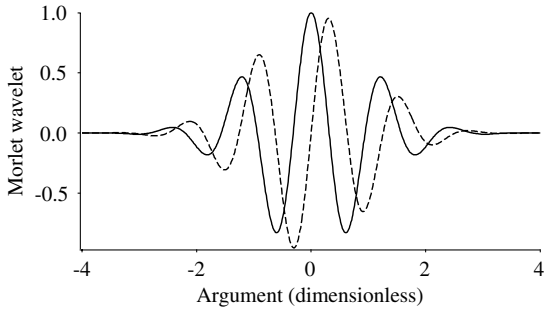

Fig. 1. Real- (full line) and imaginary (dashed line) part of the Morlet wavelet.

*e-mail: funke@esrf.fr

signal $f(t)$ according to the wavelet $\psi(t)$ is defined as:

$$W_f^{\psi}(a,b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{+\infty} f(t)\psi^*\left(\frac{t-b}{a}\right) \mathrm{d}t. \quad (3)$$

Like the FT, the WT is a mathematical complete transformation [12] of a signal. Hence, its inverse transformation recovers again the primary EXAFS signal without any loss of information. It is marked that a repeated application of the FT, using narrow window functions centered at k_i, $i = 1, \ldots, n$ results in similar contour plots as the WT, shown below.

The transition of data analysis methods based on wavelets from the time-frequency to the wavenumber (k)-distance (R) regime in the EXAFS evaluation procedure is simply done by the relations: $t \to k$ and $2\pi\omega \to 2r$. So, the expression of the WT of the k^3 weighted EXAFS data takes the form:

$$W_f^{\psi}(r,k) = \sqrt{2r} \int_{-\infty}^{+\infty} \chi(k')k'^3\psi^*(2r(k'-k))\,\mathrm{d}k', \quad (4)$$

where $\chi(k')$ is the EXAFS signal, $\psi(2r(k'-k))$ is the wavelet, k is the wavenumber, and r corresponds to the interatomic distance uncorrected by phase shifts R which is the abscissa of the FT of the EXAFS data.

In the following two model calculations are presented to demonstrate the method of operation. Then the application of the wavelet analysis is described to a special difficult environmental problem of uranium complexation on humic substances.

First ideas to the present work were published in the reports [13]. Recently, Muñoz *et al*. employed WT for EXAFS studies using the continuous Cauchy wavelet [14].

2. Model calculations

Two model signals built from two simple sine functions, the second one with doubled amplitude, each with Gaussian envelopes, are used to demonstrate the possibilities of the WT to resolve the distance (r) and wavenumber (k) dependency of a signal. In figure 2 at the top at left the signals with separated centers of the Gaussian envelopes at $k = 3.75\,\text{Å}^{-1}$ and $k = 11.25\,\text{Å}^{-1}$ and at right the same signals with coinciding centers at $k = 7.5\,\text{Å}^{-1}$ are plotted. Both "absorption" signals generate the same modul of the Fourier transform, shown in the middle. The lower graphics show the magnitudes of the wavelet transforms of both signals in form of two-dimensional contour plots. In contrast to the FT, their WT show both the distances, which also follows from the FT, and the position of the centers of the two components of the signal in the k-space. The WT shows evidently the full information about the wavenumber (k)- and Distance (r) behavior of the two model spectra.

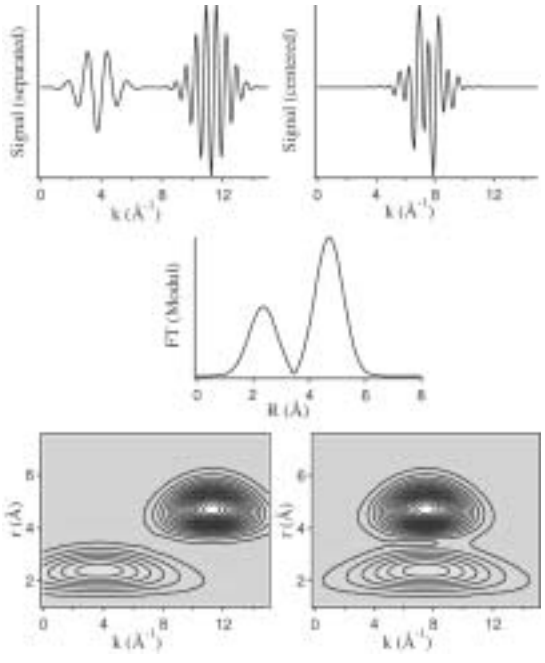

Fig. 2. Two model signals (top), their common FT modulus (middle), and the WT magnitudes of the two signals on top as a function of r and k (bottom).

3. Experimental

Three aqueous solutions were prepared at room temperature.

U-Acet: [U(VI)] = 0.025 mol/L, [acetic acid] = 0.5 mol/L, pH = 4.5.

U-Form: [U(VI)] = 0.053 mol/L, [formic acid] = 1.0 mol/L, pH = 4.5.

U-Glyc: [U(VI)] = 0.02 mol/L, [glycolic acid] = 0.25 mol/L, pH = 8.

U L_{III}-edge EXAFS spectra were measured at ROBL/ESRF. The spectra were processed following standard procedures using EXAFSPAK [6] and FEFF8 [5].

Results: U-Form: the FT of the EXAFS shows a broad peak between $R = 3.1 \ldots 4.0$ Å, which cannot be analyzed and separated using conventional FT-filtering technique. In order to find a correct approach for the structure determination of U-Form, the WT of the three spectra within the range $r = 3.2 \ldots 4.1$ are compared. See fig. 3. Thereby the spectra U-Acet and U-Glyc are used as references: spectrum U-Acet is dominated by the multiscattering at C atoms [15], while spectrum U-Glyc shows pure U-U backscattering [16].

The plot of U-Form shows two separated peaks. This means that WT is able to detect a light and a heavy scatterer at very similar distances ($\Delta r = 0.1$ Å). The extinction in the center of the WT of U-Form is a consequence of the interference of the similar backscattering waves from uranium and multi-scattering waves from carbon. Therefore, the WT analysis suggests both U- O_{ax}-U and U-O_{eq}-C structural elements, which may be interpreted as the formation of polynuclear U(VI)/formic acid complexes.

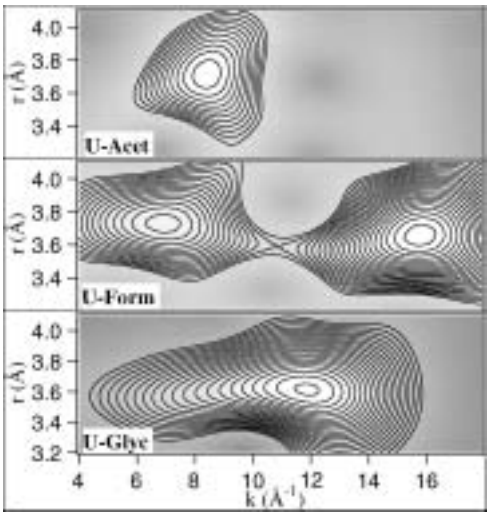

Fig. 3. The WT of the spectra U-Acet, U-Form and U-Glyc within the range $r = 3.2 - 4.1$ Å.

This example shows that the combined application of WT and FT analysis is able to provide both short-range distances and identity of neighboring atoms with unprecedented precision, and therefore may significantly improve the elucidation of complex structures.

4. Conclusions

The presented model- and real examples show that the combined application of WT and FT analysis is able to provide both short-range distances and identity of neighboring atoms with unprecedented precision.

Continuative works will be directed towards more quantitative results of the EXAFS wavelet analysis. Always important remains the question about the most suitable mother wavelet.

Abstract

X-ray absorption coefficient of Cs in the energy region of L edges has been measured on a 1 : 9 alloy of Cs and Na at room temperature. The absorption spectrum is virtually free of the structural signal. EXAFS oscillations are visible only in a ∼70 eV wide interval immediately above the edges. The short range of the signal is attributed to a strong disorder of the alloy introduced by the complete miscibility of the constituents and the large difference of their metal radii. The spectral regions above three L-edges exhibit the same pattern of sharp multielectron photoexcitation features involving electrons from outer subshells 6s to 4p as in the adjacent element xenon. The segment above the L_3 edge can be used as the atomic absorption background for the standard EXAFS structural analysis of Cs compounds.

1. Introduction

X-ray atomic absorption can be measured either directly on a monatomic gas sample [1–5] of an element or derived from an X-ray absorption spectrum of a compound sample after removal of the structural signal [6–10]. The tiny sharp features on the smooth energy dependence of the photoabsorption cross section are fingerprints of multielectron photoexcitations (MPE). These weak processes arise from the inter-electron interactions in the target atom.

The atomic absorption spectrum is a very good approximation to the atomic absorption background (AAB) in the XAFS structural analysis of a substance containing the target element. Since the structural signal and MPE occupy the same spectral region above a major absorption edge, their interference, if unrecognized, impedes the interpretation of the structural signal leading to errors in the structure parameters determined in the XAFS analysis [8, 9].

For Cs, only the most prominent resonant MPE feature has been extracted from the L-edge EXAFS spectra of amorphous materials containing Cs [11–13]. Complete atomic Cs L-edge absorption has not been determined: apparently, an experimentally demanding and costly heat-pipe cell [4] would be required. In a substitute experiment we measured Cs absorption on a thin layer of Cs/Na alloy expecting to remove the weak EXAFS signal numerically. Surprisingly, the experiment showed that the strong disorder in the alloy produces a practically pure Cs atomic absorption spectrum almost without an EXAFS component.

To assess the purity of the measured AAB a comparison with older absorption data on gaseous Xe [2] can be used. Recent studies in K-edge absorption of noble-gas/alkali-metal neighbor pairs Ar/K and Kr/Rb [4, 5] have proven that the MPE features in a pair differ only in details while following the same overall pattern.

2. Experiment

Cs/Na alloy with a concentration ratio of 1 : 9 was prepared. A small amount of the alloy was placed, together with a drop of paraffin oil to prevent oxidation, into a small lucite container between two kapton foils and squeezed into a thin layer. The container and the oil kept the metal perfectly stable for several hours of the experiment: no sign of oxidation was observed after demounting. The stability of the sample was confirmed also by the perfect reproducibility of the scans that were recorded in sequence at each of the L subshell edges.

The absorption experiment was performed at the E4 station of the DORIS ring at HASYLAB synchrotron facility, DESY (Hamburg, Germany). The beamline provides a focused beam from Au-coated mirror and a Si(111) double-crystal monochromator with 0.8 eV resolution at the Cs L_3-edge. Harmonics are effectively eliminated by a plane Au coated mirror and by detuning the monochromator crystal using a stabilization feedback control. Exact energy calibration was established with a simultaneous measurement on a Ti metal foil ($E_K = 4966$ eV) between the second and the third ionization cell.

3. Results

A compound picture of the L edges (Fig. 1) is obtained as a superposition of three scans per subshell region. Each of the edges is preceded by a resonance due to the excitation of the 2p or 2s electron to the unoccupied bound states just below the continuum.

The spectra above each of the edges are remarkably flat, almost without oscillatory EXAFS signal characteristic of solid

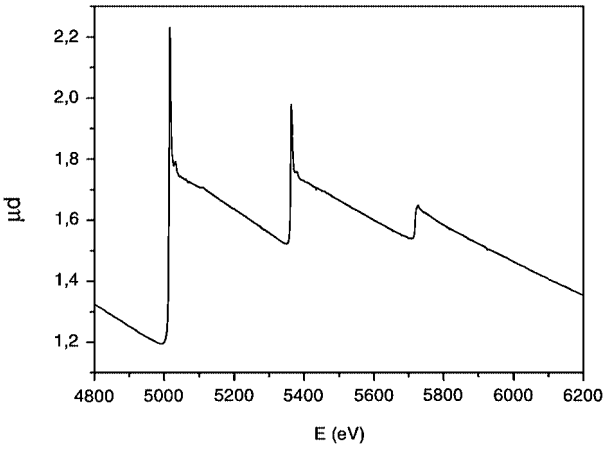

Fig. 1. The L-edge absorption spectrum of Cs measured on a thin layer of the Na/Cs alloy.

*E-mail: iztok.arcon@p-ng.si

samples. A slight convexity of the spectrum above the L_3 and L_2 edge, observed already in the L absorption spectra of some heavy elements, has been explained as a consequence of subshell polarization [14].

The strongest of the sharp MPE features are just barely visible in the spectrum. To expose the details, the average trend of each subshell region is removed from the relative cross section (Fig. 2). Several groups of MPE can be clearly discerned above each absorption edge. The groups can be identified by their energy as multiple excitations involving electrons in consecutively deeper subshells from 6s to 4p, in complete analogy with the MPE groups in the neighboring Xe [2], shown below. Hartree-Fock estimates [15] of the threshold energies of the corresponding double excitations are indicated by arrows.

Even at this level of magnification the oscillatory structural signal is visible only close to the edge. The amplitude of EXAFS oscillations is smaller than the MPE features and vanishes in the noise level about 70 eV above each edge. A more definite estimate of the EXAFS amplitude and range can be obtained from the comparison with the absorption spectrum of the cooled sample (Fig. 3). It shows that only the first two periods of the structural signal are retained in the room-temperature spectrum, further oscillations being suppressed by the Debye-Waller factor.

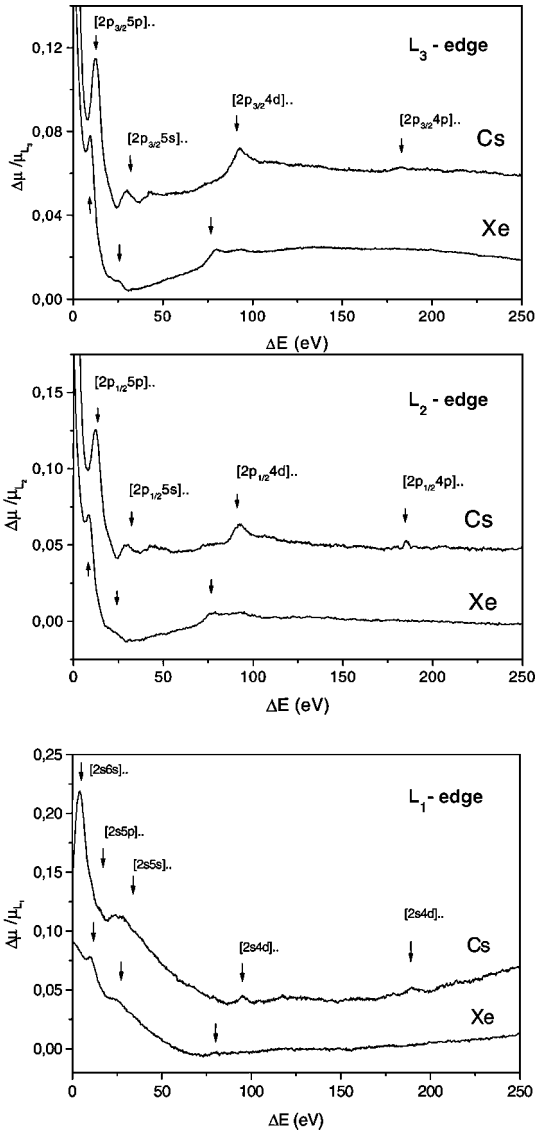

Fig. 2. The comparison of the absorption in the L subshell regions of Cs and Xe after removal of the average trend to enhance the detail. Theoretical estimates of the energy of double excited states are shown by arrows. For each subshell, the origin of the energy scale is shifted to the respective ionization threshold.

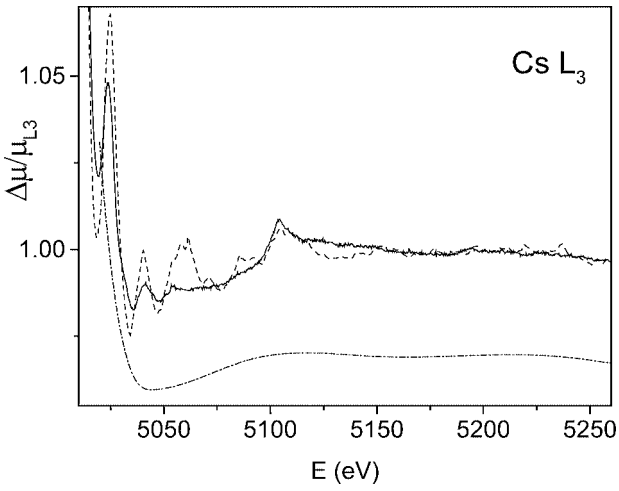

Fig. 3. The comparison of Cs/Na alloy L_3 absorption spectra at room temperature (solid line) and at liquid nitrogen temperature (dashed line). Note the contraction of the structural signal so that the atomic absorption is clearly exposed in the room-temperature spectrum from 70 eV above the edge on. Below, a standard spline background of the liquid-nitrogen spectrum is shown, shifted for −0.03 for clarity.

Incidentally, the comparison in Fig. 3 also illustrates the importance of using the proper AAB in the analysis of a weak structural signal. The XAFS and MPE are so intimately intertwined even in the low-temperature spectrum that the separation by the standard approach of the spline background constructed from the lowermost Fourier components cannot be reliable. The AAB extracted from the room-temperature spectrum, on the other hand, reproduces fully also the sharp non-structural features of the signal, as e.g. the [2p4d] edge and resonance at 5105 eV.

Abstract

This paper presents a method for choosing the optimal regularization parameter in EXAFS analysis based on the L-curve-criterion without any external parameter. The L-curve is a log-log plot of the norm of regularized solution versus the norm of the corresponding residual norm. The optimal regularization parameter is chosen as a maximum of the L-curve curvature. We apply this method in two experimental cases: crystalline Cu with well-known structure and aqua-ion Cm^{+3} with unknown structure. The optimal regularization parameter leads to a stable solution with a good convergence of the iterative process.

1. Introduction

The regularization method was suggested to EXAFS data analysis nearly two decades ago [1]. This method of numerical solution of Fredholm integral equation of the first kind which describes the EXAFS signal has been shown to be an attractive method of obtaining the structure information. After discrete approximation of the integral equation, the problem reduces to solving an ill-posed linear algebraic equation system which solution is very sensitive to the measuring error. The regularization algorithm allows to lower the influence of the measuring error and to get a stable solution. However, the choice of the regularization parameter is a difficult problem. Up to now, in EXAFS spectroscopy an external parameter – the experimental error in measuring EXAFS data – is used [2].

The EXAFS integral equation in single scattering approximation for one-component system is written as in [1]:

$$\chi(k) = \frac{4\pi\rho_0}{k} R(k) \int_0^\infty f(k,r) g(r) \exp\left\{-\frac{2r}{\lambda(k)}\right\} \times \sin(2kr + 2\delta(k) + \varphi(k,r))\,\mathrm{d}r, \quad (1)$$

where $\chi(k)$ is the normalized oscillating part of the X-ray absorption spectrum, ρ_0 is the atomic density of the material, $f(k,r)$ is the backscattering amplitude of the neighboring atom, $\delta(k)$ is the phase shift on the central atom, $\varphi(k,r)$ is the phase shift on the neighboring atom, $\lambda(k)$ is the mean free path of the photoelectron. $g(r)$ is the pair correlation function (PCF). The functions $R(k)$, $f(k,r)$, $\varphi(k,r)$, $\delta(k)$, $\lambda(k)$ are obtained from curved wave approximation using FEFF8 [3].

Let us rewrite eq. (1) in a symbolic form:

$$u = Ag. \quad (2)$$

Here u is the transformed experimental data, A is the integral operator.

As a regular approximate solution, we take the function g which minimizes in space L_2 the Tikhonov functional [4]:

$$\min M[g_\alpha] = \min\{\|(Ag - u)\|^2 + \alpha\|Lg\|^2\},\ g(r) \in L_2[a,b] \quad (3)$$

Here α is the regularization parameter and $L = I$, where I is the identity operator. The smoothness of solution $g(r)$ is taking into account when we add the second term in the functional (3). $[a,b]$ is the interval in r-space, where the unknown function $g(r)$ is obtained.

After discrete approximation of the integral operator $\boldsymbol{A}$ and the function $g(r)$, the Tikhonov solution [4] is obtained as a result of numerical calculation:

$$g_\alpha = (A^*A + \alpha L^*L)^{-1} A^* u. \quad (4)$$

The next step is an iterative procedure:

$$g_\alpha^m = (A^*A + \alpha L^*L)^{-1}(A^*u + \alpha L^* L g_\alpha^{m-1}), \quad (5)$$

where m is the number of the iteration. In our case, we obtain the solution $g^{\mathrm{m}}(r)$ from (5) and also $g^0(r)$ from (4) as a sum of peaks with lateral oscillations. During the iterative process we consider that the nearest peaks of the previous solution $g^{\mathrm{m}-1}(r)$ (in the case of experimental data for crystalline Cu we choose three peaks) can be described and replaced by the Gaussian functions [5]. After substitution $g^{\mathrm{m}-1}(r)$ in a new form to the right part of (5) we solve this equation and obtain a new solution $g^{\mathrm{m}}(r)$. This assumption is valid if we know that our sample has a crystalline form. Thus, *a priori* physical information is introduced in the algorithm to obtain a reliable solution.

2. The optimal choice of the regularization parameter using the L-curve criterion

The numerical treatment of the inverse problem arising in the EXAFS data analysis has a free parameter – the regularization parameter α. The regularized solution to an inverse problem depends essentially on the value of this parameter. A high value of the regularization parameter damps the regularized solution, on the other hand a small one leads to oscillating artifacts in the solution. So the art of solving inverse problems in the EXAFS data analysis by regularization consists in determining the optimal regularization parameter for the examined probe and the current experimental data. The L-curve-criterion gives a practical way to find the optimal value α_{opt} of the regularization parameter.

Fig. 1 shows for experimental data of crystalline Cu the L-curve which is the parametric representation of $\log(\|g_\alpha\|)$ as function of $\log(\|Ag_\alpha - u\|)$, where $\|g_\alpha\|$ is the norm of the regularized solution and $\|Ag_\alpha - u\|$ is the norm of the residual of reconstructed function obtained using the regularized solution and the transformed experimental data $u(k)$. The regularized solution itself is a function of the regularization parameter α. The L-curve shows a shape like the capital letter "L" what gave the name. The

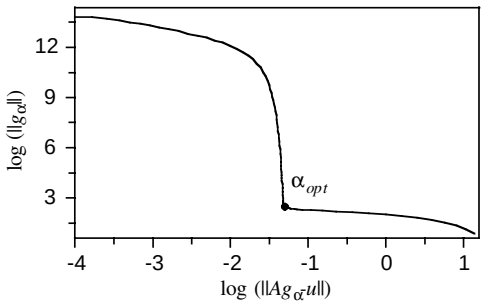

Fig. 1. The L-curve for experimental data of crystalline Cu.

L-curve-criterion means: a value α_{opt} of the regularization parameter α corresponding to the corner of the L-curve is an optimal one. Details can be found in [6, 7].

There is an empirical explanation of the L-curve-criterion. On the L-curve plot the right bottom area of the L-curve corresponds to the higher values of α, and the left upper area – the small values. As α decreases the norm of the residual function decreases much faster than the norm of the regularized solution increases as long as the values of $\alpha > \alpha_{\rm opt}$. A region of α values follows where the norm of the regularized solution starts to increase dramatically. This means a value $\alpha = \alpha_{\rm opt}$ corresponding to the corner of the L-curve gives an optimum in the effort to minimize simultaneously the norm of the residual of the solution and the norm of the solution.

To make the L-curve for an inverse problem, a set of regularized solutions g_α depending on α is needed. On the other hand the set of linear algebraic equations describing the inverse problem in EXAFS data analysis is numerically very close to singular. To deal with such sets of equations needs very powerful technique namely the Singular Value Decomposition (SVD) [8]. If the discrete matrix of the inverse problem is decomposed into $A = UWV^*$, with $UU^* = I$, $VV^* = I$ and $W = [\mathrm{diag}(\omega_j)]$ then the Tikhonov solution of the problem (4) and the iterative equation (5) can be rewritten as

$$g_\alpha = V(WW + \alpha I)^{-1} WU^* u, \tag{6}$$

$$g_\alpha^{\rm m} = V(WW + \alpha I)^{-1}(WU^* u + \alpha V^* g_\alpha^{\rm m-1}). \tag{7}$$

This formulation shows:

1. The numerical calculations of the inverse problem are shifted into the SVD. (There are good implementations of SVD in several numerical libraries, for example, in the IMSL.)
2. The regularized solution g_α is a simple function of the regularization parameter α.

That means we have an available way to calculate that value of g_α for which the curvature of the L-curve has a maximum (the corner in the L-curve). The L-curve criterion gives an optimal value of the regularization parameter.

The described optimal regularization method is implemented in the Program ALPHA of EXAFS data analysis for one-component system.

3. Experimental aspects and results

To be able to evaluate the results of our method, we choose, on the one hand, a well-defined reference – a crystalline foil Cu; on the other hand, a trivalent actinide (curium) in aqueous solution.

3.1. *Crystalline foil Cu*

The sample of crystalline Cu was prepared by EXAFS Materials Company (Danville, USA) with thickness 7 µm. The Cu K-edge of X-ray absorption spectrum was collected in transmission mode at a room temperature of sample. The measurements were performed at the Rossendorf Beamline (ROBL) at the European Synchrotron Radiation Facility (ESRF) using a Si(111) double-crystal monochromator in fixed-exit mode [9]. Harmonic suppression better than 8×10^{-4} was achieved by two Pt coated mirrors with a cut-off energy. The photon energy was calibrated using the K-edge energy of Zn foil at 9.6 keV. In addition, the background absorption of the Cu K-edge spectrum was determined by measuring the absorption spectrum without any sample. These measurements were performed before and after measurement of the K Cu spectrum without any changing amplification.

We present on Fig. 2 the PCF Cu-Cu for crystalline Cu. The model function was calculated using the table structure information and the temperature Debye $\theta_{\rm D} = 315$ K. For the known crystal structure, it is possible to calculate the multiple scattering (MS) contribution by FEFF 8 and eliminate it from the experimental input data $\chi(k)$. We obtain new 'experimental' data that should contain only SS contribution, which is described by equation (1). If we compare the Tikhonov solution of the inverse problem (6) obtained using the optimal value of regularization parameter $\alpha_{\rm opt} = 8 \times 10^{-5}$ and the model function, we note that this solution is still far from the exact solution. In this case it is necessary to perform the iterative procedure according (7). At optimal value $\alpha_{\rm opt}$ the solution is converged quickly (Fig. 3) to the stable one.

The following main characteristics of the first peak for the function $g^{\rm m}(r)$ are selected: the interatomic distance, the nearest neighbors coordination number and Debye-Waller (DW) factor. We estimated these values according to the Gauss function

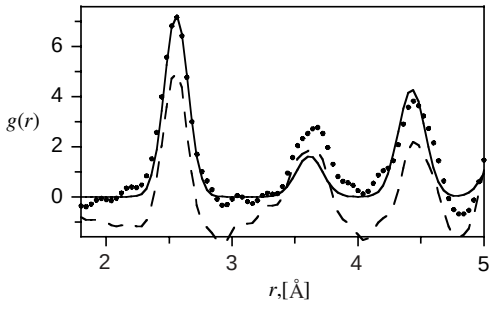

Fig. 2. Pair correlation function Cu-Cu for crystalline Cu: a) model function (solid line); b) Tikhonov solution (dashed line); c) solution after 50 iteration (dotted line).

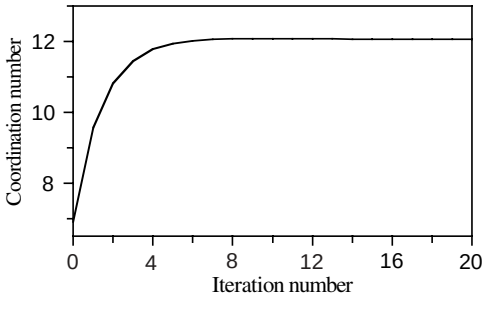

Fig. 3. Convergence of iteration procedure at solving the inverse problem for the first coordination number of crystalline Cu (experimental data).

describing the peak of the solution. In Table I we compare the final stable characteristics of the first peak with the model values and find an excellent agreement.

3.2. *Cm^{3+} in aqueous solution*

Besides plutonium, the long-lived isotope curium plays a crucial role for long-term performance assessment of nuclear waste repositories. In order to predict the mobilization and retardation of this nuclide, it is necessary to know the structures of the inorganic and organic actinide species that are involved in the process of migration. Thereby, the characterization of the Cm^{3+} aqua-ion forms the base for further investigations.

In the literature only few measurements can be found of co-ordination numbers of trivalent actinides in aqueous solutions [10–13].

In order to determine a reliable reference value for the co-ordination number of Cm^{3+} aqua ion, the samples used in our EXAFS measurements were prepared in non-complexing 1.0 M perchloric acid. High actinide concentrations (1×10^{-3} mol/L) were used in order to achieve low-noise EXAFS spectra, which enable a precise determination of bond lengths and co-ordination numbers of the Cm^{3+} aqua ion.

The experiments were performed at the Rossendorf beamline (ROBL) at the ESRF in Grenoble as described above. The radiochemistry experimental station at ROBL has been designed to perform XAFS spectroscopy of solid and liquid non-sealed radioactive samples [14]. EXAFS spectra were collected in transmission mode at the curium L_{III}-edge at 18970 eV ($E_0 = 18990$ eV). Nb metal foils were measured and the first inflection point of the X-ray absorption spectra (Nb K-edge at 18986 eV) was used for energy calibration. We used two methods of obtaining structural information from the same experimental data: 1) a regularization method; 2) EXAFS data fit by using the EXAFSPAK program package with an additional free parameter S_0 [15]. Parameters for the backscattering phase and amplitude, the mean free path, and the reduction factor were calculated using the FEFF8 code [3]. Fig. 4 shows the solution obtained by the regularization method at optimal regularization parameter $\alpha_{opt} = 6.3 \times 10^{-6}$ and $S_0 = 1.0$. Fig. 5 demonstrates the comparison the input experimental data and $\chi(k)$ obtained from solution (Fig. 4). The structural parameters obtained from EXAFS data by both methods are collocated in Table II. It is necessary to note that we don't use any model for obtaining the result by the regularization method.

Table II. *The interatomic distance R, the nearest neighbors coordination number N and Debye-Waller (DW) factor σ^2, obtained from experimental EXAFS data for Cm^{+3} aqua-ion.*

	R [Å]	N	$\sigma^2 \cdot 10^3$ [Å^2]
UV/V [10]		9	
EXAFSPAK ($S_0{}^2 = 0.9$)	2.46	9.3(0.3)	7.5
EXAFSPAK ($S_0{}^2 = 1.0$)	2.46	8.4(0.3)	7.5
Regularization	2.45	9.2	8

So, it was shown that using the L-curve criterion makes the regularization method in EXAFS spectroscopy a very perspective one for a wide range of materials.

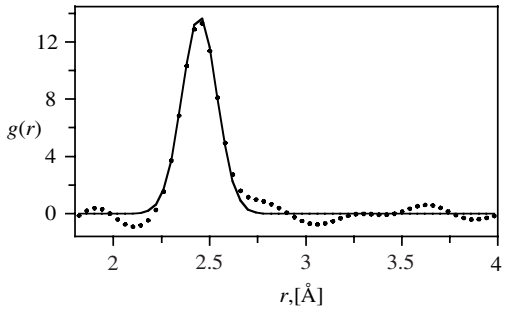

Fig. 4. The solution (dotted line) obtained by the regularization method and approximated by the Gauss function (solid line).

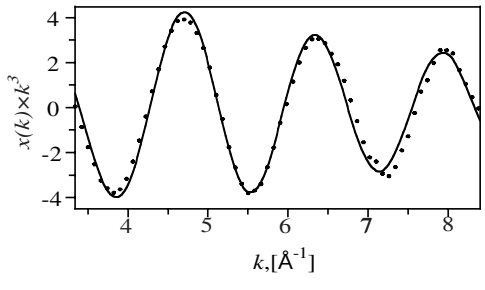

Fig. 5. Comparison the input experimental (dotted line) data and $\chi(k)$ obtained from solution (solid line).

Abstract

The anharmonic vibration of ions in solids has been measured frequently by the EXAFS technique in recent years. However, the analysis of the anharmonicity in EXAFS is still complicated. In this article, we show a new method of simultaneous fitting with constraints (SFC) which is simple and useful for the analysis of anharmonicity. As an example, copper EXAFS spectra measured at 300 K, 500 K and 700 K were analyzed by this method. Also, we propose a useful EXAFS expression for anharmonic systems. We found the physical meaning of the parameters s and δ used in the EXAFS expression for anharmonic systems.

1. Introduction

It is well known that the spectra of the extended X-ray absorption fine structure (EXAFS) change significantly with temperature [1, 2]. This phenomenon is related to the anharmonic vibration of atoms in solids. Sevillano *et al*. studied the variation of the Debye-Waller factor due to thermal vibrations [3]. In recent years, the anharmonicity of a pure metal has been discussed extensively [4]. Several methods of measuring the anharmonicity have been developed in the extended X-ray absorption fine structure (EXAFS) fields [5–10]. Amongst those methods, the cumulant method [6] is widely used to analyze the anharmonic vibration. However, the cumulant method requires very careful treatment because all cumulants and the average interatomic distance are covariant with temperatures. This article demonstrates a useful method, the simultaneous fit with constraints (SFC), to measure the anharmonicity with EXAFS techniques. This method is based on the model of effective anharmonic pair potential [7]. In this method, the effective anharmonic pair potential is obtained directly from the fitting and the thermal expansion coefficient, cumulants, and parameters of the pair distribution functions are obtained from the effective anharmonic pair potential.

2. Experiments

The XAFS measurement was carried out at the BL01B1 station of the 8 GeV storage ring in SPring-8. A couple of Si(311) crystals monochromatized the synchrotron radiation beam from a bending magnet. The photon beam was focused in the vertical direction. A Rh coated mirror was used to eliminate the higher harmonics. We measured XAFS spectra near the Cu K (8.979 keV) edge in the transmission mode using a couple of ionization chambers. The energy of the photons from the monochromator was calibrated with that of a prepeak of a 5 μm thick Cu foil with a purity of 5 N (8.97800 keV). The specimens were heated up to 900 K in an electric furnace.

3. SFC Method

The parameters of the effective anharmonic pair potential [7] can be obtained by fitting simultaneously several filtered EXAFS spectra measured at different temperatures to an anharmonic EXAFS expression with constraints. The anharmonic EXAFS expression and the constraints are explained below. This method can be applied to most anharmonic systems except for highly anharmonic vibrational systems.

An anharmonic EXAFS expression was obtained from simplification of the EXAFS equation for disordered system derived in other work [9]. The simplified equation is

$$\chi(k) = \frac{NS_0^2(k)F(k)}{kR^2} e^{-\frac{2R}{\lambda(k)}} A_c(k) \sin\{2kR + \varphi(k) + \varphi_c(k)\} \qquad (1)$$

where N is the coordination number in the first shell, R is the average bond distance, $S_0^2(k)$ is a correction factor due to multiple processes, $\lambda(k)$ is the mean free path, $F(k)$ is the backscattering amplitude and $\varphi(k)$ is the phase shift of the photoelectrons. Here, $A_c(k)$ and $\varphi_c(k)$ is the amplitude and phase corrections, respectively, due to the anharmonic vibration.

The amplitude and phase corrections are simplified from the completed expression [9]

$$A_c(k) = [1 + (2k\delta)^2]^{-\frac{s+1}{2}}, \qquad (2)$$

$$\varphi_c(k) = (s+1)[tan^{-1}(2k\delta) - (2k\delta)] \qquad (3)$$

where s and δ are the parameters of the pair distribution function [9].

From the relationship between pair distribution and the effective anharmonic pair potential as shown in the next section, we can express the distribution parameters, s and δ as a function of parameters for the Morse potential,

$$s = \frac{8}{9}\left(\frac{D}{k_B T}\right), \qquad (4)$$

$$\delta = \frac{3}{4}\sigma\left(\frac{k_B T}{D}\right). \qquad (5)$$

In the fitting process, we put constraints that the values of N, D and σ are not changed for several different EXAFS spectra obtained at different temperatures because they are independent of temperature.

4. Results and Discussion

It is interesting to know the relationship between the pair distribution and the effective anharmonic pair potential. The

pair distribution function can be obtained from the Boltzmann probability distribution function because the average bonding distance can be obtained from both distributions,

$$\langle r\rangle = \int rg(r)\,\mathrm{d}r = \int rf_B(r)4\pi r^2\,\mathrm{d}r \tag{6}$$

where $g(r)$ is the pair distribution function and $f_B(r)$ is the Boltzmann probability distribution function which is given by

$$f_B(r) = f_0 \mathrm{e}^{-\frac{V(r)}{k_B T}} \tag{7}$$

where f_0 is the normalization constant given by $f_0 = [\int \mathrm{e}^{-\frac{V(r)}{k_B T}} 4\pi r^2\,\mathrm{d}r]^{-1}$. A model of pair distribution function for disordered or anharmonic systems [9] has been proposed as

$$g(r) = g_N(r_m, s, \delta)\frac{1}{\Gamma(s+1)}\frac{1}{\delta}\left(\frac{r-r_m}{\delta}\right)^s \mathrm{e}^{-\frac{r-r_m}{\delta}} r^2 \tag{8}$$

where r_m is the minimum distance in the distribution.

Using the Morse potential as the effective anharmonic pair potential and expanding it near the equilibrium position, we obtain the following form of effective anharmonic pair potential,

$$V(r) = \frac{D}{\sigma^2}(r-r_0)^2 - \frac{D}{\sigma^3}(r-r_0)^3 \tag{9}$$

where D and σ are the dissociation energy and the potential width, respectively, and r_0 is the equilibrium distance.

From Eq. (6) and (8), we obtain

$$g_N(r_m, s, \delta)\frac{1}{\Gamma(s+1)}\frac{1}{\delta}\left(\frac{r-r_m}{\delta}\right)^s \mathrm{e}^{-\frac{r-r_m}{\delta}} = 4\pi f_0 \mathrm{e}^{-\frac{V(r)}{k_B T}}. \tag{10}$$

Expanding the logarithm of Eq. (10) about r_0 ($r_0 = r_m + s\delta$) we obtain Eqs. (4) and (5).

Here we should point out that the parameter s in Eq. (4) is given by the ratio of dissociation energy and thermal energy. The parameter δ represents thermal expansion. This is not the linear thermal expansion but the local thermal expansion of bonding distance. δ in Eq. (5) also can be expressed by [10]

$$\delta = \langle r\rangle - r_0. \tag{11}$$

The local thermal expansion coefficient α can be defined by

$$\alpha = \frac{\delta}{\langle r\rangle T}. \tag{12}$$

It has been verified that the expression for the local thermal expansion coefficient is equivalent to the expression obtained in other work [10].

Usually anharmonic vibration of ions in solids appears at high temperatures. The anharmonic vibration causes the reduction of amplitude and the shift in phase of EXAFS spectra significantly. We expect that the anharmonicity can be readily measured by EXAFS technique. The EXAFS spectra of pure copper film were measured at 300 K, 500 K and 700 K and analyzed using the SFC method for a test.

Fig. 1 shows EXAFS spectra of copper measured at the temperatures indicated. As shown in Fig. 1, the amplitude decreased and the phase increased as temperature increased. We expect that this is an anharmonic vibrational effect because there is only temperature change and there is no local structural variation.

Fig. 2 is a Fourier transform of EXAFS spectra measured above. As shown in Fig. 2, the magnitude decreases drastically as the temperature increases. Also, the higher shells are reduced significantly losing the long range order due to the anharmonic vibration.

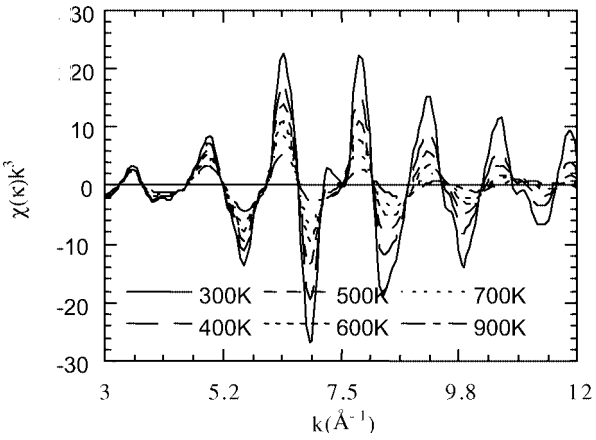

Fig. 1. EXAFS spectra for copper foil at various temperatures.

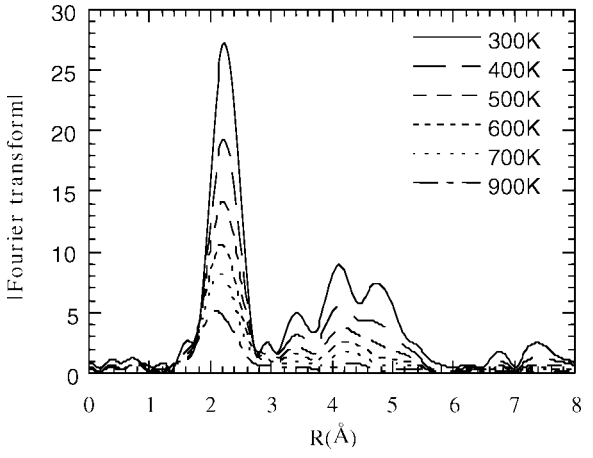

Fig. 2. Fourier transform of the EXAFS spectra for copper foil.

Table I. *Energy shift and local structural parameters at each temperature. The cumulants, C_2 and C_3 are calculated by the relationship between the cumulants and the potential parameters [10].*

Temp. (K)	ΔE (eV)	R (Å)	$C_2 \times 10^{-2}$ (Å)^2	$C_3 \times 10^{-3}$ (Å)^3
300	6.1 ± 0.2	2.55 ± 0.01	0.85 ± 0.05	0.23 ± 0.05
500	6.6 ± 0.2	2.56 ± 0.01	1.47 ± 0.05	0.68 ± 0.05
700	7.1 ± 0.2	2.57 ± 0.01	2.09 ± 0.05	1.35 ± 0.05

The first shell (first peak) in the Fourier transform was filtered by the back transform. The filtered spectra were fitted using the SFC method. From the fitting, we obtained the anharmonic vibrational parameters and the effective anharmonic pair potential.

The average bond distance and cumulants obtained by SFC method are summarized in Table I. The dissociation energy, the potential width and the local thermal expansion coefficient were

$$D = 1.28\,\mathrm{eV}, \tag{13}$$

$$\sigma = 0.92\,\text{Å}, \tag{14}$$

$$\alpha = 1.80 \times 10^{-5}/\mathrm{K}, \tag{15}$$

respectively.

The bond distances in Table I are similar to the reference values [4, 12]. The second cumulants were consistent with values obtained in other work [4]. The thermal expansion coefficient obtained for copper is also consistent with the referenced value [11]. The energy shift shown in Table I increases slightly and systematically as the temperature increases. This shows that there is some additional kinetic energy of photoelectrons at high temperatures. Unfortunately, we do not have other measurements and theoretical considerations for the energy shift, the dissociation energy or the potential width.

As shown in the above analysis, the SFC method gives consistent results on the local structural parameters with other work and we expect that this method will be useful for the analysis of anharmonicity.

5. Conclusion

We propose that the SFC EXAFS method can be used to analyze anharmonicity effectively. The method gives consistent results with other works from analysis of EXAFS spectra of pure copper measured at high temperatures.

Also, we point out that the anharmonic EXAFS expression is very useful for the analysis of anharmonicity. We found the physical meaning of the parameters s and δ used in the anharmonic EXAFS equation. It is shown that s is determined by the ratio of dissociation and thermal energy and δ is the parameter of the local thermal expansion.

Abstract

A good approximation for the electron self-energy or the electron quasiparticle properties is needed for an accurate calculation of X-ray absorption spectra. The *GW* approximation (GWA) has been found to be relatively reliable in predicting the quasiparticle energies and lifetimes in a large variety of systems. For solids, a part of a GWA calculation is the calculation of the inverse of the dielectric matrix ε^{-1}. We introduce an iterative method for calculating an accurate multi-pole approximation for ε^{-1} and we apply it in *GW* calculations. Results for quasiparticle properties are presented for LiF and Si. For LiF we use these results to calculate the inelastic X-ray scattering spectra for energy loss close to the F K-edge. Other uses for this representation of ε^{-1} will also be discussed.

For an accurate calculation of X-ray absorption or X-ray Raman scattering (XRS) a number of important effects have to be considered. Excitation transition matrix elements have to be calculated accurately, the interaction between the photoelectron and the core hole created in the excitation process has to be treated, and the energy shifts and lifetime broadening due to the interaction of the photoelectron and the core hole with the surrounding electrons has to be included. In this article we concentrate on the photoelectron self-energy effects. Examples of how other parts of the calculation can be approached are given, for example, in Refs. [1, 2].

The GW-approximation (*GWA*) proposed by Hedin [3, 4] is often used for electron self-energy and quasiparticle calculations in solids. The basis of the GWA and its properties has been given detailed treatment in a number of recent review articles [5, 6, 7]. In X-ray absorption or XRS calculations, additional problems are caused by the presence of the core-hole. Core-excited calculations are often done by solving the photoelectron Green's function in the presence of the core-hole, as is the case when one is using the *final-state* rule (FSR). This is comparable to an impurity problem, and is still a quite demanding problem to be approached with standard *GWA* methods. This is probably part of the reason why, even to this day, a simplified plasmon-pole, electron-gas self-energy model within a local-density approximation [8] is often used in FSR calculations. An alternative approach to core excited states is to use the *Bethe-Salpeter* equation (BSE) approach of Ref. [1]. In the BSE, the final-state photoelectron Green's function is calculated in a crystal without a core-hole. In this case, the electron self-energy can be calculated relatively easily using standard *GWA* methods. Within *GWA*, the self-energy is approximated by

$$\Sigma(\mathbf{r},\mathbf{r}',\omega) = \mathrm{i}\int \frac{\mathrm{d}\omega'}{2\pi}\mathrm{e}^{\mathrm{i}\delta\omega'}\mathbf{G}(\mathbf{r},\mathbf{r}',\omega+\omega')\mathbf{W}(\mathbf{r},\mathbf{r}',\omega'), \tag{1}$$

where $\mathbf{W}$ is the screened interaction and $\mathbf{G}$ is the Green's function. We use a non-self-consistent GWA and calculate the band states needed for $\mathbf{W}$ and $\mathbf{G}$ using the local-density approximation (LDA). The random phase approximation (RPA) is used for the dielectric matrix in $\mathbf{W} = \boldsymbol{\varepsilon}^{-1}\mathbf{v}$, where $\boldsymbol{\varepsilon}^{-1}$ is the inverse of the dielectric matrix and $\mathbf{v}$ is the unscreened Coulomb potential. The inverse of the dielectric matrix is related to the polarizability $\boldsymbol{\chi}$ of the system by $\boldsymbol{\varepsilon}^{-1} = 1 + \mathbf{v}\boldsymbol{\chi}$.

The current approach is based on expressing the polarizability in the electron-hole basis [9]. Additionally, the current work uses a pseudopotential approach, and all the relevant functions (wave functions, Coulomb potential, and polarizability) are expressed in a plane-wave basis. As explained in Ref. [10], the causal $\boldsymbol{\chi}$ can be expressed in matrix form:

$$\boldsymbol{\chi}(\mathbf{q},\omega) = \boldsymbol{\Psi}^{\dagger}\frac{1}{z^2 - \mathbf{H}_{RPA}}\boldsymbol{\Psi}, \tag{2}$$

where $z = \omega + \mathrm{i}\delta$. Each column of the matrix $\boldsymbol{\Psi}$ corresponds to the total electron-hole pair wave function created using

$$P^{\dagger}_{\mathbf{G}}(\mathbf{q}) = \sum_{j\mathbf{k}}^{occ}\sum_{j'\mathbf{k}+\mathbf{q}}^{unocc}\langle\phi_{j'\mathbf{k}+\mathbf{q}}|\mathrm{e}^{\mathrm{i}(\mathbf{q}+\mathbf{G})\cdot\mathbf{r}}|\phi_{j\mathbf{k}}\rangle\Delta^{\mathbf{q}}_{jj'\mathbf{k}}a^{\dagger}_{j'\mathbf{k}+\mathbf{q}}a_{j\mathbf{k}},$$

where we have $\Delta^{\mathbf{q}}_{jj'\mathbf{k}} = \sqrt{2(E^{LDA}_{j'\mathbf{k}+\mathbf{q}} - E^{LDA}_{j\mathbf{k}})}$, and $\{E^{LDA}_{j\mathbf{k}}\}$ are LDA band energies. The matrix $\mathbf{H}_{RPA}$ can be expressed as $\mathbf{H}_{RPA} = \mathbf{H}_{1e} + \mathbf{V}_{local}$, where the "single-particle" part is diagonal in the particle-hole basis $H_{1e}|jj'\mathbf{k}\rangle_{\mathbf{q}} = (E_{j'\mathbf{k}+\mathbf{q}} - E_{j\mathbf{k}})^2|jj'\mathbf{k}\rangle_{\mathbf{q}}$ [9] and the local-field operator is $\mathbf{V}_{local} = \boldsymbol{\Psi}\,\mathbf{V}\boldsymbol{\Psi}^{\dagger}$.

The order of the matrix $\mathbf{H}_{RPA}$ is $\sim 10^4$ to 10^5 and direct inversion of the matrix in Eq. (2) would be a considerable computational task. However, here we will briefly outline how an approximation to Eq. (2) can be obtained using an iterative Band Lanczos algorithm [11, 12]. At the beginning of the iteration process an orthogonalized set of vectors $\{\mathbf{v_i}\}_{i=1,n}$ are obtained from $\boldsymbol{\Psi}$ by decomposing it in the form $\boldsymbol{\Psi} = \mathbf{VR}$. We find $\mathbf{R}$ and $\mathbf{V}$ using canonical orthogonalization [13]. At each iteration step a new vector $\mathbf{v}_{i+n}$ is generated

$$T_{i+n,i}\mathbf{v}_{i+n} = \mathbf{H}_{RPA}\mathbf{v}_i - \sum_{j=i-n}^{i+n-1}T_{j,i}\mathbf{v}_j, \tag{3}$$

where coefficients $T_{j,i} = \mathbf{v}_j^{\dagger}\mathbf{H}_{RPA}\mathbf{v}_i$ are chosen so that each new vector is orthogonal to previous Lanczos vectors and is normalized. After some finite number (I) of iterations, the matrix $\mathbf{T}$ and the generated set of vectors give an approximation for the full matrix $\mathbf{H}^{(I)}_{RPA} = \mathbf{V}^{(I)}\mathbf{T}\mathbf{V}^{(I)\dagger}$. Using decomposition of $\mathbf{T}$ in terms of its eigenvalues $\{\Omega_i\}$ and eigenvectors $\{\mathbf{X_i}\}$, we can approximate Eq. (2) as

$$\boldsymbol{\chi}(\mathbf{q},\omega) = \mathbf{S}^{\dagger}\frac{1}{z^2 - \Omega(\mathbf{q})}\mathbf{S}. \tag{4}$$

We have used $\mathbf{S} = \mathbf{X}^{\dagger}\mathbf{R}$, where only the first n components of the eigenvectors $\{\mathbf{X}_i\}$ are included in the product. Using this multi-pole approximation for $\boldsymbol{\chi}$ we can avoid a numerical calculation of

*email address: aleksi.soininen@helsinki.fi

the energy integral in Eq. (1). The fact that an arbitrary number of iterations can be chosen means that the number of poles used in the calculation can be determined on a case-by-case basis. Further information on this method and its application to *GWA* calculations can be found in Ref. [10].

The quasiparticle energy $E_{n\mathbf{k}}$ can be expressed with the help of the LDA band energy $E_{n\mathbf{k}}^{LDA}$ and the matrix elements of the self-energy as $E_{n\mathbf{k}} = E_{n\mathbf{k}}^{LDA} + \langle\psi_{n\mathbf{k}}|\Sigma(E_{n\mathbf{k}}) - V_{xc}^{LDA}|\psi_{n\mathbf{k}}\rangle$, where the LDA exchange-correlation potential V_{xc}^{LDA} is used. In X-ray absorption or XRS calculations one would, in principle, need the quasiparticle corrections $\Delta_{n\mathbf{k}} = E_{n\mathbf{k}} - E_{n\mathbf{k}}^{LDA}$ for all the **k**-points and bands used in the calculation. This number is usually quite large (typically at least 4000 **k**-points, and up to about 80 bands) and explicit calculation of $\Delta_{n\mathbf{k}}$ for each band state would be difficult. Instead we form an LDA-energy dependent quasiparticle correction averaged over the **k**-points and bands:

$$\Delta E(\omega) = \frac{1}{N_{n\mathbf{k}}} \sum_{n\mathbf{k}} (E_{n\mathbf{k}} - E_{n\mathbf{k}}^{LDA}) \mathrm{e}^{\frac{-(\omega - E_{n\mathbf{k}}^{LDA})^2}{2\sigma^2}}, \tag{5}$$

where $N_{n\mathbf{k}} = \sum_{n\mathbf{k}} \exp(-(\omega - E_{n\mathbf{k}}^{LDA})^2/2\sigma^2)$ and Gaussian broadening (controlled by the width σ) is used in the averaging. This is done using a smaller number of **k**-points (on the order of 10^2). The $\Delta E(\omega)$ is calculated separately for the conduction and valence states in order to correctly describe the near band-gap region. In Fig. 1 we show $\Delta E(\omega)$ for silicon obtain using the iterative method discussed here. We compare the results for $\mathrm{Re}\,\Delta E(\omega)$ and $\mathrm{Im}\,\Delta E(\omega)$ calculated with different numbers of poles (I). The Gaussian broadening of the poles was increased so that for $I \approx 3200$, $I \approx 1600$, and $I \approx 800$ the full width at half maximum (FWHM) of the poles was 1.0 eV, 2.0 eV and 4.0 eV respectively. It easy to see that, with respect to the number of poles, the $\Delta E(\omega)$ for the conduction band states converges faster. This is especially relevant for core-excited-state calculations, because only the conduction bands are needed. For the specified Gaussian widths and number of poles, $\mathrm{Im}\Delta E(\omega)$ is finite when ω is close to the conduction band edge, i.e., the electron-hole continuum contribution to **W** is accounted for. When comparing with other approaches it is worth noting that even the highest number of poles (3200) is less than one pole per reciprocal-lattice vector pair (approximately 80 reciprocal-lattice vectors were used in $\boldsymbol{\chi}$).

In the approach introduced in Ref. [1] the dynamic structure factor for energy transfers in the vicinity of the core binding energy is approximated by

$$I(\eta, \omega) = -\frac{1}{\pi} \mathrm{Im} \langle I | \hat{\mathbf{P}}_\eta^\dagger \frac{1}{\omega - \hat{H}_{eff} + \mathrm{i}\gamma(\omega)} \hat{\mathbf{P}}_\eta | I \rangle. \tag{6}$$

Here the operator $\hat{\mathbf{P}}_\eta$ couples a solid with the probe, i.e., the dipole field in the case of X-ray absorption and the longitudinal field in the case of XRS. The parameter $\gamma(\omega)$ introduces lifetime broadening to the spectra. The initial state ($|I\rangle$) of the electron system is assumed to be the ground state expressed in a single Slater-determinant form. We approximate the full many-body final-state Hamiltonian with an effective Hamiltonian $\hat{H}_{eff} = \hat{H}_0 + \hat{V}_{e-h}$, where $\hat{H}_0$ is a single-particle part and $\hat{V}_{e-h}$ accounts for the interaction between the particle and the hole. In this paper we will concentrate on $\hat{H}_0$; details on how $\hat{V}_{e-h}$ is approximated can be found in Ref. [1]. When expressed in the core hole-electron basis $|n'\mathbf{k}'\alpha'\rangle$ of Ref. [1], the operator $\hat{H}_0$ is diagonal: $\langle n\mathbf{k}\alpha|\hat{H}_0|n'\mathbf{k}'\alpha'\rangle = (E_{n\mathbf{k}} - E_\alpha)\delta_{nn'}\delta_{\mathbf{k}\mathbf{k}'}\delta_{\alpha\alpha'}$. The core-hole energy ($E_\alpha$) is assumed to be a constant and $E_{n\mathbf{k}}$ is the photoelectron quasiparticle energy.

Using $\Delta E(\omega)$ we can approximate the quasiparticle energies needed in the matrix elements of $\hat{H}_0$ with $E_{n\mathbf{k}} \approx \mathrm{Re}\,E_{n\mathbf{k}} = E_{n\mathbf{k}}^{LDA} + \mathrm{Re}\,\Delta E(E_{n\mathbf{k}}^{LDA})$. The lifetime broadening parameter in Eq. (6) is approximated in this work by $\gamma(\omega) = \Gamma_{hole} + \mathrm{Im}\,\Delta E(\omega)$, where Γ_{hole} is the core hole lifetime parameter and $\mathrm{Im}\,\Delta E(\omega)$ is used to approximate the effect of the photoelectron lifetime. In Fig. 2 we present a calculated XRS spectrum for the F K edge in LiF and compare it with experiment [14]. In the upper panel we show the result obtained without the quasiparticle correction (i.e., $E_{n\mathbf{k}} = E_{n\mathbf{k}}^{LDA}$ and $\gamma(\omega) = \Gamma_{hole}$) and the result when the quasiparticle corrections are included. In the lower panel $\Delta E(\omega)$ is shown. The quasiparticle correction has only a small effect close to the edge. For higher energies, both the imaginary and the real parts of $\Delta E(\omega)$ have a visible effect on the spectrum. The quasiparticle damping reduces the oscillations in the spectrum when $\omega > 10$ eV, and the experimental result is more closely

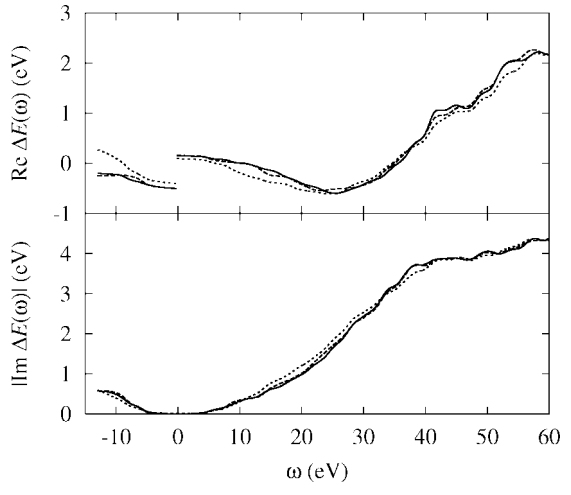

Fig. 1. The quasiparticle correction $\Delta E(\omega)$ for Si as a function of number of poles I. The upper panel shows the real part of $\Delta E(\omega)$, and the lower, the imaginary part of $\Delta E(\omega)$, in eV. The solid line gives the result for $I \approx 3200$, the dashed line for $I \approx 1600$, and the dotted line for $I \approx 800$. All of the results were obtained with $\sigma = 1.0$ eV in Eq. (5) and the pole widths are specified in the text. The horizontal axis is the LDA energy with respect to the conduction band minimum.

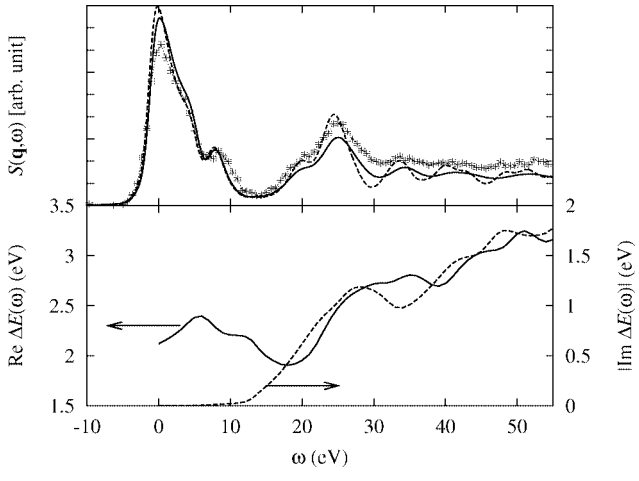

Fig. 2. The upper panel shows the comparison of the theoretical results without (dashed line) and with (solid line) the quasiparticle correction compared to experimental (line with error bars) XRS result [14]. The momentum transfer was 1.44 a.u. The experimental result was shifted in the energy scale and the zero of energy is at the conduction band minimum. In the lower panel $\mathrm{Re}\,\Delta E(\omega)$ (solid line) and $\mathrm{Im}\,\Delta E(\omega)$ (dashed line) are shown. As indicated by the arrows in the figure the vertical axis of $\mathrm{Re}\,\Delta E(\omega)$ is on the left, and of $\mathrm{Im}\,\Delta E(\omega)$ on the right.

modeled by the calculation when this effect is included. Also, the positions of the spectral features are more accurately modeled by the method including the quasiparticle shifts Re $\Delta E(\omega)$.

Besides being useful in *GWA* calculations, there are a number of ways that the pole structure of the screened interaction could be used. For example, when considering core-excited states the cross-section can be expressed as $I(\eta,\omega) = -\mathrm{Im}\langle I|\hat{\mathbf{P}}_\eta^\dagger \Pi(\omega)\hat{\mathbf{P}}_\eta|I\rangle/\pi$, where $\Pi(\omega)$ is the two-particle (core hole-electron) propagator in the particle-hole basis. In Ref. [1] the electron-hole interaction was approximated by sum of energy-independent screened interaction (V_d) and bare "exchange" (V_x) interaction terms. Using the same approximations as in Ref. [1], but including the energy dependence of the screened interaction, the inverse of the two-particle propagator is $\Pi(\omega)^{-1} = \omega - H_0 - V_x - V_d(\omega)$. The energy dependent direct interaction can be expressed as

$$(\mathbf{V}_d(\omega))_{\alpha n\mathbf{k},\alpha n'\mathbf{k}'} = \sum_p \mathbf{w}_p(\alpha n\mathbf{k}, \alpha n'\mathbf{k}') \times \left\{ \frac{1}{\omega - \omega_p - (E_{n'\mathbf{k}'} - E_\alpha)} + \frac{1}{\omega - \omega_p - (E_{n\mathbf{k}} - E_\alpha)} \right\}, \quad (7)$$

where the summation is over the poles ω_p of $\mathbf{W}$ and $\mathbf{w}_p(\alpha n\mathbf{k}, \alpha n'\mathbf{k}')$ is the matrix elements of $\mathbf{W}$ in the core hole-electron basis. Additionally, as discussed in Ref. [6], the pole structure of the screened interaction, i.e., fluctuation potentials, has several other uses in core spectroscopies.

We have reviewed a recently developed iterative scheme for calculating the pole structure of the screened interaction. The method was applied to a calculation of quasiparticle corrections needed in XRS or X-ray absorption calculations. By varying the number of poles and the width of these poles in the case of silicon, it was found that the resulting quasiparticle correction converged first for the conduction band states. The way to include these corrections into XRS or XAS calculation was discussed and results were shown for LiF. Even though these corrections are not as important at the F K-edge of LiF as they are in some other situations, it was found that they gave a clear improvement when the calculations were compared to experiment. Finally, a possible additional use for the screened interaction was suggested.

Abstract

The Fresnel theory with its numerous extensions is a well established method for the calculation of grazing incidence X-ray reflectivities for single surfaces and (multi-)layered systems. However, lateral surface correlations – which are always present e.g. for polycrystalline thin films – cannot be included in these calculations. Furthermore the application of the Fresnel theory is restricted to investigations of specular reflectivities, i.e. off specular reflectivities cannot be calculated. These limitations can be overcome by the application of the distorted-wave Born approximation (DWBA). Simulations of grazing incidence reflection mode EXAFS spectra will be presented and the results obtained using different calculation procedures such as the Fresnel theory, the Névot-Croce model and the DWBA are compared. Furthermore, we will also prove the existence of a fine structure similar to EXAFS which can be observed in the region of diffusely scattered intensities. We will show that this new EXAFS technique is surface sensitive even for grazing angles above the critical angle of total reflection.

1. Introduction

It is well known that X-ray specular reflectivity spectra recorded in the vicinity of an absorption edge exhibit a fine structure similar to EXAFS oscillations. However, in comparison to transmission EXAFS, both the real part δ and imaginary part β of the complex refractive index $n = 1 - \delta - i\beta$ contribute to the reflectivity fine structure. Nevertheless short range order structural information can be extracted from reflection mode EXAFS using the Fresnel theory for smooth surfaces and thin films [1–4].

Real surfaces/interfaces are generally afflicted with a variety of surface inhomogemities such as surface roughness and lateral correlations. In recent years the understanding of the scattering from a single rough surface and from rough multilayer interfaces has advanced rather far. The treatment of roughness is a very important part of the models describing the scattered intensities. If only vertical roughness features are considered only one single roughness parameter is required for each surface/interface. Normally the rms-roughness σ is used as a roughness parameter and in this case the X-ray reflectivity has been formulated a long time ago by extending the Fresnel theory [5–7]. But the application of the Fresnel theory is restricted to calculations of specular reflectivities and cannot explain off-specular reflectivities. This can be overcome by a complete description of the roughness and therefore lateral roughness features have to be taken into account as well. Thus two more parameters, namely the lateral correlation length ξ and the Hurst parameter h, are needed to characterize a surface/interface. To take this into account, the distorted-wave Born approximation (DWBA) [5, 8] provides an extremely useful basis for calculating the X-ray scattering of surfaces and layered systems.

For grazing incidence scattering experiments at a fixed photon energy the influence of these roughness-parameters on the scattered intensities are widely known and differences between the two mentioned cases have been discussed [9]. Nevertheless such a discussion for reflection mode EXAFS and the consequences on the extracted fine structure are still missing. Therefore it is of fundamental interest to see in which way rough surfaces influence the fine structure extracted from reflection mode EXAFS measurements.

2. Data preparation and simulation

We have chosen a gold sample as model system. The real part of the refraction index δ was calculated from an absorption measurement of a gold reference sample by means of a Kramers-Kronig transform. Thereafter the reflected intensities are calculated for different sets of roughness parameters and grazing angles θ according to the Fresnel theory for smooth surfaces, the Névot-Croce model [7] and the DWBA [5, 8]. For these calculations, a 50 mm long, semi-infinite, homogeneous and isotropic gold sample was assumed. The incident X-ray beam is collimated vertically by a 120 μm slit and the acceptance angle of the detector is equal to 0.03°.

3. Reflectivity simulation results

Reflection mode spectra calculated using the DWBA are presented in Fig. 1 for glancing angles θ below, in the vicinity and above the critical angle of reflection ($\theta_c = 0.32°$ at 11919 eV) and different values of σ. These spectra are compared to those determined by the Fresnel theory. The chosen lateral correlation length $\xi = 50$ nm and Hurst parameter $h = 0.7$ are typical values reported for sputtered gold films on glass substrates [see e.g. 10, 11]. In comparison to the spectra calculated with the Fresnel-formula, one can see a reduced absolute reflectivity for larger values of σ, as expected. In order to extract the fine structure data we use the method presented by Borthen *et al.* in [4]. In this case the X-ray reflectivity R above the absorption edge can be split into a smooth part R_0 and an oscillatory part ΔR with $R = R_0 + \Delta R$. The reflectivity fine structure χ_R is given by: $\chi_R = \Delta R(E)/R_0(E)$.

In Fig. 2 the magnitude of the Fourier-transform of the k^3-weighted fine structure data extracted from the spectra presented in Fig. 1 are compared to each other. In comparison to the spectra calculated with the Fresnel-formula, one can see significant changes in the magnitudes of the peaks in the Fourier-transformed data, especially for larger values of σ.

The lateral correlation length ξ and the Hurst parameter h have only a minor influence on specularly reflected intensities. As already discussed for grazing incidence scattering experiments at fixed photon energies, the influence of these parameters is less than two orders of magnitude on the intensity of the specularly reflected intensities (see e.g. [9]). Therefore their influence on the extracted fine structure can be neglected. Thus it is interesting to see if a simple roughness model using only one roughness parameter can describe the roughness effects. A comparison between the magnitude of the Fourier-transforms of the k^3-weighted fine

*e-mail: dirklh@uni-wuppertal.de

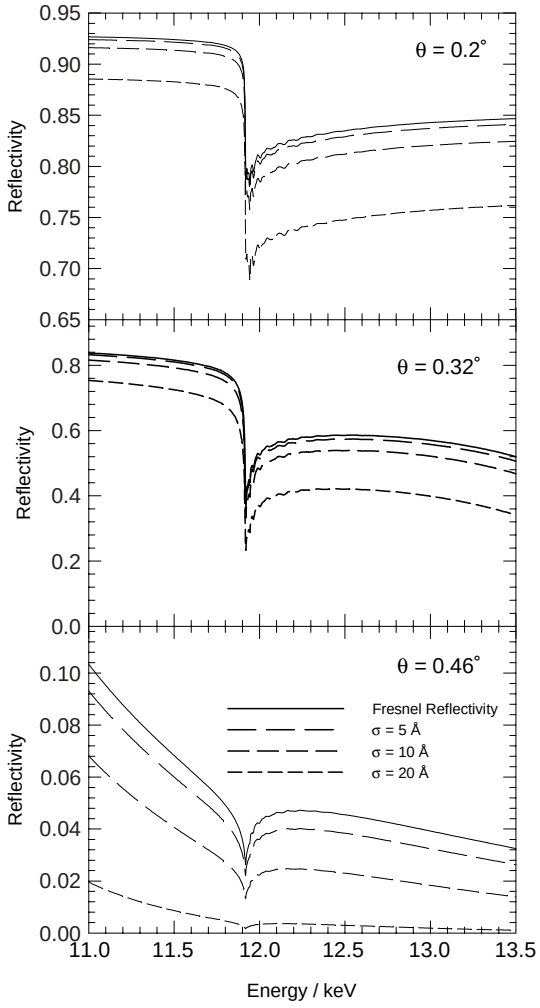

Fig. 1. DWBA and Fresnel reflectivity simulated reflection mode spectra for different grazing angles θ (as indicated) and in the case of the DWBA different values of σ (as indicated). For the simulation $\xi = 50\,\text{nm}$ and $h = 0.7$ was chosen.

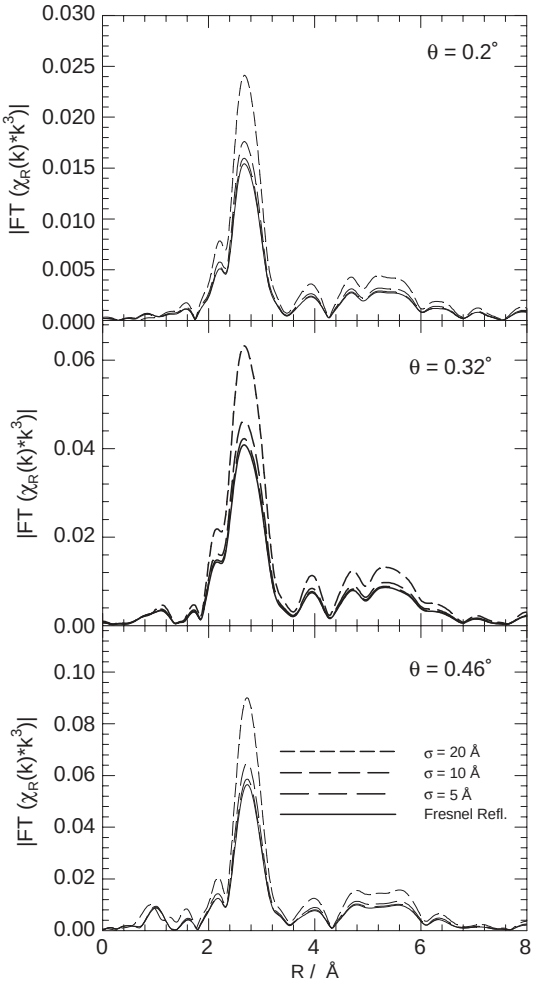

Fig. 2. Magnitudes of the Fourier-transforms of the k^3-weighted reflectivity fine structure data shown in Fig. 1 (grazing angle θ and rms-roughness σ as indicated).

structure data extracted form spectra calculated via DWBA and the Névot-Croce roughness model are presented in Fig. 3. As one can see, almost no difference between the two models can be detected in the Fourier-transforms of the k^3-weighted fine structure data.

4. Reflection mode XAFS under non-specular conditions

As mentioned above scattered intensities can also be investigated under non-specular conditions. Therefore it is of fundamental interest to see if the diffuse scattered intensities recorded in the vincinity of an absorption edge exhibit fine structure features similar to EXAFS or reflection mode EXAFS.

As an example we investigated the structure of a thin Cu-film on a float glass substrate which was prepared by magnetron sputtering. The experiments were performed at the X-ray undulator beamline BW1 [12] using a Si(111) double crystal monochromator and N_2- and Ar-filled ionization chambers as detectors for incoming and scattered intensities. The incident X-ray beam was collimated vertically by a 120 µm slit. For the in-plane non-specular X-ray reflectivity measurements a slit in front of the second ionization chamber limited the acceptance angle of this detector to approximately 0.01°. The region of interest was the so called Yoneda wing [13] which has its maximum at the position of the critical angle of total reflection. In Fig. 4 the reflection mode spectra under non-specular conditions are presented. Obviously,

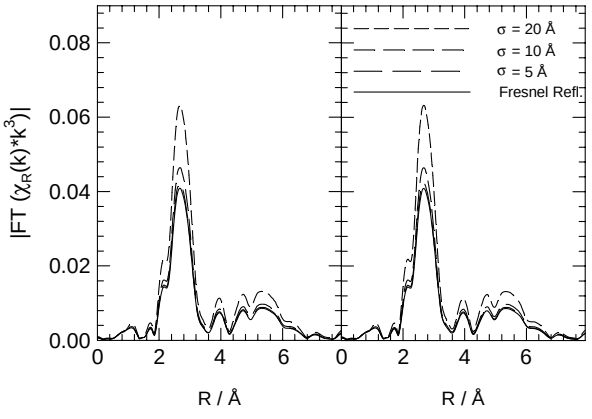

Fig. 3. A comparison between the magnitude of the Fourier-transforms from the structure data extracted form spectra calculated via DWBA (left side) and the Névot-Croce roughness model (right side). The grazing angle of the X-rays is $\theta = 0.32°$. For the DWBA calculation $\xi = 50\,\text{nm}$ and $h = 0.7$ are used.

one can see EXAFS oscillations in the spectra of the diffusely scattered X-rays.

For the further data processing we used the same method to extract the fine structure out of the non-specular spectra as described in section 3 above. In Fig. 5 the normalized magnitudes of the Fourier-transforms of the non-specular reflectivity XAFS mode as well as specular reflection mode XAFS spectra are compared to those of reference spectra obtained from a Cu metal

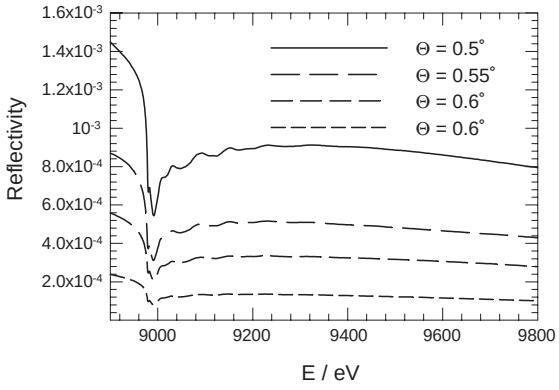

Fig. 4. Reflection mode XAFS under non-specular conditions of a sputtered Cu-film at the K-edge for several grazing angles θ as indicated. The detection angle is $\theta_d = 0.29^\circ$, which is the position of the Yoneda-wing.

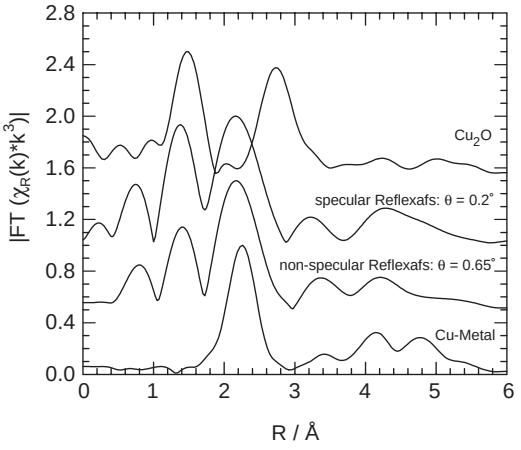

Fig. 5. Normalized magnitudes of the Fourier-transforms of the k^3-weighted fine structure function of the spectra presented in Fig. 4 and of reference compounds (Cu and Cu_2O). All curves are vertically displaced by 0.5.

foil and polycrystalline Cu_2O. Comparison shows that the Fourier-transforms derived from both types of reflection mode XAFS of the sputtered Cu-film contains characteristics of bulk Cu as well as of Cu_2O. It is well known that a thin oxide film of about 10 nm thickness is formed under ambient conditions. Thus, the peak at about 1.5 Å radial distance in the Fourier-transform of the specular reflection mode EXAFS (total information depth is about 10 nm for $\theta < \theta_c$) corresponds to the first Cu-O neighbour interaction. In the non-specular case, however the penetration depth of the X-rays amounts to about 100 nm. Therefore it is rather surprising that this Cu-O coordination is visible in the Fourier-transform of the non-specular spectra with a similar magnitude. This could be an indication that this type of EXAFS mode is still extremely sensitive to the surface structure of the sample.

5. Conclusions

Our calculations have shown that the lateral correlation length and the Hurst parameter only have an minor influence on the X-ray absorption fine structure extracted from reflection mode EXAFS spectra. Thus, it seems to be acceptable to use the Névot-Croce theory for the reflection mode EXAFS data simulation, because this approach is easier to compute. Both theoretical approaches clearly show that the surface roughness has a dramatic influence on the reflectivity fine structure, thus extreme care has to be applied when analyzing reflection mode EXAFS data in terms of coordination numbers and Debye-Waller factors.

Furthermore the existence of fine structure oscillations in the region of diffusely scattered X-rays has been successfully demonstrated. The structure of these oscillations are comparable to those known in reflection mode XAFS. We found strong evidence that this new type of reflection mode XAFS is still surface sensitive even for glancing angles much larger than the critical angle of total reflection, for which the X-ray penetration depth is in the order of about 100 nm.

Abstract

Multiple-scattering extended X-ray absorption fine structure (MS-EXAFS) was used to investigate the local structures around Ga atoms from the first to third coordination shells for GaAs crystals. The results revealed that among all the 7 multiple scattering paths in the first three coordination shells of Ga atoms, the dominant one is the scattering pathway of $Ga_0 \rightarrow As_1 \rightarrow Ga_2 \rightarrow Ga_0$ (DS2). The DS2 path is almost out of phase with the single scattering path (SS2) of the second shell, and destructively interferes with the SS2 path. The amplitude ratio of DS2 to SS2 is about 25%. We provide a simple and feasible MS-EXAFS analysis method for investigating the local structure of the first three shells of III-V semiconductors with the zinc-blende structure.

1. Introduction

In the last five years, the nano-structures such as quantum dots, wires and wells composed of IV-IV and III-V semiconductors, *i.e.*, GeSi and Ge quantum dots and wells [1, 2], Ga(In)As quantum dots [3, 4] and wires [5] have attracted much research interest. This is attributed to their tunable optical and optoelectronic performances that make them promising candidates for fabricating laser and light-emitting diode devices [6]. Since the electronic and optical properties of these nano-structures are determined by their atomic structures, it is essential to understand the atomic structure parameters of these III-V semiconductor quantum systems [7]. In fact, it is easy to obtain structural information of the first shell of the nano-structure semiconductors by extended X-ray absorption fine structure (EXAFS). For example, we have studied the local structure of $(Ge_4Si_4)_5$ quantum wells [2] and Ge quantum dots [8] using grazing-fluorescence XAFS. In order to completely determine the tetragonal distortions of these semiconductors, it is necessary to obtain the structural information of the second and third coordination shells. However, it is complicated to analyze the XAFS signals in the higher shells owing to the overlap of the second and third single scattering (SS) paths, as well as the multiple-scattering (MS) paths [9].

The FEFFIT code [10] that considers the multiple-scattering contributions, allows accurate analysis of EXAFS data for structural information beyond the first coordination shells. In this work, a simple MS-EXAFS data analysis method is proposed to study the local structure of III-V GaAs semiconductor in the higher shells. We aim to find the key-factor in analyzing the XAFS data of zinc-blende structure in high shells. In our subsequent work, we will use the proposed structural analysis method to study the high shell local structures of III-V quantum dots.

2. Experiment

Crystalline GaAs sample for XAFS measurement was prepared as follows. Fine powder with sizes of about 20 μm prepared from single crystal, was homogenously mixed with BN powder. Then, the mixed powder was pressed into tablets with diameter of 10 mm and thickness of 0.5 mm. The ratio of GaAs to BN powder was optimized by making the absorption jump $\Delta\mu x \approx 1$ at the GaK-edge.

XAFS measurements of crystalline GaAs powder were performed at the beamline U7C of the National Synchrotron Radiation Laboratory (NSRL, Hefei). The storage ring of NSRL was operated at 0.8 GeV with a maximum current of 160 mA. Fixed-exit Si(111) flat double crystals were used as monochromators. The X-ray harmonics were minimized by detuning the two flat Si(111) crystal monochromators to about 70% of the maximum incident light intensity. Ionization chambers filled with Ar/N_2 mixed gases were used to collect the XAFS spectra. The XAFS spectra were recorded in transmission mode at room temperature. XAFS data were analyzed by USTC-XAFS2.0 software package compiled by Zhong and Wei [11] according to the standard procedures.

3. Results and Discussion

The XAFS spectra were fitted in R space by the FEFFIT code [10]. The theoretical magnitudes and phase-shifts of all the single-scattering (SS) and MS paths in the first three shells were calculated by FEFF7 [12]. By selecting those paths whose amplitude have weights greater than 3% of the largest one, we obtained 10 pronounced scattering paths for GaAs, including 3 SS paths, 5 double-scattering (DS) paths and 2 triple-scattering (TS) paths. For fitting the structural parameters, the coordination numbers were fixed to the nominal composition of crystalline GaAs. In order to decrease the number of independent parameters, the parameter R was assumed to relate to changes in the lattice constant due to thermal expansion. Moreover, as a reasonable approximation, the Debye-Waller factors were set as equal for the corresponding DS and TS paths with the same half path lengths. The third cumulant $\sigma^{(3)}$ was also included in the fits for taking into account the possible asymmetry of distance distributions.

Figure 1 shows the radial structural function (RSF) of GaAs obtained from Fourier transform of the $k^2\chi(k)$ as open circles. The peaks related to the first three shells are well separated. The intensities of the second peak ($R = 3.58$ Å) and the third peak ($R = 4.38$ Å) drop to about 25% and 15% of that of the first peak ($R = 2.15$ Å). The dark solid line shown in Fig. 1 is the curve-fitting result in the R-range [1.5, 5.0] Å by using all the 10

TS1	4.916 ± 0.020	9.0 ± 0.2	0.6 ± 4.0	7.7 ± 2.4

scattering paths. One can see that the quality of the fits is pretty good. The uncertainties of these fitting parameters are the square root of the diagonal elements of the correlation matrix. The path parameters of all the SS and MS paths are presented in Table I, from which we can see that the radial distances are accurately determined. The typical uncertainty is within 0.01 Å for the first shell, and within 0.03 Å for higher shells.

In general, the RSF peaks in higher shells may originate from two types of scattering paths. One is SS path from higher shell, and the other is MS path. In order to clearly show their contributions to the EXAFS signal of GaAs, the oscillation curves of various scattering paths are shown in Fig. 2, which shows two remarkable features. The first one is that the stronger XAFS signals are the three SS paths (SS1, SS2 and SS3) and one MS path (the triangular double-scattering path DS2, $Ga_0 \rightarrow As_1 \rightarrow Ga_2 \rightarrow Ga_0$). DS2 contributes with a peak at the location of the second shell peak of SS2 and has an oscillation magnitude as high as 25% of that of SS2. The second and most noteworthy feature is the opposition

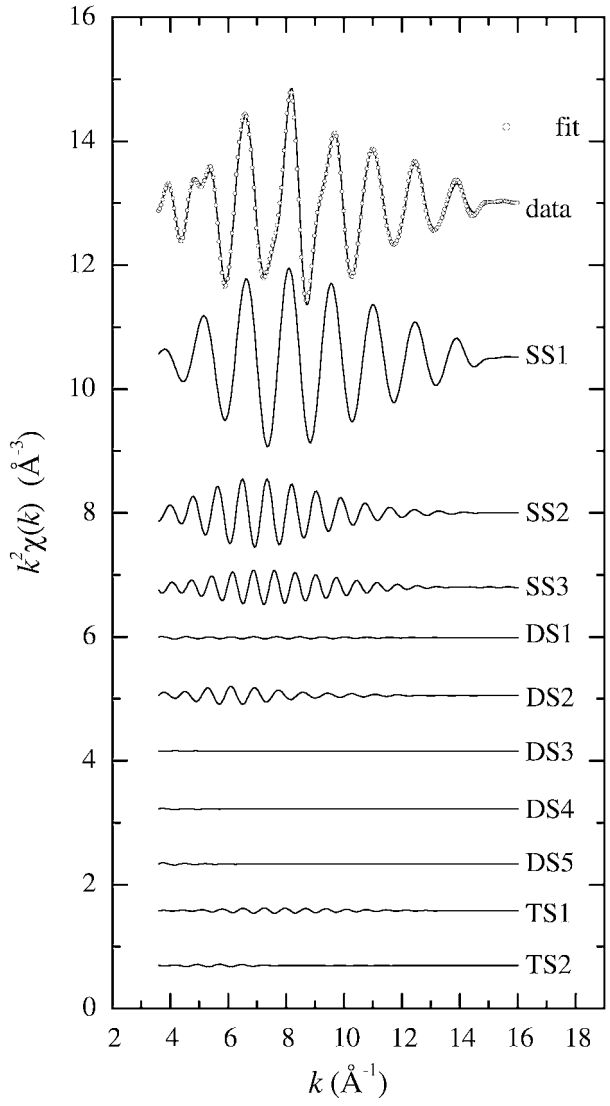

Fig. 2. Contributions of the scattering paths to the total EXAFS oscillation function $k^2\chi(k)$ for GaAs.

of phase between the oscillations of DS2 and SS2, as clearly shown in Fig. 2. Hence, the destructive interference between DS2 and SS2 paths strongly damps the intensity of the second peak, indicating that DS2 plays an important role in accurately determining the structural parameters of the second shell. If the contribution of DS2 is ignored, it would result in a larger Debye-waller factor ${\sigma_2}^2$ of the second coordination shell fitted by SS approximation than the real value. The importance of nonlinear MS process and its interference with higher shell EXAFS signals were also observed for other systems, such as metal Cu [12], and CrO_4 tetrahedron [13].

Since the other MS paths except DS2 contribute very weak signals to the EXAFS spectrum, one can expect that the features of experimental data can be well reproduced by considering only the SS paths and DS2. This result is demonstrated in Fig. 1, where the dark dash line shows the fitting result by using only these 4 paths. Furthermore, in Table I it is obvious that the structural parameters from 4 paths presented in Table I in parenthesis are almost the same as those from considering all the 10 scattering paths.

Previously Dalba *et al.* [14] investigated the MS effects of GaAs using the fast spherical approximation [15]. They calculated the dependence of the MS contribution on the bonding angle

of Ga_0-As_1-Ga_2, which corresponds to the DS2 path in this work. By comparing the amplitude of the DS2 path with that of the SS2 path, they claimed that MS effects of the second and third shells could be neglected for crystalline compounds with open structures of diamond and zinc-blende structures [14]. However, it can be easily found that Dalba *et al.*'s SS results for higher shells of GaAs ($\sigma_2{}^2 = 0.015\,\text{Å}^2$, $\sigma_3{}^2 = 0.019\,\text{Å}^2$) [14] are much larger than ours ($\sigma_2{}^2 = 0.0118\,\text{Å}^2$, $\sigma_3{}^2 = 0.0132\,\text{Å}^2$) by MS analysis.

It is interesting to note that DS1 and DS2 have the same path length, scattering atom types and Debye-Waller factors, but the amplitude peak of DS2 is significantly larger than that of DS1. The reason can be explained by Rehr's theory [12]. For a scattering path Γ, the XAFS amplitude χ_Γ can be recast in terms of the standard formula, but with an effective scattering amplitude f_{eff}:

$$\chi_\Gamma = NS_0^2 \text{Im}\left(\frac{f_{\text{eff}}}{kR^2} e^{2ikR+2i\delta_l} e^{-2k^2\sigma^2}\right), \quad (1)$$

where N is the path degeneracy, R is half the total path length, and the other parameters have their corresponding meaning as in the standard formula [7]. From Eq. (1), the intensity difference between DS1 and DS2 can be attributed to two reasons. One is that the degeneracy of DS2 is twice that of DS1. The other stems from the greatly larger effective scattering amplitude of DS2 than that of DS1, which is caused by the difference in the angle θ between the outgoing and incoming paths.

Abstract

In the Ge-structure, the forbidden Bragg reflections $hk0$ ($h + k = 4n + 2$) can be excited at the Ge K-edge due to both dipole-quadrupole scattering and dipole-dipole scattering of thermally vibrating atoms. The dipole-dipole contribution is referred to as TMI (Thermal Motion Induced) and is caused by the dependence of the atomic tensor form factors on the relative atomic displacements. This effect explains the strong increase of the 600 forbidden reflection intensity with temperature observed in experiments. In the present paper, both the dipole-quadrupole and the TMI contributions to the structure factor of the 600 reflection are calculated using the FDMNES code. Two models are considered, one assuming only displacements of the scattering atom, the other assuming all atoms in a supercell randomly displaced. Both approaches reveal a strong dependence of the dipole-dipole contribution to the tensor atomic factor on the atomic displacements and thus give a qualitative explanation of the temperature behavior of the forbidden reflection 600 observed in Ge.

1. Introduction

In the last years, resonant X-ray diffraction has become a method to study details of structural, magnetic and electronic properties of solids [1]. The "forbidden" Bragg reflections, which occur due to the polarization properties of resonant scattering, are of special interest because for these reflections, the non-resonant contributions vanish. Reflections of this type were first theoretically predicted for dipole-dipole resonant scattering in non-magnetic crystals [2, 3, 4] and later experimentally confirmed [5]. Up to now, the "forbidden" reflections have been observed in many single crystals, e.g. in $NaBrO_3$ [5], Cu_2O [6], TiO_2, MnF_2 [7], $LiHSeO_3$ [8], $Ba(BrO_3)_2.H_2O$ [9], $(Ba_{1-x}Sr_x)_2Zn_2Fe_{12}O_{22}$ [10], Fe_3O_4 [11, 12, 13], FeS_2 [14, 15], $HoFe_2$ [16] and $La_{0.5}Sr_{1.5}MnO_4$ [17].

When the dipole approximation fails to account for forbidden reflection intensities, higher order terms can be responsible for their appearance. For example, the quadrupole-quadrupole contribution causes forbidden reflections in Fe_2O_3 [18] and a mixed dipole-quadrupole contribution might be partly responsible for the forbidden reflections in Ge [19, 20]. The latter also contributes to the gyrotropic properties of crystals, for example, to optical activity and natural circular dichroism [21, 22, 23, 24].

Phenomenological considerations allow for finding sets of forbidden reflections as well as describing the polarization properties of resonant scattering. However, numerical calculations are needed for quantitative comparison between theory and experiment. The calculation of resonant X-ray scattering spectra is similar to XANES calculations for which different approaches have been developed [25, 26, 27, 28]. In the present paper, we use the FDMNES code [27] to calculate the energy dependent intensities of the forbidden reflections in Ge, which have already been theoretically studied and measured with respect to their energy spectra and azimuthal, thermal and polarization dependencies [20, 29, 30, 31, 32]. There are two main mechanisms, which can explain their existence: dipole-quadrupole resonant scattering [20] and a dipole-dipole contribution when the atomic displacements owing to thermal vibrations (TMI-contribution) are taken into account [33, 34]. Only the second contribution can explain the intensity growth with temperature. Recently, similar forbidden reflections have also been observed in ZnO [35]. In the present paper, the FDMNES program is used for studying the dipole-quadrupole and TMI contributions as well as the thermal dependence of the forbidden reflections in Ge.

2. The atomic resonant scattering factor and forbidden reflections in Ge

The tensor atomic form factor, which describes resonant scattering near an absorption edge can be represented as:

$$f_{ij}(E) = f_{ij}^{dd} + \mathrm{i} f_{ijk}^{dq} k_k + \mathrm{i} f_{jik}^{dq*} k'_k + f_{ijkl}^{qq} k_k k'_l, \tag{1}$$

where dd, dq, qq denote the dipole-dipole, dipole-quadrupole and quadrupole-quadrupole contributions, respectively, and k and k' are the incident and scattered wave vectors [36].

In a single-electron approach, the X-ray atomic form factor near the absorption edge takes the form [36]:

$$f_{ij} = -m_e\omega^2 \sum_f \frac{\langle g|O|f\rangle\langle f|O|g\rangle}{E_f - E_g - \hbar\omega + \mathrm{i}\Gamma/2}, \tag{2}$$

where $\hbar\omega$ is the photon energy, O is a transition operator coupling the initial state $|g\rangle$ of energy E_g with an intermediate state $|f\rangle$ of energy E_f.

For $00l$ ($l = 4n + 2$) reflections in Ge, the structure factor equals:

$$F(00l, l = 4n + 2) = 4(f_1 - f_2), \tag{3}$$

where f_1 and f_2 are the tensor form factors associated with the Ge atoms in the sites 000 and $\frac{1}{4}\frac{1}{4}\frac{1}{4}$. These atoms (1) and (2) are connected by inversion. Since both site symmetries are $\bar{4}3m$, the tensor $f_{ij}^{dd} \sim \delta_{ij}$, $f_1^{dd} = f_2^{dd}$ and hence, these terms are not giving rise to forbidden reflections near absorption edges. The dq term, however, yields $F_{ij}(\boldsymbol{H}) = 8\mathrm{i} f_{ijk} H_k$, where f_{ijk} is the symmetric

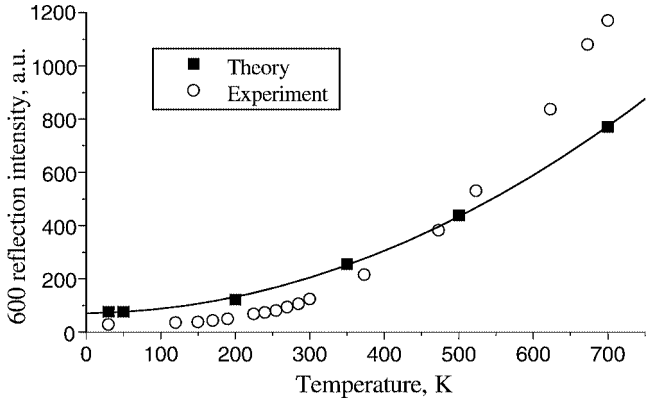

Fig. 2. Temperature dependence of the 600 integral intensity; theoretical points are fitted by a quadratic parabola.

part of a third rank tensor, which contains only one independent component $f_{xyz} = f_{yzx} = f_{zxy}$, $\boldsymbol{H} = k' - k$.

Owing to thermal motions the Ge atoms are displaced from their equilibrium sites with cubic symmetry into sites with non-cubic symmetry. Then, in accordance with the adiabatic approximation, the electrons follow the atomic displacements and since the typical time of the scattering process ($\sim 10^{-17}$ s) is much less than that of an atomic thermal vibration ($\sim 10^{-13}$ s), the scattering reflects the actual atomic configuration at the time it takes place. Generally, this configuration is characterized by atoms in sites with non-cubic symmetry and therefore, the scattering by each atom is described by an anisotropic tensor factor. It was shown in [33] that this anisotropy causes the appearance of "forbidden" $0kl$ reflections with $k + l = 4n + 2$, even in the *dd* approximation.

3. Calculation of the TMI contribution to the forbidden Bragg reflection 600 in Ge

In order to obtain the intensity of a forbidden Bragg reflection in Ge, one has to consider both the dipole-dipole TMI and the dipole-quadrupole contribution. The FDMNES program allows for calculating the tensors f_{ij}^{dd} and f_{ijk}^{dq} for any energy value within the XANES region. For optimizing the calculation time, the symmetry relations were included into the initial version of the program. But since these symmetry relations are violated by the thermal vibrations, all the Ge atoms in the unit cell become independent scatterers. This prevents performing DAFS calculations, which involve crystallographically equivalent scatterers. Hence, we have mixed analytical and numerical calculations, which means that for the scattering, the explicit theoretical expression for the scattering factor F($\boldsymbol{H}$) was applied, while the tensor atomic form factors were numerically calculated with the FDMNES program.

The first theoretical prediction of the TMI contribution [33] has used the following approximation: the tensor atomic form factor depends only on the thermal displacement $\boldsymbol{u}$ of the scattering atom. Then, for small $\boldsymbol{u}$, the *dd* term is a linear function of $\boldsymbol{u}$ resulting in a structure factor:

$$F(\boldsymbol{H})_{ij}^{dd,TMI} = 8\pi \mathrm{i} \Delta f_{ij}^{dd} H_k u_k, \tag{4}$$

where Δf_{ij}^{dd} is the correction of f_{ij}^{dd} owing to the resonant scattering atom's displacement from its equilibrium site. The product $\Delta f_{ij}^{dd} u_k$ transforms as a symmetric third-rank tensor, which possesses only one independent parameter in the cubic $\bar{4}3m$ group.

With that approximation we have calculated the TMI dipole-dipole contribution as:

$$f^{dd} = f_{ijk} T_{ijk} = \tfrac{1}{3}(f_{xy}^{dd} u_z + f_{zx}^{dd} u_y + f_{yz}^{dd} u_x), \tag{5}$$

where the different tensor components f_{ij}^{dd} were calculated using the FDMNES code. The dipole-quadrupole contribution was simulated by the invariant:

$$f^{dq} = \tfrac{1}{6}(f_{xyz}^{dq} + f_{yzx}^{dq} + f_{xzy}^{dq} + f_{zxy}^{dq} + f_{yxz}^{dq} + f_{zyx}^{dq}). \tag{6}$$

For these calculations, the random displacements of the atom in the (000) site were simulated by confining the vectors of the atomic displacements to the surface of the sphere, whose radius is defined by the mean square displacement $\sqrt{\langle u^2 \rangle}$ at a given temperature. According to the Einstein model, which is a sufficiently good approximation in the case of Ge, the mean square amplitude of vibrations was calculated using:

$$\langle u^2 \rangle = u_0^2 \coth \frac{\hbar \Omega}{2 k_B T}. \tag{7}$$

Here, $u_0 = 0.071$ Å is the zero temperature vibration amplitude, and $\Omega = 5.5 \times 10^{13}\,\mathrm{s}^{-1}$ [37].

Assuming the sphere radius to be $\sqrt{\langle u^2 \rangle}$, randomly selected spherical angles θ and ϕ were used to calculate the energy spectra associated with both invariants. Then, for each mean square displacement, the invariants were averaged over 10 random sets of angles, and finally, using the FDMPOST program, the resulting curves were convoluted with the line shape as defined by the line width Γ (Γ was varied from 1.4 eV at Fermi level to 5.7 eV at 50 eV). The obtained dependence of the forbidden reflection 600 intensity on the temperature, i.e. the atomic displacement, gives a satisfactory description of the 600 behavior. The dipole-dipole contribution rapidly increases with temperature, whereas changes of the dipole-quadrupole term are negligible.

However, these first calculations were made assuming only one atom displaced. As a consequence, the atomic potentials are more symmetric than in reality, when all atoms are displaced. Considering [30], wherein it was shown that the relative displacements of the atoms are crucial for the description of the discussed effect, the next step of our calculations took into account displacements of all atoms in the crystal.

To this purpose we used a $2 \times 2 \times 2$ Ge supercell and every atom in this supercell was displaced in such a way, that its

randomly oriented displacement-vector ended on a sphere with radius $\sqrt{\langle u^2 \rangle}$. When all supercell atoms are simultaneously displaced, the environment of a "resonant" atom is not cubic at all, hence a calculation of an invariant as in (5) does not give a good result. "DAFS" calculations are also not feasible, because all the scatterers in the cell are inequivalent. Thus, we have again used the semi-analytical approach supposing that

$$F(600)^{dd,TMI} = 8\mathrm{i} f_{ij}^{dd} \sin(\boldsymbol{Hu}), \tag{8}$$

At the azimuthal angle $\phi = 0$, only the non-diagonal terms of the second rank tensor provide a contribution to the scattering amplitude. Here, $f_{\pi\sigma}$ reaches a maximum equal to:

$$f_{\pi\sigma} = f_{xy} \cos\theta_B - f_{yz} \sin\theta_B, \tag{9}$$

where θ_B is the Bragg angle. $f_{\sigma\sigma}(\phi = 0) = f_{yy}$ vanishes for the dipole-quadrupole scattering, but not so for the TMI mechanism. However, since it is less than $f_{\pi\sigma}$, we neglect it. Hence for $\phi = 0$, one obtains: $f_{ij}^{dd} \sin(\boldsymbol{Hu})$, which coincides with the imaginary part of the "signal total" for a single atom, as given by the program FDMNES. Inserting this term into (8) allowed for calculating the scattering factor of the 600 reflection. This procedure was carried out for 3 different sets of randomly displaced supercell atoms, followed by averaging and convoluting, again taking into account $\Gamma(E)$. The results are depicted in Fig. 1. They clearly show that the dipole-dipole TMI contribution to the forbidden 600 reflection significantly grows with temperature. Similar calculations carried out for the dipole-quadrupole term revealed that in contrast to the TMI-effect the dipole-quadrupole contribution slightly decreases as the temperature is raised. The temperature dependence of the integrated 600 intensity is shown in Fig. 2. The curve is a qualitatively satisfactory description of the experimentally observed thermal dependence of the 600 reflection intensity reported in [29, 30].

Thus, the calculations of the 600 forbidden reflection intensity with the help of the FDMNES program have shown a strong dependence of the dipole-dipole atomic form factor on the atomic displacements, which leads to a qualitative description of the phenomenon. For a more quantitative comparison with the experimental data, one should: 1) calculate the scattering factor of every displaced atom in a supercell for improving the statistics; 2) take into account correlations between atomic displacements as well as dispersion of the displacement values; 3) depending on the displacements consider contributions from the diagonal terms. It seems, however, that all these measures will only give corrections to the calculated scattering factors without essentially changing the results.

4. Conclusion

Resonant X-ray diffraction provides a unique method to study the influence of atomic thermal vibrations on the electronic states of a crystal. For the cubic Ge-structure, numerical calculations of the energy spectra of the forbidden 600 reflection have demonstrated the influence of the relative displacements of all atoms on the dipole-dipole resonant tensor atomic form factor. The results derived are in good agreement with the experimental data reported before by different experimental groups. The developed method of calculation can also be applied to other crystals, for which forbidden reflection intensities growing with temperature were observed, e.g. ZnO.

Abstract

Due to the lack of long-range periodic order in quasicrystals there are restrictions concerning a straightforward structure analysis on base of X-ray diffraction data. Computed reflection intensities in X-ray diffraction patterns, which are strongly affected by the shape and occupation of hypothetical atomic surfaces, need to be compared with experimental data. The interatomic short-range correlations as to be determined by means of DAFS and XAFS have to be in agreement with these structural models. The use of linearly polarised X-rays allows for orientation sensitive determination of otherwise averaged short-range order information. Additionally wave vector-selectivity of DAFS can yield short-range order information sensitive to sites occupied by atomic species within the coherently scattering structural units.

Structural models of decagonal Al-Co-Ni were applied to compute theoretical DAFS and XAFS functions. Calculation of both, energy-dependent structure factors and pair distribution functions obtained within a hypothetical cluster of app. 81 000 atoms as the basis of computation of DAFS are outlined.

Co-K and Ni-K DAFS and XAFS measurements at 3 independent reflections of a decagonal $Al_{70}Co_{9.5}Ni_{20.5}$ single crystal were performed and the experimental data were subjected to quantitative evaluation. The reflections used involved wave vectors parallel and perpendicular to the periodic direction and in a third inclined direction. In agreement with our simulations DAFS of individual reflections and thereby corresponding short-range orders exhibited no differences within the error limits. The same was found for the case of polarized Co-K and Ni-K XAFS results.

1. Introduction

To our knowledge up to now there is no DAFS analysis of quasicrystalline phases in the literature. One advantage of DAFS compared to XAFS is its site selectivity. DAFS provides a XAFS-like radial distribution around the absorbing species, which is convoluted by their crystallographic weights. In a pioneer work Sorensen *et al*. [1] stated: "Standard crystallography cannot fully solve the structure of quasicrystals because the necessary diffraction information is distributed throughout reciprocal space in infinitely many weak Bragg peaks. This provides the motivation for pursuing further structural information with DAFS. Will all the DAFS intensities be the same, or will they look different?"

Several XAFS studies of the decagonal Al-Co-Ni phase are known from the literature [2, 3]. Both measured XAFS at the K absorption edges of Co and Ni. Braun *et al*. [2] exploited the Li/Steurer model [4], which was modified by Deus [5]. This model does not differentiate between Co and Ni atoms but unifies them in average as transition metals (TM). Comparable results were obtained from a powdered sample and quasicrystalline thin film layer at both absorption edges. This verified the radial distribution in 3 subshells (2.46 Å, 2.54 Å and 2.88 Å) as derived from the Li/Steurer model for interatomic distances $R < 3$ Å and the random distribution of Co and Ni on TM sites. Zaharko *et al*. [3] performed polarization dependent XAFS at single crystals. Electric field vector $\vec{E}$ was aligned parallel and perpendicular to periodic direction $\vec{c}$. In the Co environment the authors' fit results exhibit 3 shells of Al atoms at well separated distances (2.42 Å, 3.9 Å and 4.8 Å), exclusively. Whereas the distances did not vary depending on polarization, the higher shell's occupancy is found larger for $\vec{E} \perp \vec{c}$. In the neighbourhood of Ni atoms both, Al and TM, are found. For the case $\vec{E} \perp \vec{c}$ two distances $R_{\mathrm{Ni-Al}}$ (2.46 Å and 4.9 Å) were found to match the results in Co environment, whereas additional intermediate shells of TM at 2.65 Å and 3.6 Å were indicated. For the case $\vec{E} || \vec{c}$ the first Al and TM shells with comparable occupancies are observed again, but only one Al site at 4.0 Å is detected in the higher R range.

2. Samples

A specimen of composition $Al_{70}Co_{9.5}Ni_{20.5}$ was studied by means of DAFS and XAFS, simultaneously. This composition is at the Ni-rich edge of the narrow existence region of the decagonal phase and occurs in type I superstructure at temperatures below 620 °C [6].

The initial sample was grown from the melt by the Czochralski method as described in [7] and exhibited a size of a few cm^3, typically. As outlined below both DAFS and fluorescence XAFS analysis require careful correction for absorption and extinction effects. Hence it was convenient to prepare individual samples which were characterized by flat surfaces whose normals point in the direction of scattering vectors of strong reflections in diffraction experiments.

The initial sample was cut by means of a tungsten wire (50 µm in diameter) saw and subdivided into three samples of [00001], [00-1-11] and [10000] orientation.

The composition was confirmed by Electron Probe Micro-analysis (EPMA) within error limits of 1 at %. The mass density, ρ, was checked using a precision device based hydrostatic buoyancy in M-dodecan ($C_{12}H_{26}$) and was determined to be $\rho = 4.16 \pm 0.01$ g/cm^3.

As obtained by Laue diffraction the specimen of the subsets consisted of at least two large individual grains with relative misorientation of app. $\sim 0.3^\circ$ (angles enclosed by the normals of corresponding planes of same indexation).

3. Experimental

DAFS/XAFS experiments were carried out at the bending magnet beamline CEMO at HASYLAB/DESY. A Si(111) double crystal monochromator was used. The incident monochromatic radiation was limited by (0.2×2.62) mm^2 entrance slits and monitored with an ionization chamber.

*e-mail: andreas.kupsch@physik.tu-dresden.de

Samples were mounted to an Eulerian cradle, which allowed to adjust each of the angles (diffraction angle θ, side-ward tilting χ and the detector position 2θ) with an accuracy of 0.001°.

The measurements were carried out in the energy range 7600–9000 eV with a step width of 3 eV and effective measuring time of 15 s per step. Reflection intensities were recorded with a thermoelectrically cooled Si PIN diode. To suppress background radiation and to enhance angular resolution its entrance was narrowed by $(1.0 \times 1.09)\,\mathrm{mm}^2$ slits. Simultaneously we recorded the Co-K and Ni-K fluorescence radiation. We used an energy resolving semiconductor detector (KEVEX), which was fixed on a side-ward position about 40 mm away from the sample (grazing angle of exit). The detector entrance window was narrowed by a lead shield, resulting in an effective angle of exit of app. 7°. The use of an energy-resolving detector proved essential, since for the correct evaluation of XAFS data from the Ni-K edge (8333 eV) the fluorescence Ni-Kα and Ni-Kβ fluorescence lines have to be reliably separated from the according Co lines.

The reflections observed were rather sharp with a full width of half maximum of about 0.001°. By rocking the sample rotation at constant detector position we observed at least 4 individual crystallites, tilted by app. 0.05°.

Preliminary Bragg angle adjustment of the specimens was performed using the sample goniometer (rotation θ, tilting χ). The rough energy dependence of θ was programmed according to a second order polynomial which had been determined beforehand with the aid of a diffraction pre-experiment. Because of the rather sharp single crystal reflection, the accuracy of the θ-setting ($\Delta\theta = 0.001°$) by the sample goniometer proved insufficient for preserving the Bragg angle when changing the energy. For DAFS measurements with high-quality crystals of small mosaic spread an accuracy of θ-setting of about 0.0001° is necessary. We achieved this by adding a tuneable piezoelectric tilting table. This is described in detail by Meyer *et al*. [8].

4. Structural model

Our calculations are based on the structure model of Li *et al*. (Li/Steurer model for short) [4], which had been developed for the atomic structure of decagonal Al-Co-Cu. The refinement of Li/Steurer model by Deus [5], which was applied to the very similar Al-Co-Ni system, avoided too short interatomic distances and improved the *R*-value of structure refinement by changing the shape of the atomic surfaces.

The Deus model contains 4 hyperatoms in the 5-dimensional unit cell. The atomic surfaces are polygonal domains in 2-dimensional perpendicular (or internal) space, whose shape is of five-fold symmetry.

Hyperatoms (HA) 1 and 2 are placed at $z = 1/4$ along the periodic direction and on the body diagonal of the remaining four dimensions. HA 3 and 4, which are copies of HA 1 and 2 rotated by $\pi/5$, are placed at $z = 3/4$ along the periodic direction and on the body diagonal again.

5. EXAFS/Pair distributions

From the structural model we have calculated a 3-dimensional cluster of 140 Å in diameter, which contained app. 81 000 atoms. This huge cluster was used to derive the co-ordination numbers of the transition metals (TM) by evaluating the neighbourhood of each single TM atom. Thus we obtain a discrete spectrum of 3.22 Al at 2.45 Å, 4.88 Al and 1.12 TM at 2.55 Å, 1.41 Al and 0.35 TM at 2.88 Å, where the first and the last distance arise from pair correlations within a quasiperiodic plane, whereas the 2.55 Å distance counts for pairs in adjacent planes. If the sum of the first three distances is considered as the first shell the resulting number of app. 11 atoms is a reasonable value. A second shell is located between 4 and 5.5 Å, a third between 6.2 and 6.7 Å. At higher distances we state a dense distribution, which cannot be subdivided in shells from this simple point of view.

Since our experiment is performed with linear polarized radiation, $\vec{\boldsymbol{p}} = p\vec{\boldsymbol{e}}_p$, and single crystals of well defined orientation we make use of the effective co-ordination number $N^* = 3\sum_j \langle \vec{\boldsymbol{e}}_j, \vec{\boldsymbol{e}}_p \rangle^2$, where $\vec{\boldsymbol{e}}_j$ denotes the unit vectors of atomic sites $\vec{\boldsymbol{r}}_j$.

The reflection positions considered were adjusted by uniaxial rotation around a vector within the quasiperiodic plane parallel to the polarization vector, thus not affecting the effective co-ordination number. Therefore we expect identical XAFS spectra for the reflections selected. Since N^* proves insensitive to rotations around the periodic direction $\vec{\boldsymbol{e}}_p$||[10000] can be taken as the general case. We obtain 4.84 Al at 2.45 Å, 2.59 Al and 0.57 TM at 2.55 Å, 2.08 Al and 0.56 TM at 2.88 Å, i.e. the "in plane" correlations are emphasized.

As an example the measured XAFS, its simulation and the fit parameters recorded simultaneously with the 10000 DAFS are shown in Fig. 1 and Table I.

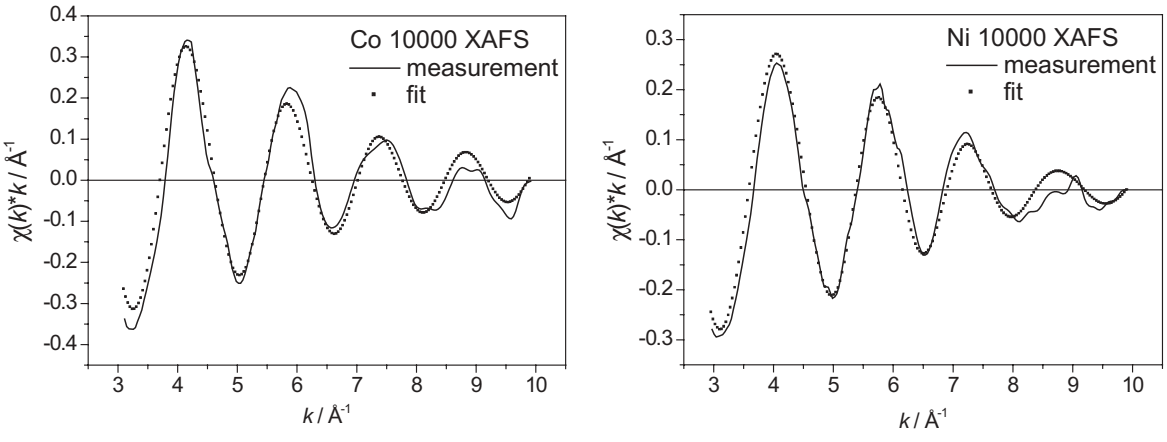

Fig. 1. Measured and fitted XAFS spectra at the Co-K (left) and Ni-K absorption edge (right).

6. Structure factor of decagonal AlCoNi

The structure factor of quasicrystals is given by Yamamoto [9] as

$$F(\vec{\boldsymbol{Q}}) = \sum_j f_j(\vec{\boldsymbol{Q}}_\parallel)\exp[-B(Q_\parallel)^2/4]\exp[2\pi \mathrm{i}\,\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_j]G_j(\vec{\boldsymbol{Q}}_\perp) \quad (1)$$

by summing over all hyperatoms j in the high-dimensional unit cell, where $G_j(\vec{\boldsymbol{Q}}_\perp)$ represents the Fourier transform (FT) of the atomic surface Δ of hyperatom j in perpendicular space:

$$G_j(\vec{\boldsymbol{Q}}_\perp) = \int_\Delta \mathrm{d}V_\perp \exp[2\pi \mathrm{i}\vec{\boldsymbol{r}}_\perp \vec{\boldsymbol{Q}}_\perp]. \quad (2)$$

In case of polygonal shaped atomic surfaces $G_j(\vec{\boldsymbol{Q}}_\perp)$ can be calculated analytically by decomposition in triangles since the Fourier transformation is linear. Following Yamamoto's [9] description its FT then is given by

$$G(\vec{\boldsymbol{Q}}_\perp) = |\vec{\boldsymbol{e}}_1 \times \vec{\boldsymbol{e}}_2| \frac{q_1[\exp(\mathrm{i}q_2) - 1] - q_2[\exp(\mathrm{i}q_1) - 1]}{q_1 q_2 (q_1 - q_2)}, \quad (3)$$

where $\vec{\boldsymbol{e}}_1$ and $\vec{\boldsymbol{e}}_2$ are two edge vectors defining a triangle and $q_i = 2\pi\vec{\boldsymbol{e}}_i\vec{\boldsymbol{Q}}_\perp$.

The FTs prove real valued and radial symmetric, leaving us with the dependence on the magnitude $Q_\perp$, only, and no differences between HA1/HA3 and HA2/HA4, respectively. Fig. 2 depicts the FT's radial dependencies for the three different occupation domains of HA1 and HA2.

Up to this point we have introduced all auxiliary tools to derive the structure factor numerically. To keep the notation short we neglect the Debye-Waller term in equation (2), which is not due to changes within one DAFS scan at constant temperature (here: room temperature), since the Bragg condition keeps the momentum transfer $\vec{\boldsymbol{Q}}_\parallel$ constant.

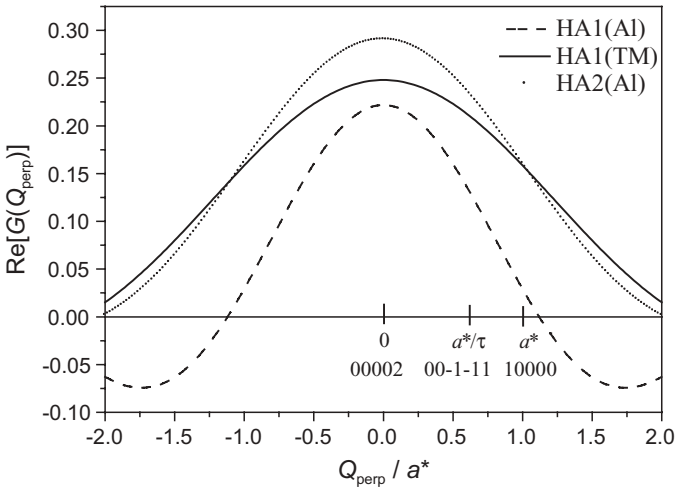

Fig. 2. Radial dependence of the Fourier transforms of the occurring occupation domains on $Q_\perp$.

Introducing the smooth resonant terms of the atomic scattering amplitude we get

$$\begin{aligned} F_s(\vec{\boldsymbol{Q}}, E) &= \sum_j (f_0 + f' + \mathrm{i}f'')_j \exp[2\pi \mathrm{i}\,\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_j]G_j \\ &= \sum_j G_j\{[(f_0 + f')_j \cos(2\pi\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_j) - (f'')_j \sin(2\pi\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_j)] \\ &\quad + \mathrm{i}[(f_0 + f')_j \sin(2\pi\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_j) + (f'')_j \cos(2\pi\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_j)]\} \end{aligned} \quad (4)$$

The term "TM" unifies the Co and Ni atoms contained. However, we have to regard their relative contributions to atomic scattering amplitude, when introducing the oscillatory terms, which can arise from one species, only. We simply weigh f_{TM} with respect to the nominal composition: $f_{\mathrm{TM}} = c_{\mathrm{Co}}/(c_{\mathrm{Co}} + c_{\mathrm{Ni}})f_{\mathrm{Co}} + c_{\mathrm{Ni}}/(c_{\mathrm{Co}} + c_{\mathrm{Ni}})f_{\mathrm{Ni}} = w_{\mathrm{Co}}f_{\mathrm{Co}} + w_{\mathrm{Ni}}f_{\mathrm{Ni}}$, with $w_{\mathrm{Co}} = 0.317$, $w_{\mathrm{Ni}} = 0.683$.

For example $F_s(10000)$ then reads:

$$\begin{aligned} F_s(10000) &= 2(f_0 + f' + \mathrm{i}f'')_{\mathrm{Al}}[-\cos(\pi/5)G_{1\mathrm{Al}} \\ &\quad + \cos(2\pi/5)G_{2\mathrm{Al}}] \\ &\quad -2w_{\mathrm{Co}}(f_0 + f' + \mathrm{i}f'')_{\mathrm{Co}}\cos(\pi/5)G_{1\mathrm{TM}} \\ &\quad -2w_{\mathrm{Ni}}(f_0 + f' + \mathrm{i}f'')_{\mathrm{Ni}}\cos(\pi/5)G_{1\mathrm{TM}} \end{aligned} \quad (5)$$

or in compact style

$$\begin{aligned} F_s &= (f_0 + f' + \mathrm{i}f'')_{\mathrm{Al}}G_{\mathrm{Al}} + (f_0 + f' + \mathrm{i}f'')_{\mathrm{Co}}G_{\mathrm{Co}} \\ &\quad + (f_0 + f' + \mathrm{i}f'')_{\mathrm{Ni}}G_{\mathrm{Ni}}. \end{aligned} \quad (6)$$

Table II summarizes the coefficients G_j for the different reflections considered. As to be shown below, the coefficients of the absorbing species play the role of crystallographic weights.

We now introduce the oscillating contributions of the atomic scattering amplitude to the structure factor. To distinct between smooth and oscillating parts the index s is applied on all smooth terms derived above. We isolate the oscillating contributions f'_{os} and f''_{os} to the atomic scattering amplitude of the resonantly

Table II. *Coefficients G_j of the atomic species at three reflections as introduced in equ. (6).*

	G_{Al}	G_{Co}	G_{Ni}
10000	0.0521574	−0.0812844	−0.1751334

scattering species l:

$$F_{os}(\vec{\boldsymbol{Q}},E) = \sum_j (f_0 + f_s'' + \mathrm{i}f_s'')_j \exp[2\pi\mathrm{i}\,\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_j]G_j + \sum_l (f_{os}' + \mathrm{i}f_{os}'')_l \exp[2\pi\mathrm{i}\,\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_l]G_l = F_s + \sum_l (f_{os}' + \mathrm{i}f_{os}'')_l \exp[2\pi\mathrm{i}\,\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_l]G_l. \quad (7)$$

To be consistent with the DAFS literature (e.g. [1]) we introduce the so-called crystallographic weights $\alpha_m(\vec{\boldsymbol{Q}})$. They are given by the sum over all the occurrences in the unit cell of each equivalent site k, producing one weight for each inequivalent site m. In conventional crystallography the crystallographic weights are defined by

$$\alpha_m(\vec{\boldsymbol{Q}}) = \sum_k \exp(2\pi\mathrm{i}\,\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_k). \quad (8)$$

Regarding the expression obtained in equ. (7) in the case of quasicrystals we insert the Fourier transform of the atomic surface $G_k(\vec{\boldsymbol{Q}}_\perp)$ at sites k into the crystallographic weights:

$$\alpha_m(\vec{\boldsymbol{Q}}) = \sum_k G_k(\vec{\boldsymbol{Q}}) = \sum_k w_k G_k(\vec{\boldsymbol{Q}}_\perp)\exp(2\pi\mathrm{i}\,\vec{\boldsymbol{Q}}\vec{\boldsymbol{r}}_k) \quad (9)$$

as introduced in equ. (6).

This is the crucial difference between DAFS on conventional, 3-dimensional periodic crystals and on quasicrystals: the contribution of the resonantly scattering atomic species is not only defined by their crystallographic sites but is essentially determined by the size and shape of the atomic surfaces.

With that compact notation the scattered intensity reads as in the DAFS theory on conventional crystals:

$$I = |F_s|^2 + 2\mathrm{Re}(F_s)\sum_m [(f_{os}')_m \mathrm{Re}(\alpha_m) - (f_{os}'')_m \mathrm{Im}(\alpha_m)] + 2\mathrm{Im}(F_s)\sum_m [(f_{os}')_m \mathrm{Im}(\alpha_m) + (f_{os}'')_m \mathrm{Re}(\alpha_m)], \quad (10)$$

where, in our case, the terms $\mathrm{Im}(\alpha_m)$ can be neglected, since the sum in equ. (9) results in real values for the selected reflections derived by the given structural model.

Summarising the numerical results in the energy dependent reflection intensities, e.g. in the vicinity of Co-K edge, are of the general form

$$|F_{os}(\vec{\boldsymbol{Q}})|^2 = |F_s|^2 + 2\mathrm{Re}(F_s)(f_{os}')_{Co}G_{Co} + 2\mathrm{Im}(F_s)(f_{os}'')_{Co}G_{Co}. \quad (11)$$

7. DAFS measurements and data evaluation

The as-measured DAFS intensities are depicted in Fig. 3 for the 10000 reflection as an example. They are subject to the well-known corrections which are usually applied to diffraction data.

Careful handling of the absorption correction $A(Q,E)$ is of outstanding importance for evaluation of the oscillating diffracted intensities. The absorption of the radiation on its pathway within the sample produces, analogously to XAFS, an additional fine structure of the intensity detected.

Since the standard absorption as given by Sorensen *et al.* [1] did not work properly, we applied the modified absorption correction developed by Meyer *et al.* [10], which takes into account secondary extinction effects, which come into being in case of extended single crystals of small mosaic spread or highly textured polycrystals. In the limit of an infinitely extended crystal the absorption correction reads as:

$$A(Q,E) = \frac{\sin(\theta)}{2\mu(E)}\left[1 - \frac{m|F(Q,E)|^2\sin(\theta)}{2\mu(E)}\right], \quad (12)$$

where m is a proportionality factor, which is a measure for the impact of the extinction effects.

With that successfully applied absorption correction we finally find the measured DAFS normalised to the square of smooth structure factor F_s, as depicted in Fig. 4 at the example of 10000 reflection at both absorption edges.

The calculation of theoretical DAFS intensities as performed in the following is based on the oscillating fine structure easily obtained by XAFS. This way was chosen since we have stated great influences of absorption correction on further handling of experimental DAFS data. As we will outline below by that strategy a verification of validity of the structure model by DAFS is possible in the present case.

As mentioned above we recorded the fluorescence XAFS signal simultaneously to DAFS intensities. Extracted functions $\chi(E)$ probed to be nearly identical for the different reflections. Having in mind that $\chi(E)$ as obtained from XAFS corresponds to the imaginary part of the complex-valued fine structure function $\tilde{\chi}(E) = \chi'(E) + \mathrm{i}\chi''(E)$ we obtain $f_{os}''(E) = f_s''(E)\chi''(E)$. Since f_{os}'' is connected with f_{os}' by causality we subjected it to Kramers-Kronig transformation to get f_{os}'. Both are shown in Fig. 5. Having derived f_{os}' and f_{os}'' we now take advantage of the structural assumptions and insert them into equ. (11). The resulting contributions to the DAFS intensity are shown in Fig. 6.

Eye inspection of Fig. 7 indicates that there is a good correspondence of calculated and absorption corrected measured

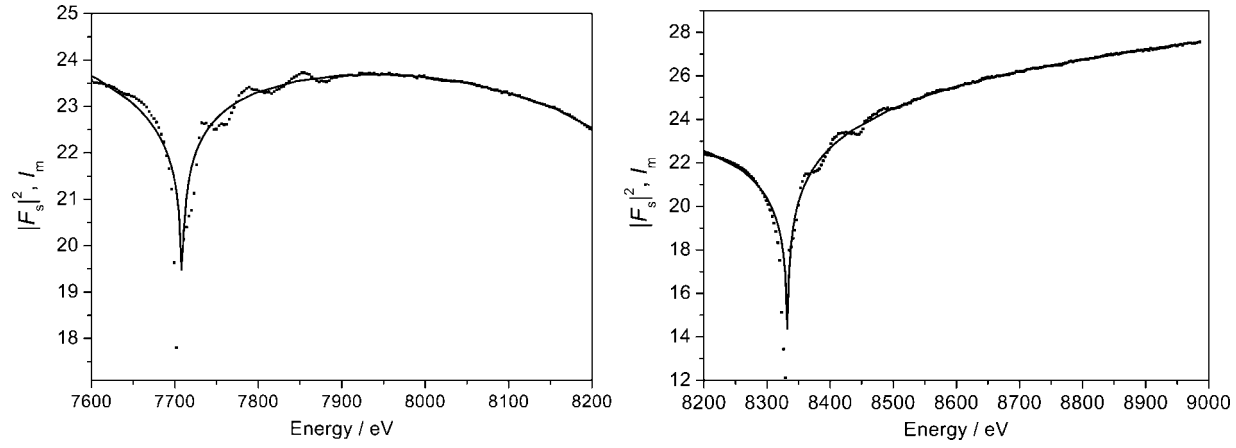

Fig. 4. Measured DAFS 10000 intensities corrected for absorption and normalised to theoretical smooth intensities $I_s(E)$ at the Co-K (left) and the Ni-K (right) absorption edges.

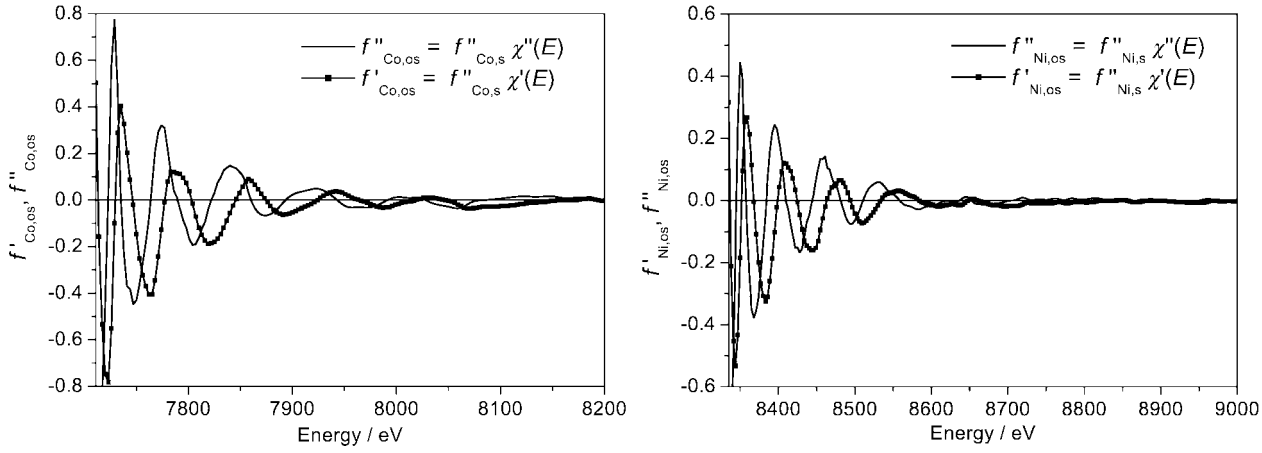

Fig. 5. Comparison of real and imaginary parts, $f'_{os}(E)$ and $f''_{os}(E)$, as obtained from Kramers-Kronig transformation and fluorescence XAFS, respectively. Note the phase difference at both edges.

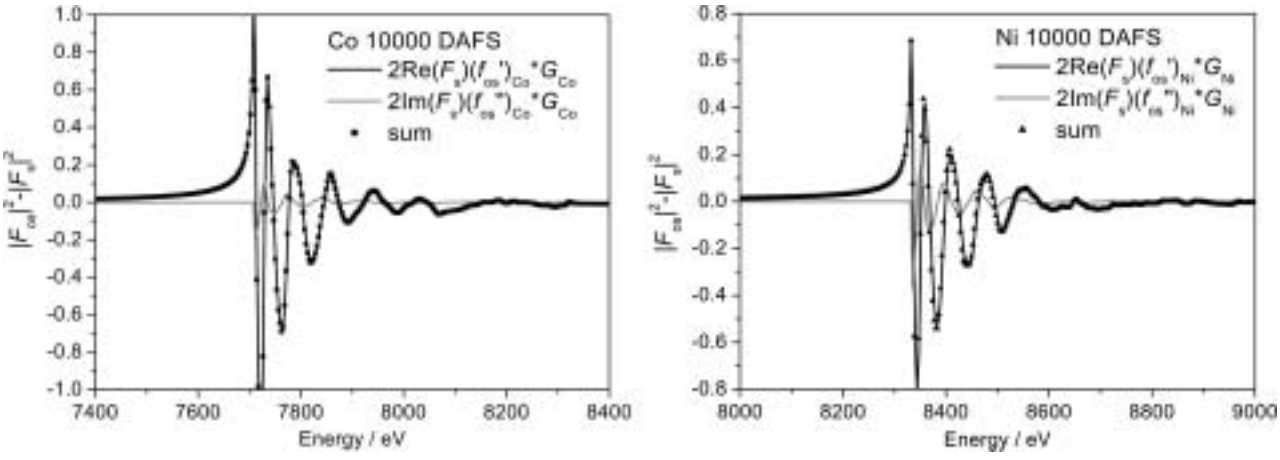

Fig. 6. Oscillating contributions to $|F_{os}(E)|^2$. Since $|\mathrm{Re}(F_s)| \approx A\ |\mathrm{Im}(F_s)|$ ($A \approx 12$ at the Co edge (left), $A \approx 5$ at the Ni edge (right)) the sum is clearly dominated by $f'_{os}(E)$.

10000 DAFS at both the Co and Ni-K absorption edge. Whereas this holds at the Ni edge for all three reflections, the computed and experimental 00-1-11 and 00002 DAFS oscillations at the Co edge differ in phase and amplitude (not shown here). These problems are attributed to the real structure of the specimen to be obtained from experiments providing more information necessary for appropriate absorption correction.

8. Conclusions

For the first time we have extended the standard approach of kinematical quantitative DAFS analysis to quasicrystalline (here: decagonal) structures. The main extension is the additional consideration of FT of the atomic surfaces (perpendicular space) to the DAFS crystallographic weights. The DAFS calculated

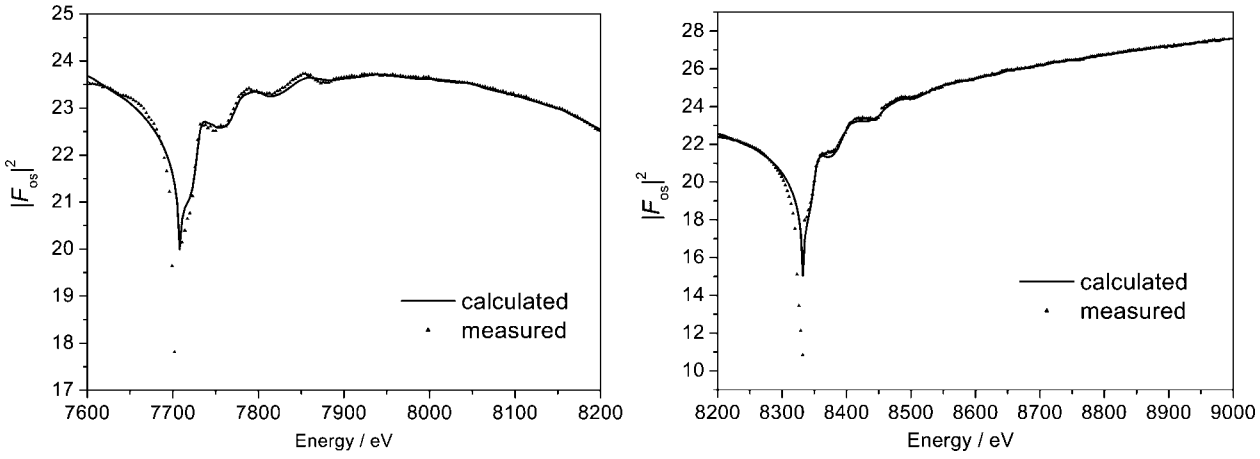

Fig. 7. Comparison of measured 10000 DAFS intensity with calculated intensity at the Co-K (left) and the Ni-K absorption edge (right).

according to the structural assumptions of the model fits the experimental data. The sum of relative deviations in the whole measuring is less than 10%.

The agreement of XAFS results with the modified Li/Steurer model of structure of decagonal Al-Co-Ni and the matching of computed and measured DAFS intensities indicate the validity of both the structural assumptions and the quantitative DAFS approach.

Acknowledgment

The authors like to thank K. Richter for the assistance with the synchrotron measurements, T. Leisegang for the determination of mass density, and T. Stephan (all Tu Dresden) for the EPMA measurements. We are particularly indebted to Prof. R. Frahm (Univ. Wuppertal) for stimulation of starting DAFS activities in our group. Financial support of the Deutsche Forschungsgemeinschaft (DFG) and the Fonds der Chemischen Industrie is gratefully acknowledged.

Abstract

Interplanetary Dust Particles (IDPs) are derived from primitive Solar System bodies like asteroids and comets. Studies of IDPs provide a window onto the origins of the solar system and presolar interstellar environments. We are using Total Reflection X-ray Fluorescence (TXRF) techniques developed for the measurement of the cleanliness of silicon wafer surfaces to analyze these particles with high detection sensitivity. In addition to elemental analysis of the particles, we have collected X-ray Absorption Near-Edge spectra in a grazing incidence geometry at the Fe and Ni absorption edges for particles placed on a silicon wafer substrate. We find that the iron is dominated by Fe_2O_3.

1. Introduction

Small dust grains in the plane of the ecliptic within the inner solar system give rise to the Zodiacal light, first reported by Cassini in 1693. Astronomical observations reveal the presence of similar dust systems around both young and evolved stars. Dust grains in the solar system are referred to as interplanetary dust particles (IDPs) and are described as asteroidal and cometary. Asteroidal IDPs exhibit evidence of compaction and aqueous alteration but cometary IDPs exhibit little if any evidence of parent body processing. They are likely well-preserved remnants of the original interstellar particulate matter from which the solar system formed. Understanding the nature of IDPs not only helps us understand the origins of our solar system but also aids in the understanding of astronomical observations of other solar systems [1, 2].

IDPs are collected in the stratosphere at ∼20 km altitude using NASA ER2 aircraft. Although all IDPs are frictionally pulse heated for ∼1 second as they decelerate from cosmic velocities at ∼90 km altitude, many of them survive with minimal alteration because they are high porosity, low density objects. Recently particles have been collected by hypervelocity capture in aerogel on board the Soviet Mir Space Station. Some of these particles also appear relatively intact and they have not been exposed to the upper atmosphere.

Once collected, the particles can be assayed by a wide variety of techniques, including isotopic abundance, elemental analysis and morphology. The thermal history of an IDP can be assessed by several techniques. Obvious changes in morphology can indicate complete melting of the particle during re-entry. On a more subtle level, the oxidation state of the iron in the IDP can sometimes be an indication of the thermal history of the particle, taken in aggregate with information on the other minerals present in the IDP. From the X-ray Absorption Near-Edge Structure (XANES), information on the unoccupied density of states can be obtained and the oxidation state of the element of interest can be determined [3]. By measuring the XANES in fluorescence yield in a grazing incidence geometry, trace levels of impurities can be analyzed non-destructively. In cases where there are several different oxidation states, a decomposition of the near-edge structure into suitable reference materials can resolve significant components. There are several synchrotron-based groups who are currently working with IDPs or have done so in the past [4, 5]. In a recent experiment using soft X-rays microspectroscopy of IDPs at the carbon edge has been performed [6].

For several years a program has been active at the Stanford Synchrotron Radiation Laboratory (SSRL) to determine the cleanliness of silicon wafer surfaces by employing Total Reflection X-ray Fluorescence Spectroscopy (TXRF) [7]. This program has been a collaboration between SSRL and members of the Sematech consortium. During this process we have developed state-of-the-art techniques for detecting transition metal contaminants on silicon surfaces.

2. Experimental

TXRF and XANES measurements were performed on BL 6-2 at the Stanford Synchrotron Radiation Laboratory (SSRL), sourced by a 54-pole wiggler. A toroidal mirror and Si(111) double crystal monochromator deliver roughly 10^{11} photons/s through a 0.5 mm wide by 2 mm tall aperture. If multilayers are installed in the monochromator the flux through the pinhole is increased by two orders of magnitude, resulting in a minimum detection limit of 8×10^7 atoms/cm^2 for transition metals. This corresponds to a sensitivity to 1 femtogram of impurities. To preclude unintentional contamination of the surfaces the TXRF instrument is housed in a class 1 clean room and includes a wafer-handling robot for transferring samples into the vacuum chamber. The energy resolution of the double crystal monochromator was 1 eV at 8.9 keV. A detailed description of the beam line setup can be found elsewhere [8]. Three samples were analyzed; one dust grain collected by a NASA ER2 aircraft, one grain of Orgueil meteorite (a type CI carbonaceous chondrite), and the third an IDP collected using hypervelocity capture into aerogel on the Mir space station [9, 10]. Typical particle size is 15–20 μm diameter, although the particles are far from spherical. All three particles were mounted on 10 cm square (100) silicon wafer surfaces, the first two using static electricity for adhesion, the third, because it is still incased in a sliver of aerogel to enable easier handling of the IDP, was attached to the substrate. For standard measurements of wafer cleanliness involving atomically dispersed impurities the wafer surface is illuminated at a grazing angle of incidence of 1.7 mrad, which is below the critical angle of total external reflection for silicon, resulting in the highest detection sensitivities. However, for the analysis of particles a

*Electronic address: sean.brennan@stanford.edu

zero angle of incidence is preferable, essentially eliminating the background signal from the silicon substrate on which the particle rests. In order to convert the measured fluorescence signal observed at zero angle to an elemental concentration, a similar spectrum is collected under standard conditions and compared to the spectrum from a calibration standard containing 1×10^{11} atoms/cm^2 of Fe, Ni and Zn atoms mono-dispersed on the surface.

From these measurements the concentration of elements within the particle can be determined to a few percent. Since the apparatus is designed for the study of transition metal contaminants on silicon, a 25 μm teflon filter is routinely installed in front of the detector window to reduce the intensity of the Si Kα fluorescence. Only 0.2% of those photons are transmitted through the filter, whereas 87% of the Fe Kα photons are transmitted. For the IDP measurements this also reduces the measured signal from other elements of interest such as Al, Mg, and S. In future measurements that filter will be removed. For the XANES measurements the incidence angle on the substrate was zero. Data were collected from 7060 eV to 7210 eV, with 2 eV steps in the pre-edge, 0.5 eV steps at the edge, and 1 eV steps above the edge. Because beam passes over the sample Fe foil transmission data was collected simultaneously. Reference spectra from oxides and sulphides could also be collected in transmission mode. Data have been normalized at 7200 eV. Ni edge XANES were collected from 8300 to 8410 eV, with otherwise identical conditions to the Fe edge data.

3. Analysis

Prior to performing XANES measurements on the samples, fluorescence spectra were collected under two sets of conditions: 11.2 keV and 1.7 mrad angle of incidence (our standard conditions) and at 14 keV (to excite Br atoms expected to be present in the IDP) and zero incidence angle. Figure 1 shows a TXRF spectrum of an IDP collected by a NASA ER2 aircraft. The spectrum was taken with an excitation energy of 14 keV. The spectrum is dominated by the Fe Kα and Kβ peaks, whereas the Cr, Mn and Ni fluorescence lines show a significantly smaller contribution. The Fe peak is due to 400 picograms (pg) of atoms

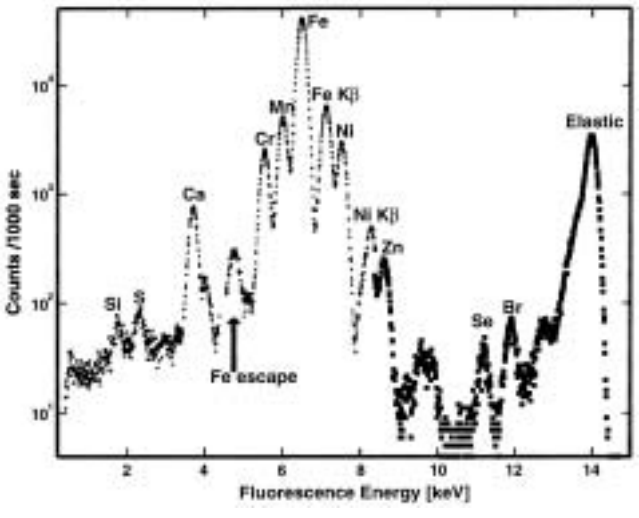

Fig. 1. Fluorescent spectrum from 20 μm meteorite with incident photon energy of 14 keV. The IDP was collected by an ER-2. Counts per 1000 s plotted on a log scale. The Fe Kα peak is the strongest.

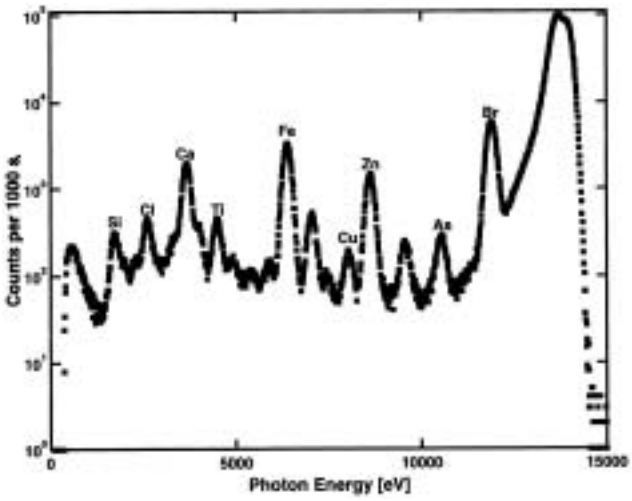

Fig. 2. Fluorescence spectrum from meteorite embedded in aerogel in which it was collected by hypervelocity capture. The high elastic peak and background is due to the aerogel matrix. Some of the observed elements (*e.g.* Br) are also present in aerogel far from the IDP.

and the Ni peak is due to 20 pg, or roughly 2% of the iron concentration. The Br peak results from only 0.1 pg of material. Although the S peak is quite weak, due to the teflon absorption and a significantly smaller fluorescence yield, it comes from 400 pg of material as well. Error bars on the S peak are much larger than for the Fe, where the error is roughly 5%.

The IDP embedded in aerogel posed a special challenge because the scattered signal from the aerogel is larger than the fluorescence from the IDP. This higher scattering contributes to a ten-fold increase in background, as is seen in Figure 2. Due to our excitation geometry the entire aerogel sliver is illuminated. The elemental constituents of this IDP are clearly different from those of the first IDP, with little Ni, strong Zn and Ca, and very strong Fe and Br. The Br raises questions because it is also observed in spectra taken from sections of the aerogel keystone where no IDP is present, suggesting either contamination during fabrication of the aerogel or during processing of the keystone. The iron signal in Figure 2 corresponds to 40 pg of material. The Br peak, although more intense, is due to 20 pg of Br atoms because the absorption cross-section is higher. The Si peak corresponds to 50 ng of material, due to the aerogel in the beam. Again, the apparent weakness of that peak is due to the teflon absorber in front of the detector window.

The Fe concentration from the sample of Orgueil meteorite was determined from the fluorescence spectrum to be 40 pg. Other significant elemental components were Ca (30 pg), K (3 pg) and Ti (3 pg). Mn, Cr and Ni were all found to be less than 1 pg. This particle was examined using Fe K-edge XANES and the results are presented in Figure 3 together with the absorption spectra of an Fe foil, Fe_2O_3, Fe_3O_4 and FeS_2. Comparing the XANES with reference spectra using a non-linear least-squares routine, the data were found to fit those from a pure Fe_2O_3 reference. Often, significant amounts of pyrite (FeS_2) are found in IDPs. However, the FeS_2 bulk XANES pattern is not consistent with the Orgueil data, nor with any of the IDPs in this study. The Fe-edge XANES from the other two IDPs are very similar, but are better fit by a combination of 20% Fe_3O_4 and 80% Fe_2O_3. All three samples have a very sharp leading edge after the pre-edge feature typically due to a 1s-3d transition [11].

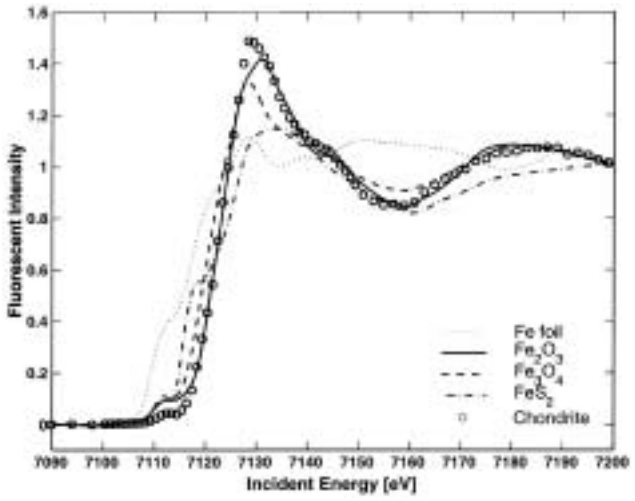

Fig. 3. XANES spectra from Fe edge of Orgueil meteorite as well as spectra from a Fe foil, FeO, Fe_2O_3, Fe_3O_4.

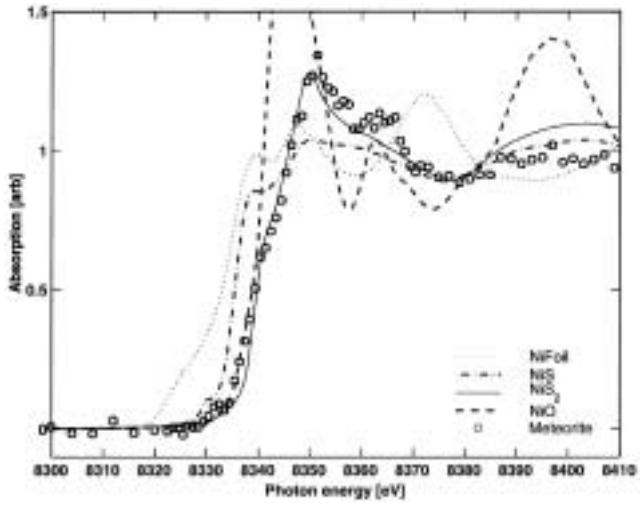

Fig. 4. XANES spectra from Ni edge of meteorite as well as spectra from a Ni foil, NiS, NiS_2, and NiO. The IDP was collected by an ER-2. While the meteorite data are noisy, the similarity to the NiS_2 spectrum is striking.

An attempt was made to measure the XANES at the Ni-edge for an IDP collected using the NASA ER2 plane. The fluorescence spectrum for this IDP is shown in Figure 1. Figure 4 shows the data as well as XANES from standards such as Ni metal, NiO, NiS and NiS_2. The quality of the data is worse than that from the Fe-edge, due to the lower concentration. However, it is sufficient to rule out both the Ni metal and oxide samples, and the data seem to fit the NiS_2 spectrum better than the NiS spectrum. Due to the poor data quality, however, no attempt was made to fit the data to a weighted sum of the two. We are confident that increases in beam intensity made possible by the SPEAR3 upgrade will enable us to do XANES from this concentration routinely.

4. Conclusions

We have performed both X-ray fluorescence and X-ray absorption near-edge spectra on interplanetary dust particles of typically 20 μm size in a grazing incidence geometry. These initial measurements were performed on a system designed for the measurement of surface contaminants on silicon wafers. As such, the instrument is currently not optimized for certain aspects of the measurements, such as quantitative analysis of low-Z elements (*e.g.* Mg, Al, Si) but in other aspects the system is very-well suited to the requirements of such an analysis, since it features a clean sample environment as well as low background and parasitic signals. The dominant element observed in the XRF spectra is iron, with a concentration in one case of roughly 400 pg by weight, but we have identified components with as little as 0.1 pg of material. This is possible due to the extremely low background we have achieved by placing the IDP on a silicon wafer and using a zero degree angle of incidence to the wafer. We find that the Fe-edge XANES for all three particles studied are well-characterized by either Fe_2O_3 or a combination of Fe_2O_3 and Fe_3O_4. The Ni-edge XANES for the ER2 particle is better characterized by NiS_2 than by NiO or Ni metal. It is clear that more reference spectra will be needed to exclude other, more exotic oxidation states. The installation of a microfocusing beam line at SSRL and the new SPEAR3 accelerator will enable us to map out the concentrations of elements within the heterogeneous particles as well as microspectroscopy. A focused beam will also significantly reduce the scatter from the aerogel in embedded samples.

Abstract

Correlations in the atomic motions can significantly change the interpretation of thermal effects in structural data. Including correlations of the stretching of the Zr-O bond with transverse O vibrations in the W-O-Zr linkage, in ZrW_2O_8, can explain the apparent discrepancy between a small σ^2_{W-Zr} in EXAFS data and a large O thermal parameter U^2. This work also shows that in some cases a small value of σ^2 does not always mean that the vibration frequency is high.

The presence of correlated atomic motions in crystalline structures is well known in the EXAFS community. Perhaps the best known example is the very narrow width (small σ) for the nearest neighbor pair distribution function when long wavelength acoustic phonons dominate the atomic vibrations. On a scale of a few unit cells, all the atoms locally are moving in the same direction, the stretch of the nearest neighbor bond length is small, and $\sigma^2 \ll U_A^2 + U_B^2$, where U_A^2 and U_B^2 are the diffraction thermal parameters for the two atoms. In this case, the displacements of the nearest neighbors are said to be positively correlated. Conversely if short wavelength optical phonons dominated, the displacements of the nearest neighbors would be in opposite directions (negatively correlated), and the bond length would have a large vibration amplitude. The very large value of σ^2 observed in that case would produce a low amplitude peak in the Fourier transformed XAFS data. For simple systems, the acoustic phonons usually dominate for $T < 300$ K, and the local atomic displacements are positively correlated.

For systems with more complex, open unit cells, new degrees of freedom exist. In particular, there are many optical modes; if some of them have low frequencies, they can dominate the vibration spectra. For ZrW_2O_8 which we consider here, the cubic unit cell (space group $P2_13$) is quite complex. This material is formed of corner-joined WO_4 tetrahedra and ZrO_6 octahedra, and has a number of unusual features:- a negative thermal expansion from 15–1000 K [1, 2], a large contribution to the specific heat at low T which has been modeled by two Einstein modes at 38 and 67 K [3], and two low energy peaks in the phonon density of states obtained in neutron scattering experiments at similar energies [4]. The unusual negative thermal expansion in ZrW_2O_8 has been attributed to these low energy vibration modes; EXAFS experiments suggest that these modes involve the massive WO_4 and ZrO_6 units. [5] Thus for the lowest optical modes these polyhedra units appear to vibrate as "large atoms", although some stretch of a unit is required. These motions involve highly correlated displacements of the polyhedral clusters and are not direct extensions of modes observed in simple systems.

The EXAFS data for the ZrW_2O_8 system have been presented previously [5] – here we focus on the correlations that must be present to understand the apparently conflicting results from EXAFS and diffraction. In Fig. 1 we show part of the crystal structure (a cut-away of the cubic unit cell, viewed perpendicular to a ⟨111⟩ axis) to show the local environment about the WO_4 tetrahedra. One corner of each tetrahedron, aligned along a ⟨111⟩ axis, is not connected to any other unit and is therefore unconstrained. The tetrahedra can move into empty space along this ⟨111⟩ axis with little cost in energy. The other three corners, in a plane perpendicular to the ⟨111⟩ axis, are linked to ZrO_6 octahedra. The EXAFS data show that the amplitude of the W-O peak (W L_{III} edge data) changes only a few percent up to 300 K; consequently, the W-O bonds are very rigid. For ZrO_6 however, there is a small broadening of the Zr-O pair distribution function – the Zr-O bond is not completely rigid up to 300 K in contrast to the assumptions in the rigid unit model (RUM) [6]; small distortions of this bond allow vibrations of the polyhedral units.

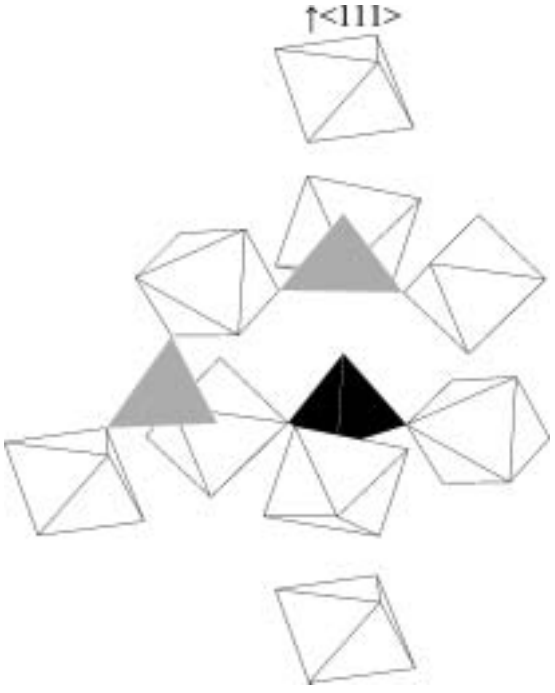

Fig. 1. A cut-away section of the cubic unit cell to show the local structure about the W(1)O_4 (gray) and W(2)O_4 (black) tetrahedra. Each tetrahedron is corner-connected to three ZrO_6 octahedra; the forth vertex, oriented along a ⟨111⟩ axis (vertical), is unconstrained. A third W(1)O_4 (gray) tetrahedron aligned along another ⟨111⟩ axis is also shown.

More surprising is the weak T-dependence of the W-Zr (or Zr-W) peak which includes multiple scattering path contributions. There is essentially no temperature change up to ∼125 K and only a small change up to 300 K that is comparable to the net change for the Zr-O peak. The T-dependences of σ^2 for the Zr-O and the W-Zr (or Zr-W) peaks are very similar.

Diffraction measurements show a large U^2 parameter for the different O atoms and smaller but significant U^2 parameters for the heavy metals, U_W^2 and U_{Zr}^2 [1, 7, 8]. The interpretation of the

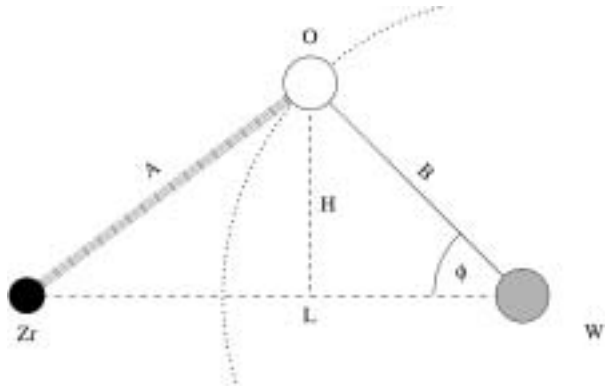

Fig. 2. The geometry of the Zr-O-W linkage; the angle ϕ is exaggerated to show the different distances. The W-O bond length B is rigid and the O would move on the dotted arc about the W atom. Between Zr and O there is a stiff spring (but the bond is not rigid).

diffraction data focused on the transverse vibrations of the O in the W-O-Zr linkage, and ignored stretching of the Zr-O bond and translations of the WO_4 tetrahedra as a rigid unit. (At least part of the O motion must correspond to the latter.) Under the assumption of rigid rotating units and uncorrelated displacements, a transverse O vibration would lead to a contraction of the Zr-W distance consistent with the observed macroscopic contraction. However it would also lead to a very large σ^2 for W-Zr or Zr-W which is not observed in the EXAFS data. If one includes the Zr-O bond stretching vibrations in the W-O-Zr linkage, but still assumes that the stretching vibration and the transverse O vibrations are uncorrelated, then the EXAFS data would imply that the transverse O vibration amplitude must be small, in conflict with the diffraction U^2 parameters. However, when correlations are included a significant transverse O vibration is possible with still only a weak temperature dependence for σ^2_{W-Zr}.

The W-O-Zr linkage is shown in Fig. 2; it is the important connection between a tetrahedron and an octahedron. The W-O bond B is taken to be rigid based on the EXAFS data, while the Zr-O bond A stretches as the W/Zr polyhedra units undergo thermal vibrations, a combination of translations and rotations. The O atom must move on an arc (to keep B rigid) and its motion is not completely transverse but includes a small component parallel to the Zr-W distance. This suggests a coupling between the rotations of the O about W and stretching of the spring A. Note that even if A were an ideal spring, the motions would not be harmonic. In the limit of no vibrations of the Zr-W distance (like the ends of a guitar string) the Zr-O bond would stretch completely in phase with the O transverse motion. For various assumptions about the stretching of A and the degree of correlation with the transverse O vibration, we need to consider the changes in the length L ($\Delta L = L - L_0$; L_0 is the length at low T) and the variance of the thermal fluctuations, $(\Delta L)^2$.

We initially allow the possibility that the motions involve two different modes – i.e. that the stretch of the Zr-O may arise from acoustic phonons while the transverse O motions might arise from low frequency optical modes. The time dependence of A and H are modeled as sinusoidal vibrations about the static values, A_0 and H_0.

$$\begin{aligned} A &= A_0 + A_1(t), \\ H &= H_0 + H_1(t), \\ A_1(t) &= a_1 \cos(\omega_A t), \\ H_1(t) &= h_1 \cos((\omega_H t + \theta). \end{aligned} \tag{1}$$

Here a_1 and h_1 are the vibration amplitudes and ω_A and ω_H are the frequencies for the stretching and transverse motions. The total Zr-W distance, L, is given by:

$$L = \sqrt{A^2 - H^2} + \sqrt{B^2 - H^2}. \tag{2}$$

To simplify the final results we will set $B = A_0$. Substituting for A and H, expanding the square roots to second order, and keeping terms up $A_1^2(t)$, $H_1^2(t)$ and $A_1(t)H_1(t)$, then

$$\begin{aligned} L = L_0 &+ \frac{1}{L_0}[2A_0A_1(t) + A_1^2(t) - 4H_0H_1(t) - 2H_1^2(t)] \\ &- \frac{1}{L_0^3}[4A_0^2A_1^2(t) + 8H_0^2H_1^2(t) - 8A_0H_0A_1(t)H_1(t)] \end{aligned} \tag{3}$$

where $L_0 = 2\sqrt{A_0^2 - H_0^2}$. Next we need to calculate the average length change $\langle \Delta L \rangle = \langle L - L_o \rangle$ and its variance, $\sigma^2_{thermal} = \langle (\Delta L)^2 \rangle$. To calculate these averages, we integrate each term over time, e.g. for $A_1^2(t)$:

$$\langle A_1(t)A_1(t) \rangle = \int A_1(t)A_1(t)\,\mathrm{d}t. \tag{4}$$

Using Eqn. (1) in this integral then:

$$\begin{aligned} &\langle A_1(t) \rangle = \langle H_1(t) \rangle = 0, \\ &\langle A_1^2(t) \rangle = a_1^2/2; \qquad \langle H_1^2(t) \rangle = h_1^2/2. \end{aligned} \tag{5}$$

The average of $A_1(t)H_1(t)$ depends on ω_A and ω_H; if $\omega_A \neq \omega_H$, then $\langle A_1(t)H_1(t) \rangle = 0$; for $\omega_A = \omega_H = \omega$,

$$\begin{aligned} \langle A_1(t)H_1(t) \rangle &= \frac{1}{T}\int_0^T h_1 a_1 \cos(\omega t)\cos(\omega t + \theta)\,\mathrm{d}t \\ &= \frac{h_1 a_1 \Phi}{2}, \end{aligned} \tag{6}$$

where $\Phi = \cos\theta$ is called the correlation parameter and can vary from -1 to 1. After averaging and simplification

$$\langle \Delta L \rangle = -\frac{1}{L_0(A_0^2 - H_0^2)}[A_0^2h_1^2 + H_0^2a_1^2/2 - A_0H_0a_1h_1\Phi]. \tag{7}$$

For $a_1 = 0$ (i.e. Zr-O is rigid), $\langle \Delta L \rangle \sim -h_1^2/L_0$ as used earlier [7]. For $a_1 \neq 0$ and Φ positive, $\langle \Delta L \rangle$ is reduced but for the relevant parameters the reduction is not large. In contrast the correlations have a very large impact on $\sigma^2_{thermal}(\Phi)$:

$$\sigma^2_{thermal}(\Phi) = \frac{2}{L_0^2}[A_0^2a_1^2 + 4H_0^2h_1^2 - 4A_0H_0a_1h_1\Phi]. \tag{8}$$

When A_1 and H_1 are uncorrelated ($\Phi = 0$) then

$$\sigma^2_{thermal}(0) = \frac{A_0^2}{2(A_0^2 - H_0^2)}\left[a_1^2 + 4\frac{H_0^2}{A_0^2}h_1^2\right]. \tag{9}$$

This is the typical results for two uncorrelated mechanisms; the contributions to the broadening add up in quadrature. For positively correlated motions, $\sigma^2_{thermal}$ is reduced because of the minus sign (Eqn. (8)). When $\Phi = 1$, Eqn. (8) simplifies to:

$$\sigma^2_{thermal}(1) = \frac{A_0^2}{2(A_0^2 - H_0^2)}\left[a_1 - 2\frac{H_0}{A_0}h_1\right]^2. \tag{10}$$

In this case, correlations effects are very large because $\sigma^2_{thermal}$ depends on the difference, $a_1 - 2H_0h_1/A_0$.

Using σ^2_{Zr-O} and U^2_O from diffraction to estimate the vibration peak amplitudes ($a_1 \sim 0.08$ Å, $h_1 = 0.21$ Å), $H_0 = 0.4$ Å for W(1)-O-Zr, and $A_0 \sim 2$ Å, then for $\Phi = 0$ $\sigma^2_{thermal}(0) \sim 7.0 \times 10^{-3}$ Å^2, while for $\Phi = 1$, $\sigma^2_{thermal}(1) \sim 8.3 \times 10^{-6}$ Å^2. For

negatively correlated displacements $\sigma^2_{thermal}$ can be very large, > 0.01 Å^2. Consequently, $\sigma^2_{thermal}(\Phi)$ can have a wide range of values depending on the value of Φ.

In this simplified discussion we have not accounted for any static distortions or zero-point motions and have not considered the multiple scattering contributions for W(2)-O-Zr. We have also used the maximum value of h_1 obtained in diffraction experiments, which assumed that the oxygen thermal parameter U^2_O arises solely from O transverse motion. This overestimates h_1, as part of the O displacement must correspond to translations of the WO_4 (and ZrO_6) units – i.e. rotations/translations of the W-O-Zr linkage. Unfortunately in Eqn. (8) h_1 and Φ are coupled and cannot be uniquely determined.

This work shows that in some cases it is crucial to recognize that atomic motions can be highly correlated and may involved quite large clusters of atoms. Although the O thermal parameters (U^2_O) from diffraction cannot be uniquely decomposed into two components – one corresponding to an O transverse motion and the other a translation of the WO_4 unit, including correlations in the atomic displacements essentially removes the discrepancies between the small value of σ^2_{W-Zr} and the relatively large values of U^2_O. The calculation also shows that in some cases, a small value of σ^2 does not necessarily mean that the thermal vibration causing the broadening has a high frequency. For the W-O-Zr linkage the Zr-O bond stretches slightly to accommodate the low frequency motions of the WO_4 and ZrO_6 units; the small stretch of the Zr-O bond is a *byproduct* of a low frequency mode and is not directly a measure of the Zr-O spring constant, κ (i.e. $\sigma^2 \sim kT/\kappa$ at high T) as is often assumed.

Acknowledgments

This work was supported by NSF grant DMR0071863 and was conducted under the auspices of the U.S. Department of Energy (DOE), Office of Basic Energy Sciences (OBES). The experiments were performed at SSRL, a national user facility operated by Stanford University on behalf of the DOE/OBES.

Abstract

The rutile-type structure is found in many dioxides. The rutile samples in this study, difluorides of the first-row transition-metals, MF_2 (M = Mn, Fe, Co, Ni), are important materials from the view point of electronic and magnetic properties. Although almost rutile-type difluorides have the positive thermal expansion coefficient, FeF_2 has a negative thermal expansion coefficient along the c axis in the high temperature region. In this study, we could obtain a detailed information about the thermal vibration of atoms by the analysis of EXAFS Debye-Waller factors. We discuss on the atomic momentum in the local structure of the difluorides. The EXAFS Debye-Waller factor is sensitive to short-range correlation of mutual atomic motions.

The displacement correlation functions (DCF) for each neighbor atom were determined by using both the mean square relative displacement (MSRD) and the mean square displacement (MSD) by X-ray diffraction. It was proved that DCF/MSD in the second-nearest neighbor atoms of FeF_2 is small, compared with other difluorides. This result suggests that in FeF_2, the correlation between second-nearest neighbor atoms (Fe-Fe) is weak. Furthermore, we could estimate the force constant between absorbing and scattering atoms from the temperature dependence of EXAFS Debye-Waller factor. The value of the force constant suggests that in FeF_6 octahedron in FeF_2, two apical bonds are stronger than four equatorial bonds.

1. Introduction

There are many compounds with composition AB_2, having the rutile-type structure, such as TiO_2 from which the name derived. They are mostly dioxides or difluorides. The rutile-type structure was first described by Vegard [1] and has been studied, for various materials, repeatedly and with increasing accuracy over the years. The rutile type tetragonal unit cell (space group $P4_2/mnm$) contains two cations at (0, 0, 0) and (1/2, 1/2, 1/2), and four anions at $(1 \pm u, 1 \pm u, 0)$ and $(1/2 \pm u, 1/2 \mp u, 1/2)$. The rutile structure has edge-sharing octahedra which form chains along c-axis. The distance between the second-nearest neighbor cations is equal to the c edge distance. Some fluorides composed of first-row transition metals with the rutile-type structure have been investigated. Although almost difluorides have the positive thermal expansion coefficient, FeF_2 has been a negative thermal expansion coefficient along the c-axis in the high temperature region [2]. The negative coefficients of expansion in the cases of calcite and graphite have been explained by the Poisson contraction arising from the large thermal expansion coefficient in a perpendicular direction [3, 4, 5]. Such an explanation is not applicable in the case of FeF_2 which does not have a large coefficient of expansion along the other direction. In spite of the interesting thermal behavior, we have found only very few theoretical papers. In this study, we try to give an explanation of that behavior with the EXAFS technique from the viewpoint of the thermal vibrations of local structure.

EXAFS spectroscopy is a useful method for local structural investigation around a particular kind of atom in materials and provides important information on the interatomic distance and the thermal vibration of local structure. The EXAFS spectra are specific to a given cation and provide averaged data over time and positional information. EXAFS analysis provides an effective pair potential with temperature-independent shape from the Debye-Waller factor [6, 7]. The Debye-Waller factor determined by EXAFS means the mean-square relative displacement (MSRD) of the backscattering atoms with respect to the absorbing atom. The MSRD contains contributions from the mean-square displacement (MSD) of both absorbing and backscattering atoms and the displacement correlation function (DCF). The MSD of each atom from the crystallographically equivalent position is determined by diffraction methods. The MSRD is sensitive to the short-range correlation of vibrational motion of the pair of atoms considered [8, 9].

$$\begin{aligned} &MSRD_{AB} = MSD_A + MSD_B - 2DCF_{AB}, \\ &MSD_i = \langle (\boldsymbol{R}_{AB} \cdot \delta \boldsymbol{u}_i)^2 \rangle, \\ &DCF = \langle (\bar{\boldsymbol{R}}_{AB} \cdot \delta \boldsymbol{u}_A) \cdot (\bar{\boldsymbol{R}}_{AB} \cdot \delta \boldsymbol{u}_B) \rangle, \\ &\delta \boldsymbol{u}_i = \boldsymbol{u}_i - \langle \boldsymbol{u}_i \rangle, \quad i = \mathrm{A}, \mathrm{B} \end{aligned} \tag{1}$$

with $\langle\ \rangle$ being the thermal average where $\boldsymbol{u}_i$ is the displacement of atom i = A or B and

$$\bar{\boldsymbol{R}}_{AB} = \boldsymbol{R}_{AB}/|\boldsymbol{R}_{AB}| \text{ [10]}. \tag{2}$$

In this study, we have attempted to determine the local structure and MSRD in order to evaluate the DCF for each backscattering atom. The coefficients of the effective pair potentials between the absorbing atom and backscattering atom were determined from the Debye-Waller factors. The results of analysis for FeF_2 were compared with those for MnF_2, CoF_2 and NiF_2. We discussed the thermal vibration of FeF_2 in view of local structure.

2. Experimental and Analysis

The well-ground powder samples ($\sim 0.1\,\mu$m) of MF_2 (M = Mn Fe, Co and Ni) were mixed with boron nitride in an agate mortar and pressed into pellets of 1.0 mm in thickness and 10.0 mm in diameter. The samples had edge-jumps with 1 ($\Delta\mu d$), where μ and d are the linear absorption coefficient and the thickness of the samples, respectively. The EXAFS absorption spectra near the K-edge of the cations were measured in a transmission mode in the temperature range from 20 K to 700 K at BL-7C of the Photon Factory in High-Energy Accelerator Research Organization (KEK), Tsukuba. The positron storage ring current and energy were approximately 300 mA and 2.5 GeV, respectively. The synchrotron radiation was monochromatized by a Si (111) double crystal monochromator. Ionization chambers were applied as incident and transmission beam intensity detectors. N_2 gas was used for the incident detector and N_2 (85%) + Ar (15%) or N_2

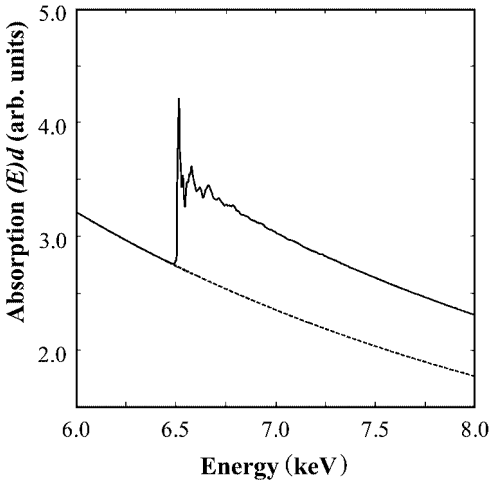

Fig. 1. X-ray absorption $\mu(E)d$ near the Mn K-edge of MnF_2 at 20 K (solid line) with Victoreen function fitted (dashed line).

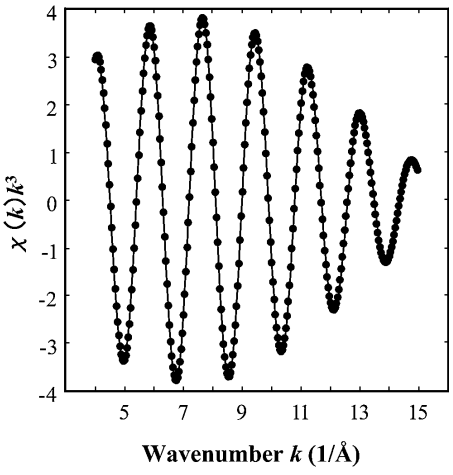

Fig. 2. Fourier-filtered EXAFS spectra (dotted curve) and least-squares fit (solid curve) for the first-nearest Mn-F distance in MnF_2 at 20 K.

(75%) + Ar (25%) gasses were employed for the transmission detector to achieve optimum signal-to-noise ratio. Mirrors were used to eliminate higher harmonics in the measurement of spectra near the Mn K-edge. On the other hand, in the measurement of spectra near Fe, Co and Ni K-edges, the 60% detuning of the monochromator was carried out in order to eliminate them. The photon energy E was calibrated with a Cu foil by assigning 8.9788 keV to the pre-edge peak of the absorption. Figure 1 shows the X-ray absorption $\mu(E)d$ near the Mn K-edge of MnF_2 at 20 K. The fitted Victoreen function is also shown in the figure.

The EXAFS interference function, $\chi(k)$, was extracted from the measured absorption spectra using standard procedures [11], where k denotes the wave number of a photoelectron: $k = [2m(E - E_0)/\hbar^2]^{1/2}$. $\chi(k)$ was normalized using MacMaster coefficients according to the EXAFS workshop report [12]. The programs *XAFS93* and *MBF93* [11] were employed for the data analysis to determine local structure parameters. The EXAFS formula is based on single-scattering theory and expressed by the cumulant expansion [9, 13]:

$$\chi(k) = \sum_j \frac{N_j}{kR_j^2} |f_j(k,\pi)| \exp\left(-2\sigma_j^{(2)}k^2 + \frac{2}{3}\sigma_j^{(4)}k^4\right) \exp\left(-\frac{2R_j}{\lambda_j}\right) \times \sin\left[2kR_j - \frac{2k}{R_j}\left(1 + \frac{2R_j}{\lambda_j}\right)\sigma_j^{(2)} - \frac{4}{3}\sigma_j^{(3)}k^3 + \Psi_j(k)\right], \quad (3)$$

where N_j is the coordination number in the jth shell at distance R_j from the absorbing atom, $|f_j(k,\pi)|$ is the back-scattering amplitude of photoelectrons, and $\Psi_j(k)$ is the total phase shift function [14]. The quantities $\sigma_j^{(n)}$ are the nth cumulants. The mean free path λ_j of the photoelectron was taken to depend on the wave number k with the relationship $\lambda_j = k/\eta_j$. In this study, because we take a harmonic vibration model, the quantities $\sigma_j^{(3)}$ and $\sigma_j^{(4)}$ must be zero. A Fourier-filtered EXAFS function of the peak in real space was compared with a theoretical EXAFS function. In the parameter fitting, the theoretical EXAFS function was filtered in the same way as the observed one in order to eliminate truncation effects through the Fourier transformation. The k range of the data used was 4–15 $Å^{-1}$ and 4–12 $Å^{-1}$ in the high and low temperature region, respectively. A double-shell fitting was carried out for the nearest neighbor distance in FeF_2, because FeF_2 is characterized by four longer coplanar Fe-F bonds over 0.1 Å than two axial bonds in FeF_6 octahedron. The coordination number in FeF_2 was fixed at the crystallographic values as $N_1 = 2$ and 4 corresponding to axial and coplanar bonds, respectively. A single-shell fitting was carried out for first-, second- and third-nearest neighbor distances in each material except for the first-nearest neighbor distance, Fe-F, in FeF_2: the number of neighboring atoms was fixed at the crystallographic value as $N_j = 6$, 2 and 8 in the first-, second- and third-nearest neighbor atoms, respectively. The equal deformation of observed and calculated EXAFS functions improves the accuracy of the parameter fitting. The determined values of the distance and $\sigma_j^{(2)}$ between the absorbing and backscattering atoms are listed in Table I. The reliability of converged parameters by least-square procedure,

$$R = \sum_s |k_s^3\chi(k_s)_{\exp} - k_s^3\chi(k_s)_{calc}|/|k_s^3\chi(k_s)_{\exp}|, \quad (4)$$

between the experimental and calculated EXAFS functions are also listed in Table I. The quality of fit between $k^3\chi_{\exp}$ and $k^3\chi_{\text{calc}}$ is shown in Figure 2.

3. Results and Discussion

3.1. *Interatomic distances and force constants*

Interatomic distances between first-, second- and third-nearest neighbor atoms determined by EXAFS analysis are shown in Table I. The errors are considered on the basis of the theory in EXAFS workshop report [12]. The results at room temperature are quite in agreement with the results derived by diffraction methods [15, 16]. In FeF_2, the distance of the second-nearest neighbor atoms, Fe-Fe, contracts as the temperature rises in the high temperature region. The coefficient of contraction is consistent with that of negative thermal expansion by diffraction experiments [1]. That is to say, the negative thermal expansion along the *c*-axis in FeF_2 is induced by the local contraction of the second-neighbor atoms distances.

Fig. 3 shows the temperature dependence of the Debye-Waller-type factor, $\sigma_j^{(2)}$ of the second-nearest neighbor atoms in FeF_2. The values of $\sigma_j^{(2)}$ do not follow a straight line in the low temperature region because of zero-point vibration. The variable $\sigma_j^{(2)}$ includes the effects of static and dynamic disorders. The static disorder is the configurational disorder, while the dynamic disorder arises from the thermal vibration of atoms. In addition, there is a correlation in calculation between $\sigma_j^{(2)}$ and the mean free path length, λ, of the photoelectron. If it is assumed that a harmonic approximation is applied up to 700 K, a straight line with the same gradient passes through the origin and the deviation of the absolute values is attributed to the static disorder and to the correlation between $\sigma_j^{(2)}$ and λ. The contribution of the thermal vibration (the straight line in Fig. 3), $\sigma_{thermal}^{(2)}$, can be extracted from $\sigma_j^{(2)}$. The same deviation from the values estimated under the assumption of classical statistic dynamics is observed in other studies [6]. We can evaluate the harmonic effective interatomic potential,

$$V(u) = \alpha u^2/2, \tag{5}$$

from the contribution to the thermal vibration ($\sigma_{thermal}^{(2)}$), where u is the deviation of the distances between the absorbing atom and backscattering atoms from the location of the potential minimum. The variable $\sigma_{thermal}$ is related to the potential coefficient,

$$\alpha = k_B T/\sigma_{thermal}^{(2)}, \tag{6}$$

where k_B is the Boltzman constant. The potential coefficient, namely the force constants, α, derived from the gradient for the experimental $\sigma_j^{(2)}$ in Figure 3, are essentially temperature independent and are listed in Table II. The longer the distances between atoms, the smaller are the values of α for the most

second-nearest neighbor				
DCF	6.76(6)	4.44(5)		4.03(8)
DCF/MSD	0.745(9)	0.601(7)		0.734(10)
third-nearest neighbor				
DCF	5.18(6)	3.38(4)		2.72(10)
DCF/MSD	0.469(9)	0.471(7)		0.469(13)

part in each material. In FeF_2, the values of α of axial bonds in FeF_6 octahedron are larger over 3 eV/Å^2 than that between the second-nearest neighbor atoms, while in other materials, the values of α between first- and second-nearest neighbor atoms are relatively close. This might be caused by the influence on 3d electrons which participate in the combination of atoms in FeF_2. These results mean that Fe-F bonds in FeF_6 octahedron are much stronger than the interaction between the second-nearest neighbor atoms (Fe-Fe). This case is quite peculiar compared with other rutile-type fluorides.

3.2. *The displacement correlation function (DCF)*

Eq. (1) is useful as we wish to discuss separately the role played by the MSD and by the DCF. It is significant to see the ratio of the DCF to MSD given by $2DCF/(MSD_A + MSD_B)$. Those at room temperature are shown in Table III. We referred to the previous study for the values of MSD [17, 18]. There are no useful MSD data for CoF_2. The magnitudes of the DCF terms to the MSD in three materials are almost equal within 1.3% and 0.2% between the first- and third-nearest neighbor atoms, respectively. On the other hand, the magnitudes of the DCF terms to the MSD between the second-nearest neighbor atoms in FeF_2 is over 13% smaller than those in the other two fluorides. These results show that the correlation between the second-nearest neighbor atoms in FeF_2 is smaller than that in the other two fluorides.

3.3. *Negative thermal expansion and thermal vibration of FeF_2*

The above results suggest the following structural thermal vibration model. A FeF_6 octahedron whose six Fe-F bonds have large force constants has the largest vibrational mode, which is perpendicular to the *c*-axis, and the vibration of each octahedron shifts the half phase for the neighboring share edged octahedral shown in Figure 4. The second-nearest neighbor Fe atoms vibrate with half phase shift to each other. This mode is reasonable to the results that the correlation with the second-nearest neighbor atoms is small. If the thermal vibrational mode of this model increases among all thermal vibrational modes, the second-nearest neighbor distance (the length of the *c*-axis) decreases. In the high temperature region, this mode contributes largely to the thermal vibrations in FeF_2, while in the low temperature region, the contribution of this mode is small.

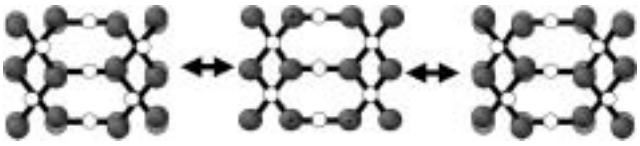

Fig. 4. Thermal vibration model of FeF_2 on the (110) plane. ● and ○ shows fluorine atom and iron atom, respectively.

Abstract

Copper and silver oxide share the rather unusual cuprite structure, formed by two interpenetrating networks of corner-sharing M_4O tetrahedra (M = Cu, Ag). Negative thermal expansion of the cell parameter has been observed from 5 to about 200 K for Cu_2O and up to 470 K for Ag_2O by powder diffraction. In the case of Ag_2O, it has been shown by EXAFS that the lattice contraction is accompanied by an expansion of the Ag-O distance and that the deformation of the Ag_4O tetrahedral is not negligible. In this work we present a comparison between EXAFS and XRD results for both compounds. The comparison between local and lattice thermal expansions, measured by EXAFS and XRD, respectively, and the differences found between the two compounds, allow to gain original insight on the mechanism of negative thermal expansion in framework structures.

1. Introduction

Thermal expansion is a relevant property for a wide variety of technological applications, as micromechanics, electronic devices, biomedical materials and so on [1]. In recent years, particular attention has been focused on solids exhibiting a negative thermal expansion (NTE) over a large temperature range, which could be employed to produce composite materials with specifically tailored thermal expansion properties.

NTE has been frequently observed over a large temperature range in framework structures [2] as ZrW_2O_8, where the lattice parameter contracts from 0.3 to 1050 K [3]. Framework structures are formed by networks of corner-sharing tetrahedral and/or octahedral structural units. The cuprite structure (Ag_2O and Cu_2O, space group Pn3m) can be described as a framework of two networks of corner-sharing M_4O tetrahedra (M = Ag, Cu), in which each M atom is linearly coordinated to two O atom, and each O atoms is tetrahedrally coordinated to four M atoms.

In framework structures the net thermal expansion is often attributed to the competition between two contributions: a positive contribution due to the potential anharmonicity, and a negative contribution of geometrical origin attributed to the network folding induced by low frequency rigid unit modes (RUM) [4]. Explaining NTE in terms of local structure and dynamics is a basic problem, and to this aim it is important to directly measure the thermal expansion of the nearest-neighbours distance and the degree of rigidity of the corner-sharing basic units. Owing to its selectivity of atomic species, insensitivity to long range order and sensitivity to correlation of atomic motion, EXAFS is particularly suited to study the thermal properties within a few coordination shells of a selected atomic species. Temperature dependent measurements and a data analysis based on the cumulant expansion method [5, 6] (when applicable) allow to effectively distinguish anharmonicity and geometrical effects [7]. Let us consider the instantaneous thermal displacements of absorber and back-scatterer atoms, $\bar{u}_0$ and $\bar{u}_j$ respectively. EXAFS is sensitive to the mean square relative displacement $\langle \Delta u^2 \rangle = \langle (\bar{u}_j - \bar{u}_0)^2 \rangle$, which is conveniently decomposed into its projections parallel and perpendicular to the bond direction, $\langle \Delta u_{||}^2 \rangle$ and $\langle \Delta u_{\perp}^2 \rangle$ respectively. The first EXAFS cumulant C_1^* is the average value of the distribution of the interatomic distances; it is always larger than the distance R between the centres of probability distribution functions measured by diffraction (XRD), owing to the effect of thermal vibrations perpendicular to the bond direction; quantitatively $C_1^* \cong R + \langle \Delta u_{\perp}^2 \rangle / 2R$ [8]. The second EXAFS cumulant C_2^* is the variance of the distribution of distances, and corresponds to a very good approximation to the mean square relative displacement *parallel* to the bond direction: $C_2^* \cong \langle \Delta u_{||}^2 \rangle$.

A direct comparison between EXAFS and XRD measurements not only gives original information about the correlation of atomic motion [9, 10], but also allows to obtain fundamental inputs to understand the connection between the bond length thermal expansion and the macroscopic thermal expansion, particularly in the case of NTE in framework structures. In this paper the experimental results obtained through a joint EXAFS-XRD work on the cuprite structures will be reported.

2. XRD measurements and results

High-resolution X-ray powder diffraction measurements on Cu_2O and Ag_2O have been performed with synchrotron radiation in the temperature range from 5 K to room temperature at the BM16 beam line (now transferred to ID31) of ESRF in Grenoble. The wavelength used was 0.3545 Å, calibrated against standard silicon SRM 640B (also used as a standard for line position). The temperature control was achieved by a closed-cycle helium cryostat. The angular range was between 5° and 28° 2ϑ, corresponding to $\sin\vartheta/\lambda$ between 0.12 and 0.68 $Å^{-1}$; in order to correctly estimate the goniometer zero, the lattice parameter for SRM 640B silicon, calculated from the thermal expansion taken from Swenson [11], was kept fixed. The structural refinements were performed with the Rietveld method, using the GSAS code [12].

High temperature data (from room temperature to 630 K for Cu_2O and to 470 K for Ag_2O) were collected in argon flux with a Philips X'pert ϑ-ϑ laboratory diffractometer equipped with a hot chamber (AHT PAP1600) [13], and carefully calibrated for sample position and temperature. The CuKα wavelength was used. The refinement method was the same as for the synchrotron data.

The relative thermal expansion $\Delta a/a$ of the lattice parameter a is shown in Figure 1 for both crystals: Cu_2O exhibits NTE up to about 200 K; between 200 and 300 K the lattice expansion is roughly zero; for temperature higher than 300 K the thermal expansion becomes positive but very small. This behaviour is in good agreement with the results found by Schäfer and Kirfel with

*e-mail: sanson@science.unitn.it

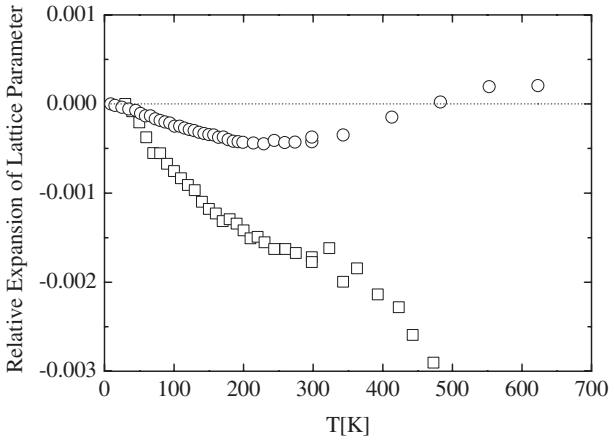

Fig. 1. Relative expansion of lattice parameter for Cu_2O (circles) and Ag_2O (square).

neutron powder diffraction [14]. In the case of Ag_2O, a stronger NTE is present on the whole temperature range considered. This result for Ag_2O is in contrast with previous measurements performed with laboratory diffractometers, which gave positive thermal expansion [15, 16].

3. EXAFS measurements and results

EXAFS data for Cu_2O were collected at the K-edge of copper in the temperature range from 25 to 410 K at the beamline BM29 of ESRF; an independent measurement run was performed at the beamline BM08 (Gilda) in the temperature range from 4 to 300 K. EXAFS measurements at the silver K-edge in Ag_2O were performed at the beamline BM08 of ESRF in the temperature range from 7 to 500 K. All the samples were prepared by depositing Cu_2O or Ag_2O powders on polytetrafluoroethylene membranes, the thickness being chosen so as to have an edge jump $\Delta\mu x \cong 1$. EXAFS was measured in transmission mode, using silicon monochromators with (311) and (111) Bragg-reflecting faces at the BM08 and BM29 beam lines, respectively.

The EXAFS signals were extracted from the experimental spectra after a careful alignment of the energy axes according to well established procedures [17]. The Fourier transforms of the EXAFS signals at low and room temperature are shown in Figure 2 for both compounds. The first peaks between about 1 and 2 Å corresponds to the first coordination shell (two oxygen atoms, at 1.85 Å for Cu_2O and at 2.04 Å for Ag_2O). The first-shell EXAFS contributions at different temperatures were singled out by Fourier back-transform and analysed by the ratio method [5, 6], using the lowest temperature spectra as reference.

The second peak between about 2 and 3.5 ÷ ·4 Å in Fig. 2 contains, in addition to the single scattering contribution from the second shell (12 Cu at 3.02 Å for Cu_2O and 12 Ag at 3.34 Å for Ag_2O), also the single scattering contribution from the third shell (6 O at 3.54 Å for Cu_2O and 6 O at 3.91 Å for Ag_2O), together with the contribution from multiple scattering (MS) paths. To estimate the relative importance of the different contributions on the analysis of the second peak, a simulation with FEFF code [18] was performed: this procedure allowed to reliably single out the structural parameters of the 2nd shell by the ratio method.

The temperature dependence of the first EXAFS cumulants in Cu_2O and Ag_2O is shown in Figure 3 for the first shell, and in Figure 4 for the second shell. (The first cumulants have been calculated using a fixed photoelectron mean free path value $\lambda = 8$ Å [6]). The second EXAFS cumulants (parallel MSRD) for the first and the second shell of both compounds are shown in

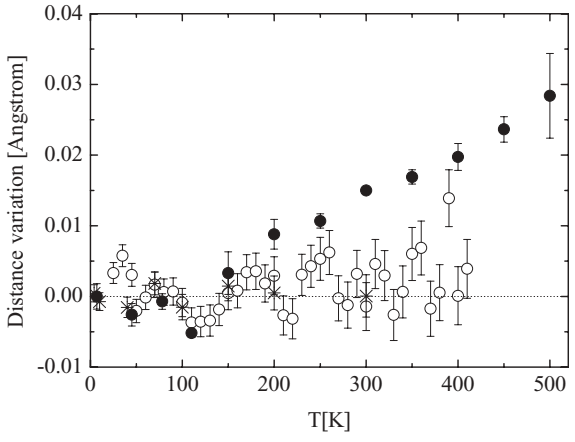

Fig. 3. Temperature dependence of the first shell distance Cu-O (open circles measures performed at BM29, stars at BM08) and of the first shell distance Ag-O (full circles).

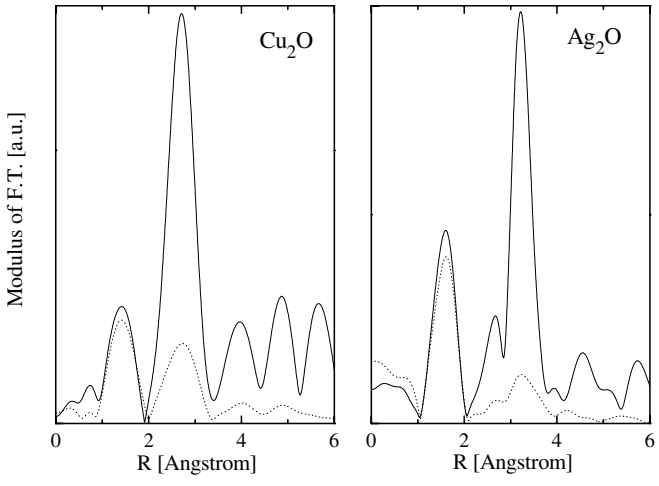

Fig. 2. Fourier Transforms for Cu_2O at 25 and 300 K (left) and for Ag_2O at 7 and 300 K (right).

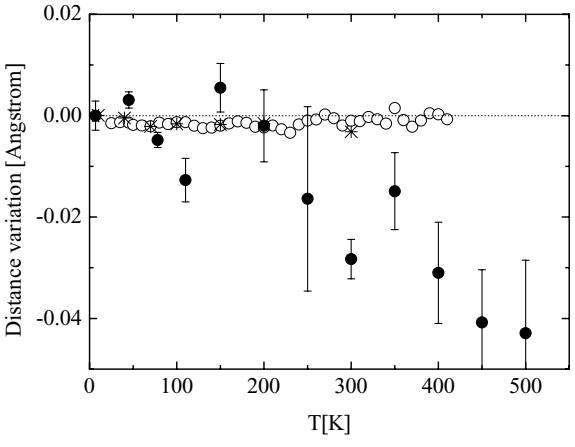

Fig. 4. Temperature dependence of the second shell distance Cu-Cu (open circles measures performed at BM29, stars at BM08) and of the second shell distance Ag-Ag (full circles).

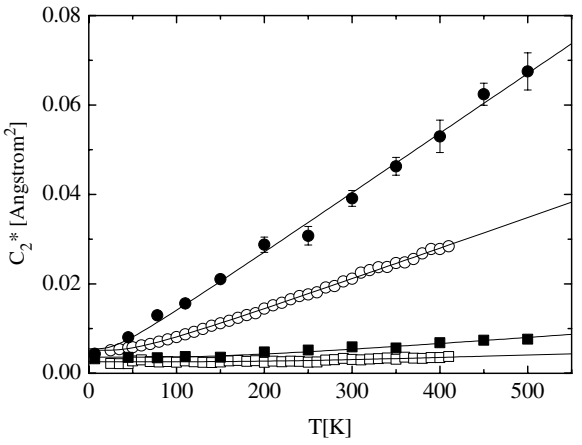

Fig. 5. Parallel MSRD for the first (open squares) and second (open circles) shell in Cu_2O, for the first (full squares) and second (full circles) in Ag_2O. Lines are the corresponding Einstein model fits.

Figure 5: the lines are the corresponding best-fitting correlated Einstein models [8].

The ratio between the intensities of the 2nd and 1st peak in the Fourier transforms is larger in Cu_2O than in Ag_2O (Fig. 2); the effect of temperature is however much stronger for the 2nd shell in Ag_2O than in Cu_2O. For these reasons, the analysis of EXAFS data were particularly difficult for the 1st shell of Cu_2O and the 2nd shell of Ag_2O. In the case of Cu_2O, a further difficulty was represented by the closeness of the peaks. These considerations in part justify the scattering of data, particularly for the Cu-O and Ag-Ag distances.

4. Discussion

The NTE of the lattice parameter measured by XRD is much larger in Ag_2O than in Cu_2O (Fig. 1). This result is qualitatively reproduced by EXAFS, where the second distance Ag- Ag exhibits a strong contraction with the temperature, while the Cu-Cu distance variation is only slightly negative or zero (Fig. 4). Of the 12 M atoms of the 2nd shell, 6 belong to the same network of connected tetrahedra as the absorbing atom (type A), while the other 6 are between different networks (type B). EXAFS measures the average behaviour, weighted by the respective Debye-Waller factor [19]. The 1st-shell results (Fig. 3) emphasize the peculiarity of EXAFS with respect to XRD, but also again show a difference between Ag_2O and Cu_2O. The Ag-O bond length exhibits a strong increment with the temperature, while the Cu-O bond length expansion is only slightly positive or zero.

The EXAFS results for Ag_2O enlighten the competition between anharmonicity of the interaction potential (increment of Ag-O distance) and geometric effects (decrease of Ag-Ag distance, probably stronger for type B pairs) in determining the lattice NTE. In the case of Cu_2O this effect is by far weaker. Some clues on the local origin of NTE, as well as on the difference between the two compounds, can be obtained by looking at dynamical properties.

The MSRD Einstein frequency allows us to estimate an effective bond-stretching force constant [8]. The obtained ratio between M-O and M-M force constant is very similar for both compounds (Fig. 5): 9.8 ± 0.2 for Cu_2O and 9.1 ± 0.2 for Ag_2O. The high value of the ratios is related to the intense transverse thermal motion of the metallic atom with respect to the O-M-O direction, and should be directly connected with the origin of NTE [20]. The absolute MSRD values are however quite different (Fig. 5), Cu_2O exhibiting a by far less intense vibrational motion than Ag_2O. It is possible that the weaker dynamics observed in MSRD explains the weaker difference between 1st and 2nd shell thermal expansion measured by EXAFS in Cu_2O with respect to Ag_2O. The different shapes of the lattice thermal expansion curves (Fig. 1) could instead require, to be explained, interactions within a longer range than observable by EXAFS.

In the case of Ag_2O, a sophisticated comparative analysis of 1st and 3rd cumulants of the 1st shell allowed to deduce the lack of rigidity of the tetrahedral units, and consequently the inadequacy of a RUM model [7] in explaining NTE. The same analysis cannot be made for Cu_2O, owing to lower signal to noise ratio in the temperature dependence of cumulants. Nevertheless, the high value of the MSRD of Cu-Cu distance suggests that tetrahedral units are probably not rigid also in Cu_2O.

5. Conclusions

A combined EXAFS-XRD temperature dependent study on Cu_2O and Ag_2O has been reported. Both compound exhibit lattice NTE, although with different intensities and within different temperature intervals. EXAFS allows to distinguish a remarkably different behaviour between 1st and 2nd shells in Ag_2O (positive and negative expansion, respectively). The difference is by far less evident in Cu_2O. These results open new perspectives for getting original experimental information on the connection between local dynamics and NTE, and stimulate the development of suitable theoretical models.

Abstract

X-ray absorption fine-structure spectroscopy was used to ascertain the individual metal oxidation states involved during the electrochemical insertion and extraction of lithium with layered $Li_xNi_{0.5}Mn_{0.5}O_2$ electrodes in lithium cells. These results, along with electrochemical cycling data, suggest that the $Li_xNi_{0.5}Mn_{0.5}O_2$ ($0 < x \leq 2$) electrodes operate predominantly via two-electron redox couples, Ni^{4+}/Ni^{2+} and Mn^{4+}/Mn^{2+}, between 4.5 and 2.0 V ($0 < x \leq 1$) and below 1.07 V ($1 < x \leq 2$) versus metallic Li, respectively. In the upper voltage region, the Ni-O bond changes by nearly 0.14 Å, while the Mn-O bond remains at nearly a fixed length. In the low-voltage region, the $LiNi_{0.5}Mn_{0.5}O_2$ electrode undergoes a two-phase reaction with Li to form a dilithium compound, $Li_2Ni_{0.5}Mn_{0.5}O_2$; during this reaction, charge transfer occurs at the Mn metal center.

1. Introduction

Layered transition metal oxides ($LiMO_2$; M = transition metal ion) such as lithium cobalt oxide ($LiCoO_2$), lithium nickel oxide ($LiNiO_2$), or lithium nickel-cobalt oxides ($LiNi_{1-y}Co_yO_2$), are commonly used as cathodes in commercial Li-ion batteries. These materials have a layered structure with trigonal symmetry, R-3m. Metal-oxygen octahedra form a hexagonal array, while lithium is located between the metal oxide layers. During discharge of the battery, lithium ions are electrochemically inserted between the metal-oxide layers with a concomitant reduction at the metal center; the reverse process occurs on charging the battery. In most $LiMO_2$ electrodes, the transition-metal undergoes a reversible one-electron transfer process, shuttling back and forth from a trivalent state at full discharge to a tetravalent state at full charge. Recent developments have shown that it is possible to synthesize $LiMO_2$ compounds with Mn and Ni, such as $LiNi_{0.5}Mn_{0.5}O_2$ and $LiCo_{0.33}Ni_{0.33}Mn_{0.33}O_2$ in which the charge is distributed unequally between the transition metal ions [1–4]. Moreover, it has been recently discovered that $LiNi_{0.5}Mn_{0.5}O_2$ can accommodate an additional lithium ion to form a $Li_2Ni_{0.5}Mn_{0.5}O_2$ compound without destroying the layered $Ni_{0.5}Mn_{0.5}O_2$ framework structure [5, 6]. The aim of this work has been to study, by *in situ* X-ray absorption spectroscopy (XAS), the structural transformations and charge transfer processes that occur when lithium is inserted into, and extracted from an $Li_xNi_{0.5}Mn_{0.5}O_2$ electrode over a wide range of x ($0 < x \leq 2$). Other groups have reported XAFS data on this material [7–9]. However, the analysis has typically been limited to a qualitative evaluation. A quantitative discussion of the results can highlight some important characteristics of the material.

2. Experiment

The sample preparation is described in detail elsewhere [5]. Analysis of the metal composition by ICP-AES showed the as-synthesized material to be $Li_{0.906}Ni_{0.506}Mn_{0.494}O_2$, assuming complete oxidation [5]. The sample will be identified as $LiNi_{0.5}Mn_{0.5}O_2$ for clarity.

The battery cell was assembled in a polypropylene bag with lithium counter electrodes on either side of the metal oxide cathode. The cell construction is described in more detail in [10]. While in the beam, the bag cell was pressed between two 0.32 mm thick beryllium foils to ensure intimate contact between the electrodes and the separators as well as maintain a constant cell thickness during the experiment. During the measurements at high-potential, the cell current was 0.18 mA/cm^2, and the charge rate was approximately C/4. The second battery cell, for the low-potential studies, was heated to 50 °C to improve the reaction kinetics and increase the speed of the discharge to faster than a C/2 rate.

X-ray absorption fine-structure spectroscopy (XAFS) measurements were performed on the insertion device beamline of the Materials Research Collaborative Access Team (MRCAT) at the Advanced Photon Source (APS), Argonne National Laboratory. A cryogenic double-crystal Si(111) monochromator was used to select the X-ray energy and an uncoated ULE glass mirror was used to remove the higher-order harmonic content from the beam. The monochromator was continuously scanned using a bin size of 0.35 eV and time per data point of 0.06 s for the X-ray absorption near-edge structure (XANES). Extended X-ray absorption fine-structure (EXAFS) and XANES spectra for both the Mn and Ni K edges were collected at a repetition rate of about 10 minutes. Transmission XAFS measurements of Mn or Ni foils accompanied every measurement to provide energy calibration and place all data from either the Mn or Ni data sets on the same energy scale to within 0.05 eV. The first inflection points of the normalized absorption spectra were set to 6538.0 eV and 8333.0 eV, for Mn and Ni, respectively. Given this reference energy, the accuracy of the edge energies reported is within ±0.20 eV.

3. Data Analysis

The data were fit to scattering paths calculated with self-consistent fields using *feff* (version 8.2) [11]. The *feffit* code [12] was used to fit the data between $k = 2.5$–14 Å^{-1} ($k = 2.5$–11.5 Å^{-1} for Mn) and $R = 1.23$–3.19 Å. Eight variables ($2E_0$'s, $2R$'s, $2\sigma^2$'s, and $2N$'s) and three single-scattering paths (M-O, M-Mn, M-Ni, where M indicates Mn or Ni) were used in the fit. Identical values were used for all the M-M paths in an individual fit. Equal numbers of Mn and Ni were assumed for the second shell, although this precise distribution would require an unusual arrangement of the metal atoms. Nonetheless, the backscattering amplitudes and phases are sufficiently similar for this approximation to be useful. The residual error was typically about 1.5%. When the individual coordination numbers and

†email: kropf@cmt.anl.gov

distances were allowed to vary, we observed a preponderance of Ni around Mn and visa versa, as expected for most arrangements of the metal centers. In this case, we did observe an intermediate Mn-Ni distance. The XANES data were fit by both principle component analysis and a linear combination of spectra.

4. Results and Discussion

Figure 1 shows several examples of the $\chi(k)$ data for the Mn and the Ni edges. The Mn data range was limited by a very small Fe impurity in the sample. It is immediately clear that the Ni spectra are changing far more than the Mn spectra between 3.60 V and 4.60 V. Figure 2 shows the Ni-O and Mn-O bond lengths as a function of the scan number. The data were collected over the initial charge and a subsequent discharge and charge cycle. The cell potential (vs. lithium) is shown at several points on the plot. For the purposes of this fit, one Ni-O bond length was assumed. Between 3.60 V, the open circuit voltage (OCV), and 4.60 V, the Ni-O bond length decreased by nearly 0.14 Å, while the Mn-O bond length decreased by only 0.01 Å. The striking difference between the Mn and the Ni bond lengths is clear evidence that the Ni is the primary actor in the redox reaction, while the Mn is merely a bystander at higher potential. If one compares the Ni-O bond length ($R_{\text{Ni-O}}$) from this electrode with that from $LiNi_{0.8}Co_{0.2}O_2$ from [10] (1.89 Å to 1.93 Å), it is clear that the change in $R_{\text{Ni-O}}$ is much greater for $Li_xNi_{0.5}Mn_{0.5}O_2$. This corroborates the supposition that Ni is in a lower +2 oxidation state.

As $R_{\text{Ni-O}}$ changes from longer to shorter distance with Li extraction, the Debye-Waller factor increases from 0.007(1) $Å^2$ up to 0.012(1) $Å^2$ (scan 17) and then decreases to 0.005(1) $Å^2$ from 3.60 V to 4.60 V during the initial charge. At the extremes, when the Ni oxidation state is closest to +4 or +2, the Debye-Waller factor is at its lowest. If $R_{\text{Ni-O}}$ truly had a length characteristic of only the +2 and the +4 states, the Debye-Waller factor would increase to at least 0.023 $Å^2$, due to the separation of at least 0.14 Å between the two lengths. Since σ^2 does not exhibit this behavior, it leads to the interpretation that the Ni atoms have a global average oxidation state that changes smoothly, as suggested by the near-edge spectra, rather than individual Ni atoms snapping from +2 to +4.

Fig. 3 shows that less lithium is stored in the electrode during the first discharge than was removed during the first charge. This is consistent with the metal-oxygen distances from Fig. 2; at the end of the first discharge, the Ni-O distance does not recover to the initial distance of 2.04 Å, but only reaches 2.01 Å.

Figure 4 shows representative near-edge spectra from the initial charge. The near edge structure, being sensitive to the oxidation state provides an independent probe of the electrochemical reaction. The Mn edge spectra change shape somewhat during the initial charge, but do not shift in energy, indicating that the Mn oxidation state is relatively constant. On the other hand, the

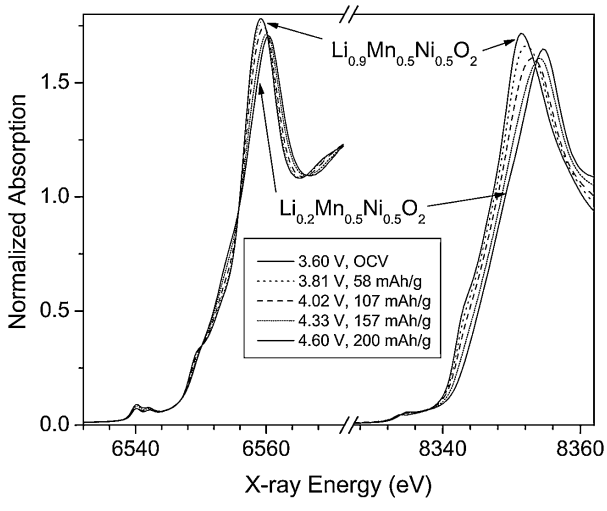

Fig. 4. Selected Mn (left) and Ni (right) XANES from initial charge.

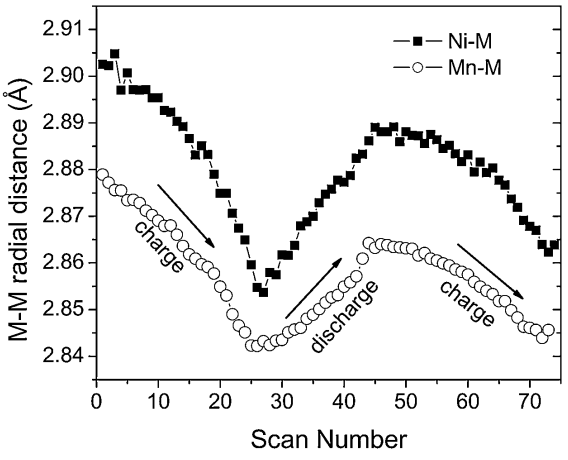

Fig. 5. Average Mn-*M* and Ni-*M* 2nd shell bond lengths. The metal-metal distance has been modeled by a single length. The relatively constant Debye-Waller factor of about 0.005 Å^2 indicates this is a reasonable choice.

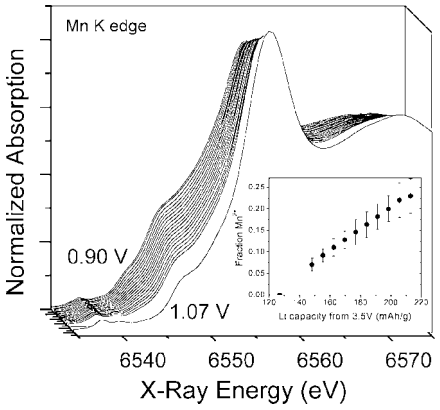

Fig. 6. Mn K edge XANES at low potential with the fraction of Mn^{2+} below 1.07 V (inset).

Ni edge ($\mu x = 0.5$) shifts to higher energy, from 8343.07 eV (at OCV, 3.60 V) to 8345.45 eV (at 4.60 V), as the lithium is removed. If one assumes a Mn^{4+} oxidation state and a fully oxidized sample (O^{2-}), one can calculate the expected Ni oxidation state from the measured composition. The initial average Ni oxidation state should be +2.21, while at the end of the first charge the oxidation state should be +3.61. By comparing the measured Ni XANES to Ni(II)O (8342.26 eV) and $LiNi(III)O_2$ (8344.67), we can estimate the Ni oxidation state to be +2.34 at the beginning of the measurement and +3.32 at the end. The as-prepared powder had an edge position of 8342.90 eV, only 0.17 eV lower than the electrode in the cell at the beginning of the measurement. Over the charge/discharge cycle, the Ni spectra behave similarly to other electrodes with similar structure, such as $LiNiO_2$ and $LiNi_{0.8}Co_{0.2}O_2$ reported in the literature [10, 13, 14].

Figure 5 shows the average metal-metal second shell bond lengths, reflecting the intralayer lattice parameter. Both the Mn-metal and the Ni-metal bond lengths decrease by about 0.04 Å, although the Ni-metal distance shrinks by a slightly larger amount. Since $R_{M\text{-}M}$ is changing by a similar amount for both Mn and Ni, while the Mn-O distance remains more or less constant, we conclude that the Mn and Ni are intimately mixed in the cathode and not phase-segregated; i.e., the Ni octahedra share edges with Mn octahedra.

If the Mn is not participating in the redox chemistry of the cell at high-potential, the Ni must cycle between Ni^{4+} and Ni^{2+}, possibly by a 2-electron process, to account for the capacity of the battery in the high-voltage region. Since the Ni edge shifts smoothly, this could indicate a global average oxidation state change, rather than a local change at individual Ni atoms.

Measurements of a second cell (with Li_2TiO_3 added) at low potential showed that the redox-active metal changes from Ni to Mn at around 1.07 V. This value could be somewhat lower than the actual potential due to the fast discharge rate. Figure 6 shows the Mn near-edge structure at low-potential. In contrast to the Ni, for which the edge position shifts smoothly from higher to lower energy with increasing lithium content, the Mn XANES spectra exhibit behavior that looks more as if the Mn is changing directly from 4+ to 2+; Mn^{2+}-like features increase as the cell potential decreases. This is consistent with a reaction that involves larger structural changes. Inset into Fig. 6 is a plot of the Mn^{2+} fraction as a function of cell potential. The Mn edge spectrum taken at 0.90 V was fit by a linear combination of the Mn^{4+} (from this cell) and a Li_2MnO_2 standard. By the end of the discharge, 23±4% of the Mn has converted to Mn^{2+}, or $Li_2Mn_{0.5}Ni_{0.5}O_2$.

The Ni edge position at 1.07 V is 8342.54, while at the end of the run, the Ni K edge energy was 8342.47 eV, a very small shift, and only 0.60 eV lower than the open circuit voltage at the beginning of the run. The Ni edge position is within 0.21 eV of the Ni(II)O standard.

5. Conclusions

Layered $LiMO_2$ compounds that contain manganese and nickel are attractive insertion electrodes for lithium-ion cells that operate at a high potential. Those that can accommodate an additional lithium within their structures, such as $LiMn_{0.5}Ni_{0.5}O_2$, hold promise for providing systems that remain stable over a very wide compositional range because the two-electron transfer processes, Ni^{4+}-Ni^{2+} and Mn^{4+}-Mn^{2+}, which occur during charge and discharge bypass the Jahn-Teller active ions Ni^{3+} and Mn^{3+} that can lead to more severe structural distortions and instabilities. Li_2MO_2 compounds are attractive because they can provide a source of excess lithium to compensate for the capacity that is typically lost at the negative electrodes of high-voltage lithium-ion cells during the first charge.

Abstract

The homogeneity of typical electrolessly plated Pd/Ag membranes for H_2 separation was investigated with XAFS and XPS depth profiling. Next the crucial mixing of the separate Pd and Ag layers, obtained after the two sequential plating steps, was followed in situ with XRD. The results show that some low temperature alloying procedures found in the field are insufficient for obtaining a well-mixed Pd/Ag alloy membrane.

Finally the Pd/Ag-H XANES was determined for the first time. In contrast to the Pd-H and Pd/Ag systems, shifts in electron density from the Ag or H atoms to the Pd could not satisfactorily explain the observed XANES. Not only is the intensity of the whiteline higher than expected, the shape and the intensity of the anti-bonding Pd 4d H 1s feature have also significantly changed. Local geometry is expected to account for these deviations.

1. Introduction

Thin $Pd_{77}Ag_{23}$ films on inert, porous supports such as α-Al_2O_3, Vycor glass or porous stainless steel are very important membrane materials [1–3]. Applications vary from separating H_2 from gas streams to use as a membrane reactor in hydrogenation or dehydrogenation reactions.

Electroless plating is the most suited technique for large scale production of these membranes. A typical electroless plating solution contains a metal salt, a strong reducing agent (here hydrazine), buffer reagents (here ammonia), water and a complexing agent (here Na_2EDTA). With electroless plating, in contrast to the electroplating technique, it is possible to deposit a metal film on a non-conducting support material such as Al_2O_3.

A Pd/Ag mixture is obtained by consecutively depositing a Pd and an Ag layer followed by a heat treatment to attain alloying. However there is no consensus on the required alloying treatment; temperatures vary from 450–900 °C, treatments last from a few hours to dozens of hours and finally both inert and H_2 atmospheres are used by different researchers [3–6].

Inadequate mixing is expected [4, 5] to seriously limit the performance and lifetime of the membranes. Therefore the homogeneity of the Ag distribution in typical electrolessly plated samples is studied in this paper with K-edge XAFS and XPS depth profiling. Furthermore the alloying of the Pd and Ag layers is studied *in situ* using XRD.

Finally the Pd/Ag-H system is studied as well; with L_3-edge XANES to learn more about the fundamentals of this system.

2. Experimental Section

The following samples were obtained with electroless plating: pure Pd on α-Al_2O_3, pure Ag on α-Al_2O_3 and samples with both a Pd (first) and an Ag layer (second) on α-Al_2O_3 (intended Ag content 23 at%). One of the Pd/Ag samples was alloyed at 500 °C under 5% H_2/He for 150 hours, the others were alloyed during the *in situ* XRD experiments described below. Visual inspection with SEM confirmed that the samples were several μm thick as intended.

A 750 nm $Pd_{80}Ag_{20}$ sample on a Si wafer (with 20 nm Ti adhesion layer) obtained with bi-sputtering, *i.e.*, the simultaneous sputtering of two pure targets to produce a binary alloy, was received from the MESA$^+$ institute of the University Twente.

Pd and Ag K-edge XAFS measurements were performed with the electrolessly plated samples at the X1 beamline of the HASYLAB facility in Hamburg, Germany. All measurements occurred in transmission mode. The samples were first measured in vacuum at 77 K. This was followed by one hour of exposure to H_2 (100 ml min^{-1} flow) at room temperature, after which the cells were closed, cooled to 77 K and the samples were measured again.

The XDAP 2.2.2 program was used for the data analysis. For each measurement at least two scans were averaged. In the subsequent procedure the pre-edge and background were subtracted, as described in [7], before fitting the data. The fit parameters can be found in Table I and II.

At the E4 beamline of the HASYLAB facility the L_3 XANES of pure, electrolessly plated, Pd and of the Pd/Ag bi-sputtered sample in vacuum and H_2 atmosphere (1.5 bar) were determined. The measurements were performed at room temperature using a fluorescence detector. At least two scans were averaged for each measurement. The pre-edges and backgrounds were subtracted and the measurements were normalised at 50 eV beyond the edge. Some saturation was visible when comparing the results to the literature [8]. A numerical compensation was determined for Pd and Pd/Ag under vacuum, which was also applied to the hydrogen measurements.

XPS depth profiling of the Pd/Ag samples were performed in our laboratory. In regular steps the metal layer was removed by sputtering with Ar^+ ions until the support material was detected. Unfortunately it is not possible to determine the amount of material removed with sputtering with our XPS set-up. Therefore, total thicknesses of the samples had earlier been determined with Rutherford backscattering with 2 MeV protons. Since the masses of the isotopes of Pd and Ag are too similar the two elements cannot be distinguished from one another with RBS. However the densities of the elements are also very similar so that there are no problems in determining the total thicknesses of the metal (alloy) layers. With the total thicknesses the rate of removal during XPS depth profiling could be calculated.

Co K-edge XRD ($\lambda = 1.78897$ Å) was used to study the alloying of the Pd and Ag domains *in situ* at temperatures from 400–600 °C in He. After the heat treatments the average Ag content was determined. For this purpose, a lattice constant vs. Ag content diagram was constructed using literature data [9, 10].

3. Results

3.1. *Homogeneity of the Pd/Ag mixtures*

In Table I the Pd K-edge and in Table II the Ag K-edge fit results are shown. Fits were carried out with the coordination number (N-cor) fixed at 12 (typical for the fcc structure).

The behaviour of the pure Pd and pure Ag membrane on exposure to H_2 was as expected: the Ag membrane showed no significant change and the Pd-Pd distance changed from 2.74 to 2.86 Å. The Pd-Pd distance in bulk Pd at 25 °C is 2.7511 Å [11]. The lattice constant of bulk β-$PdH_{0.6}$ at 25 °C is 4.025 Å [12], which corresponds to a Pd-Pd distance of 2.8461 Å. The Ag-Ag distance in bulk Ag at 25 °C is 2.8894 Å [11].

Also in case of the Pd/Ag sample the change in distance between the average Pd atom and its closest neigbours (Pd or Ag) on exposure to hydrogen corresponds with the literature values. However, the most interesting results are the Ag edge measurements of this sample.

The XAFS results suggest that on exposure to hydrogen a small change in distance to the nearest neighbour occurs, 2.81 to 2.83 Å, which can only be explained by the assumption that the average Ag atom has a relatively large number of Pd neighbours. Yet complete dissolution of atomic Ag in a true alloy of Pd and Ag is not achieved, seeing the large difference between the average Pd-X and Ag-X (X = Pd or Ag) distances. Either the Ag atoms are present in small clusters in a Pd sea or the metal layer consists mainly of Pd/Ag clusters (with different Ag contents).

The XPS depth profile of the Pd/Ag electrolessly plated sample showed an inhomogeneous Ag distribution; from 40 at% at the surface to 15 at% in the bulk and the bottom. Both microscopicly and macroscopicly the alloying is clearly incomplete.

In contrast; the Ag content of the bi-sputtered sample was very constant at 20 at% although the surface showed a small Ag enrichment (25 at%). This sample proves that a properly mixed Pd/Ag system can be synthesized. It is important to note that the result corresponds with the thermodynamic equilibrium [13, 14] and is therefore the most homogeneous Ag distribution obtainable.

With our XRD setup the alloying could be studied *in situ*. The reflections of the Pd and Ag domains present in the unmixed

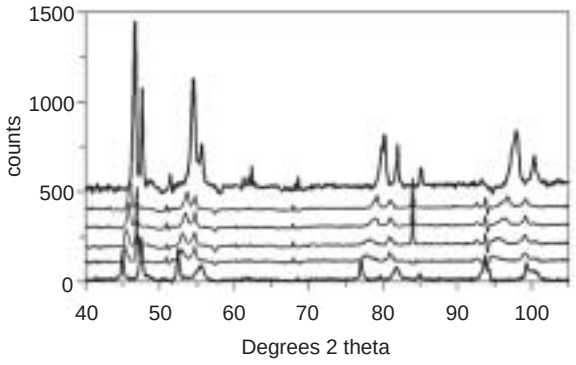

Fig. 1. From bottom to top: $t = 0$ (RT), $t = 3$ hours (375 °C), $t = 4$ hours (first measurement at 400 °C), $t = 18$ hours (400 °C), $t = 57$ hours (last measurement at 400 °C), $t = 60$ hours (RT).

electrolessly plated samples are nicely separated, as shown in figure 1. Beyond about 400 °C these reflections started to disappear and new Pd/Ag alloy reflections appeared. However even after 54 hours at 400 °C the reflections of the separate Pd and Ag domains were not completely removed.

Shorter periods of time (<20 hours) at 500 and 600 °C did completely remove these reflections. Yet the XPS depth profile of the sample alloyed at 500 °C (for a total time of 30 hours) showed that the thermodynamic equilibrium had not yet been reached and the sample was still quite inhomogeneous; the Ag content varied from 38 at% at the surface to 18 at% at the alumina support. Obtaining an Ag profile as homogeneous as the bi-sputtered sample requires a more intense treatment.

3.2. *The Pd/Ag-H XANES*

Figure 2a shows that the addition of Ag to Pd gives a lower white line, which is in agreement with results in the literature [8]. This

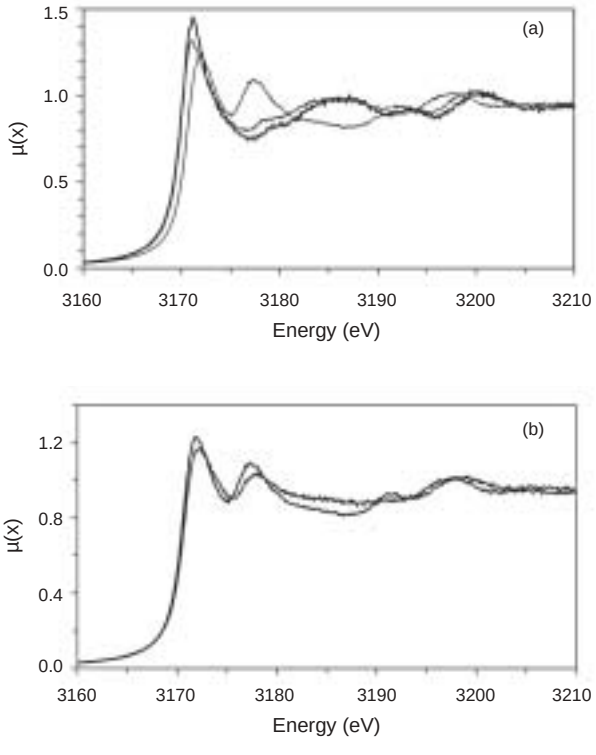

Fig. 2. (a) Pd in vacuum (black), Pd/Ag in vacuum (grey) and Pd in H_2 (thinner line). (b) Pd in H_2 (black) and Pd/Ag in H_2 (grey).

can be attributed to a decrease of the number of 4d holes in Pd, *i.e.*, to a shift of electron density from the Ag to the Pd metal. The peak at approximately 3200 eV is shifted to lower energy for Pd/Ag, indicating an increase in the lattice constant, in full agreement with the EXAFS analysis. In addition, figure 2a shows that dissolving hydrogen in Pd causes a decrease in whiteline intensity, a blue shift and a new peak at +7 eV from the whiteline [15]. This new feature is attributed to the unfilled Pd4d-H1s anti-bonding orbital and the decrease of the white line is expected because part of the empty Pd 4d states are now part of this anti-bonding orbital.

As far as we are aware of, the XANES of the Pd/Ag-H system has not yet been reported. Figure 2b, indicates that the Pd/Ag-H system is not a simple combination of the separate effects of Ag and H described above. Not only is the intensity of the whiteline higher then expected, the shape and the intensity of the hydrogen feature have also significantly changed. In our opinion these changes are a reflection of differences in the local geometry between Pd-H and Pd/Ag-H. Several effects can cause the more intense white line and broader anti-bonding state of Pd/Ag-H, for example: (1) a displacement of the H atoms from their normal octahedral position because of a preference for Pd atoms, (2) (some) clustering of Ag atoms within the Pd sea, (3) local deviations from the bulk lattice constants resulting in a range of slightly different storage sites for hydrogen atoms. The averaged local geometry obtained with XAFS cannot settle this discussion yet. At this time FEFF 8.0 calculations are performed to check whether changes in local geometry can explain our observations in more detail.

4. Conclusions

Alloying of Pd and Ag starts at low temperatures (400 °C), nevertheless achieving total bulk mixing is more problematic. Some low temperature alloying procedures found in the field most likely have resulted in inhomogeneous Ag distributions.

For the first time the Pd/Ag-H XANES was determined. The current model of electron density shift cannot completely explain the observed differences in the XANES of Pd-H and Pd/Ag-H. It is expected that local geometry has a strong influence as well, which is currently being researched with FEFF 8.0 calculations.

Abstract

When complex metal oxides show locally ordered substitution of cations amongst crystallographic sites, a single-model description of the structure is relatively straightforward. Distinct local and long-range space groups, element specific cation sites, and local distortions of the oxygen lattice may be employed to give a reasonable description of the structure. Averaging over possible orientations of the local cell may be performed to simulate the effect of domain structure or stacking faults where a dual space group description is inappropriate. Full multiple scattering calculations, over multiple edges, may be performed using these models, allowing all the XAFS data to be analysed within a cluster of 5 Å or more, and information on cation-cation correlations may thus be obtained. When substitution is more or less random, such approaches are less helpful. In order to extend the range of compounds which can be studied using the combined XAFS/Powder Diffraction (PD) method, a Reverse Monte-Carlo method has been developed, which includes multiple scattering XAFS contributions, and allows crystallographic symmetry to be superimposed on the finite model. Various restraints can be applied, for example, to minimise the difference between the structure and the starting model, to maximise the symmetry of a particular site, or to minimize unreasonable departure from bond valence sums. The necessity for such a method and an example of its application is given by reference to the disordered 8–8–20 perovskite derivative $La_8Ni_4Co_4O_{20}$.

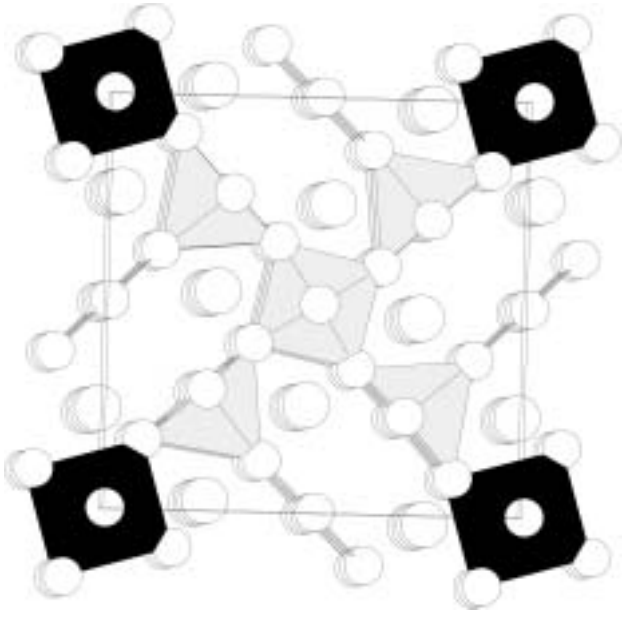

Fig. 1. The structure of $La_8Ni_4Co_4O_{20}$ in the $P4/mbm$ model.

1. Introduction

1.1. *8–8–20 perovskite derivatives*

The 8–8–20 perovskite derivatives are formed when topotactic reduction of fully oxygenated precursors gives rise to an ordered superstructure of oxygen vacancies, where omission of alternate rows of oxygen produces a combination of square planar (4-fold), square pyramidal (5-fold) and octahedral (6-fold) sites rather than the solely octahedral B sites of the parent compound (see Fig. 1). At least three different cations (including both A or B sites) must be present in order for the structure to be stable. These compounds have been extensively studied by powder neutron diffraction and XAFS methods [1–3], in order to unravel the complex local structure resulting from the lack of, partial, local, or complete ordering of their cation sites. XAFS was immediately able to identify those sites which were largely ordered, and those which were not, and indicated significant local distortions of the structure around cation sites in all the compounds studied, in comparison with the accepted structure. This structure was initially described from $La_{6.4}Sr_{1.6}Cu_8O_{20}$, as tetragonal, $P4/mbm$. Our conclusion, from having studied the systems $La_8Ni_4Co_4O_{20}$, $La_8Ni_{6.4}Mn_{1.6}O_{20}$, $La_{6.4}Ca_{1.6}Cu_6Ni_2O_{20}$ and $La_{6.4}Ca_{1.6}Cu_6CoO_{20}$ is that many of the distortions revealed by the XAFS/neutron PD refinement, and the weak additional reflections observed in some PD patterns, can be explained if a doubling of the c-axis is assumed, and an orthorhombic space group of $Pbnm$ (or $Pnma$ etc.) is used. This new cell is $2\sqrt{2} \times 2\sqrt{2} \times 2$ in terms of the basic perovskite cell. We believe this is the true space group for all the compounds we have studied, and it will therefore be used as the starting point of the analysis. However, it does not explain all the features of the XAFS spectra. Additional distortions, which are probably not ordered throughout the cell, are found in all the compounds. We note that the true stoichiometry of the cell is therefore 16–16–40.

1.2. $La_8Ni_4Co_4O_{20}$

The method described here was developed initially to resolve problems encountered in a previous analysis of compounds such as $La_8Ni_4Co_4O_{20}$ [1, 3]. Although a subsequent refinement in $Pnma$ was more successful than in the tetragonal space group used originally, a number of problems remain. The fit to the Co K-edge is actually rather good, due to a near perfect fit to bonded oxygen shells. There are significant discrepancies in the fit, however, for non-nearest neighbours. The Ni K-edge data has similar discrepancies, and in addition has a very poor fit to the first shell, for which the model produces a shell that is at too long a distance, and different in profile. The fit to the PND is also about 2% worse, in terms of the commonly used measure of fit (R_{wp}), than to the end-member or similar compounds. A number of procedures were attempted in order to improve the model, and accommodate local distortions in the lattice: The Ni/Co (5-fold) site, which is in a general position, was allowed to assume a different coordinate depending on its occupancy, nearest-neighbour dependency of the oxygen coordinate was

accommodated, by adding a neighbour dependent translation vector to the bridging oxygen coordinate, so Co−O−Co, Ni−O−Co and Ni−O−Ni can differ in terms of bond distances and angles, and the use of a dual *Pnma*/*P*1 space group, allowed the local structure seen by XAFS to be independent of bulk symmetry. None of these approaches were successful. In addition, the structure was analysed by refining the shell coordinates in order to fit the XAFS data. Although more successful in fitting the spectra, it was not possible to derive a useful model of the structure using this approach.

2. Method

2.1. *Reverse Monte-Carlo method*

The most obvious approach to solving such a structure is the Reverse Monte-Carlo (RMC) approach [4–10]. With this method, the starting model for crystalline materials is a supercell of the crystal lattice, presumed to have periodic boundary conditions. A fitting function χ^2 is calculated, utilising the sum of squares of residuals from the fits to experimental data, together with those for any restraints that are to be applied to the solution. Random changes are made to the coordinates of the model, which are accepted with probability $P(\Delta\chi^2) >= 0$ if $\Delta\chi^2$ is +ve or 1 if $\Delta\chi^2$ is −ve. The procedure is then repeated until convergence to a minimum has been achieved. A number of obstacles to using the method for cases such as $La_8Ni_4Co_4O_{20}$ exist however. These are the complexity of the crystal structure, and the fact that multiple scattering (MS), which dominates the non-nearest neighbour structure, must be included in order to derive information on metal-metal distributions and metal-oxygen-metal bond angles. This makes the calculation intrinsically more time consuming. As the neutron data that is available is not amenable to whole-profile fitting, Bragg peaks only are required. However, a small supercell behaves essentially like a *P*1 cell. It may give rise to all possible reflections, and all supercell reflections. These only disappear for very large system sizes (10 s of thousands of atoms). Smoothing of supercell reflections is possible, but is not an ideal solution. XAFS however, requires only an average over a few tens of each atom type to reproduce the data. The procedure has therefore been modified in a number of ways to allow the XAFS of systems involving randomly substituted sites to be analysed using the RMC method. In particular, when the powder pattern is calculated, the space group symmetry is applied to each atom, and the occupancy reduced by a factor equal to the multiplicity of the general position. This is equivalent to generating an extended cell, containing all symmetrically unique orientations of the supercell. Multiple scattering is included, at least approximately, in the XAFS calculations. Some changes have also been made to improve convergence for crystalline materials. The need for this can be illustrated using a combined fit to Cu metal. It is very easy to fit the first shell of Cu. It is simply necessary to add a random vector $\boldsymbol{V} = 2\sigma\boldsymbol{R}(\boldsymbol{r}_i, 0\text{–}1)$ where σ^2 is the mean square variation in first shell distance, $\boldsymbol{R}(\boldsymbol{r}_i, 0\text{–}1)$ a random vector between 0 and 1, of dimension N (number of atoms), which modifies each box coordinate $\boldsymbol{r}_i$. It is subsequently very hard to achieve further convergence for the outer shells, and for the powder diffraction profile, although an increase in the higher cumulants of the first shell is soon observed. The solution adopted here is to move atoms as clusters rather than individually. Normally a cluster is the bonded coordination sphere, or 13 atoms in Cu. This allows the expected gradual increase in the 2nd cumulant to develop, allowing a good fit to both XAFS and PD data. In general, convergence may be quite dependent on step size, so the step size may be varied, if necessary for each atom type individually. The refinement procedure for $La_8Ni_4Co_4O_{20}$ involved stages which moved all the atoms, the cluster, or individual atoms as required.

2.2. *Analysis of $La_8Ni_4Co_4O_{20}$*

Room temperature powder neutron diffraction data and the XAFS spectra above the La L_{III}, Ni K and Co K edges were refined using the MS RMC method, using the program P [11]. Details of sample preparation and data collection have been previously described [1, 3]. The starting configuration was a box of 27 unit cells, 1996 atoms in total, refined using a conventional XAFS/PD analysis. The B sites were randomly occupied by Co and Ni cations. A minimum cut-off distance of 1.7 Å was used as a constraint, with any step generating shorter distances being rejected. Three refinements were performed, using increasing weightings of a constraint which minimised departure from the original structure. Results are presented for the third, which appeared to show the greatest degree of convergence. The cluster size used for XAFS calculations was 5.5 Å. Multiple scattering was limited to paths involving only two different scattering atoms, in which the first was always oxygen. For M−O−M′−M paths, scattering angles were always obtuse at the oxygen atom, with angles greater than about 130° being included. For M−O−O−M paths, scattering angles were acute at each scattering atom. The final result, however, involved a complete MS calculation for the 5.5 Å cluster. Minimising the discrepancy between the two calculations is one of the most difficult aspects of the technique, and is the subject of ongoing development. The program is able to derive a great deal of information from the atomic coordinates, *via* the moments of different distributions. As the initial configuration is 'remembered', the cumulants of the atomic positions, modulo $\boldsymbol{r} = (a, b, c)$, can be displayed. The second cumulant is therefore equivalent to the anisotropic displacement factor for the atom. The cumulants of the individual paths may be classified by atom type, by crystallographic site, and in the latter case, sub-divided according to the character of the next-nearest neighbour. This may yield individual bond distances and mean-square variation in path length, in the very restricted case that an interatomic distance obeys a strict geometric rule, in which thermally averaged distances are strictly a function of their first few neighbour atom types. Evaluating these relationships remains a long term goal of this method. As we cannot yet confidently equate distances derived from the refinement with chemical bond distances, no attempt has been made to estimate errors in the distances.

3. Results

Refinement produced fits (see Fig. 2) which had none of the obvious problems of those derived from the starting values, with a good fit to both the Co and Ni K edges. The fit to the La L_{III} edge is less satisfactory, in part due to the exclusion of 3-scatterer MS paths during the course of the refinement, but also because the presence of two-electron channels causes perturbations in the background, reducing the quality of fit even for model compounds. For the powder diffraction data, R_{wp} (in %) is reduced by 1. Given the large number of distinct metal-metal distances, and the similarity of the scattering factors for Ni and Co, it would not be expected that a refinement, using minimal restraints, could yield a unique solution, where all distances and angles are chemically

realistic. Rather, these initial weakly constrained refinements were intended to demonstrate the feasibility of the method, and provide insights into the mechanism by which randomly substituted cations are incorporated into the structure. The results of the refinement are shown in Table I. The positions of the oxygen atoms originally in special positions x, 1/4, z in *Pnma*, remain so, with mean y values very close to 0.25. Similarly, Co atoms in positions 0, 0, 0 (6 fold), and 0, 0, 1/2 (4 fold), stay close to these positions. Ni atoms show larger off-site movements, and this appears to be a critical factor in explaining the structure. Both Co and Ni in the 5-fold sites show large movements, probably because the initial position was a compromise between XAFS and neutron diffraction data. The overall bond valence sums of 2.003 fo Ni^{2+}, 2.241 for Co^{2+} and 2.860 for La^{3+}, are within or close to acceptable values. For La, Co and some of the oxygen atoms the second cumulants of the positions are on average similar to the expected thermal contribution to disorder. For some Ni coordinates, and other oxygen coordinates, however, they are clearly larger. This is especially true of the O atoms (O11) which link the square pyramidal sites along the *b*-axis (i.e., the *c*-axis of the tetragonal model). This could be due to a genuinely random distribution, or the presence of two or three alternate neighbour-dependent sites. As it is not yet clear whether such detailed information can be trusted or how error bars can be obtained, no attempt has been made to pursue the analysis for the 5-fold sites, except to note that for Ni, axial elongation makes the site closer to square planar than for Co. For the bonds linking the square planar and octahedral sites along the *b*-axis most of the distances appear plausible, and reveal for example that Co−Co distances are longer than Ni−Ni distances, as well as the expected result that mean Ni−O distances are shorter than Co−O distances.

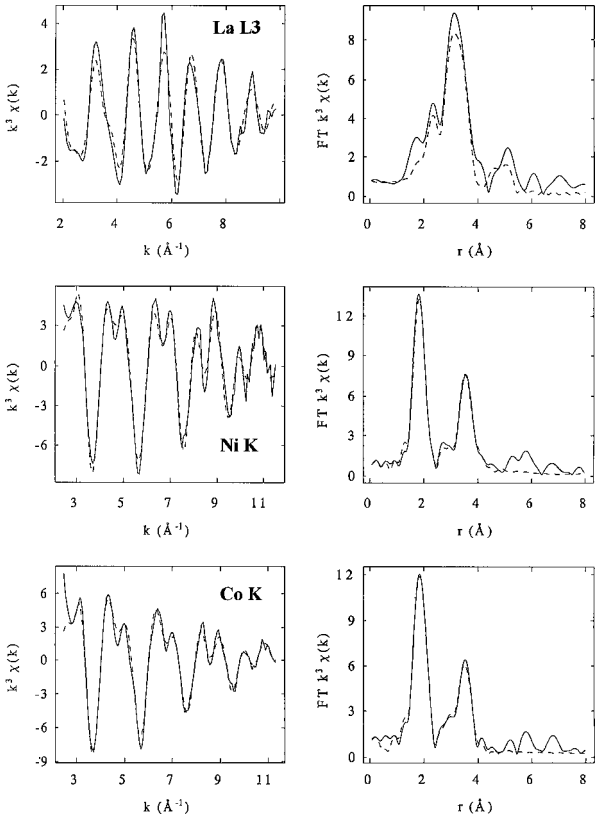

Fig. 2. Fit to the La L_{III}, Ni K and Co K edges of $La_8Ni_4Co_4O_{20}$ using the multiple scattering reverse Monte-Carlo method.

Selected values are given in Table II. Bond angles appear to be highly conserved throughout the structure.

4. Conclusions

$La_8Ni_4Co_4O_{20}$, synthesised directly from its fully oxygenated precursor, forms an ordered Pmna structure in which the three types of B site are randomly occupied by Ni or Co. (Occupancies $50+/-5\%$ of each atom). Although the initial fit to the XAFS and powder data was poor, a Multiple Scattering RMC approach has shown the feasibility of this model. A number of new features, which improve the RMC method as applied to complex crystalline materials, have been described. For the 4- and 6-fold sites, Co occupies special positions in the lattice. Ni however, occupies off centre positions in at least one of these sites.

Oxygen in special positions in *Pnma* remains in special positions during the RMC refinement, but other oxygen coordinates vary according to the nature of the neighbouring atoms. A more detailed description of this process will require the use of additional restraints, in order to test simple physical models. An example would be that the M-O Debye-Waller terms, for a specific M′-O-M-O-M″ linkage, would be restrained using values derived from end-member compounds.

Abstract

It is well known that metallic contamination on the silicon wafer, suffered during VLSI fabrication processes such as thin film depositions and etching, brings about lowering device performance. Determination of the chemical or structural properties of contamination metals is necessary in order to specify and remove the cause of contamination. However, the measurements are extremely difficult, because the contamination metals have very low concentrations. Grazing incidence XAFS by the X-ray fluorescence yield method is useful for the purpose. We applied the technique for the investigation of iron and copper contaminations on silicon wafers after fabrication processes.

The silicon wafers contaminated intentionally in the process chamber were used as samples. The contamination level of iron and copper was of the order of 10^{11}–10^{13} atoms/cm^2. The measurements were performed at the beamline 12C of the Photon Factory in KEK. The incident angles from the silicon surfaces were about 1 degree. A Lytle type ionization chamber was used in order to detect X-ray fluorescence photons in large solid angles. Good quality spectra were obtained. It was found from the analysis of the spectra that iron is mainly binding to fluorine and copper is binding to chlorine. The results were very useful for process improvements.

1. Introduction

It is well known that metallic contamination on a silicon wafer, suffered during VLSI fabrication processes such as thin film depositions and etching, brings about lowering device performance. Conventionally, using ICP-MS or X-ray fluorescence techniques, the quantitative analyses of trace elements for silicon wafers treated through some semiconductor process are conducted, and the obtained data are used for improvements of fabrication instruments and process sequences.

However, with growing and diversifying the ULSI fabrication process, a great number of experiments, such as quantitative analyses after process treatments, become required for reducing metallic contaminations. If the determination of the chemical bonding of each contamination metal is possible, we can identify process steps or conditions for occurring metallic impurities, and improve components and materials of the fabrication system and consequently reduce metallic contaminations. Because of low concentrations of metals on the silicon wafer, XAFS is the only technique for chemical state or structural analysis.

We have determined the local structures around residual iron and copper elements treated through the titanium nitride film deposition process with XAFS analysis using the fluorescence yield method.

2. Experimental

2.1. *Sample preparation*

The silicon wafers were set into the TiN film deposition chamber after cleaning. The samples were treated according to the conditions shown in Table I. Three kinds of samples, suffering different contaminations, were prepared. The contamination levels of iron and copper of the prepared samples were found to be of the order of 1×10^{11}–10^{13} atoms/cm^2 using the total reflection X-ray fluorescence method.

Table I. *Condition of sample preparation.*

Wafer temperature	580 degree	
Deposition stepping time	30 s	
Pressure in process	40 Pa	
Gas flow condition*	$TiCl_4$	30 sccm
	NH_3	400 sccm
	N_2	350 sccm
Dry cleaning condition	ClF_3	200 sccm
	N_2	1300 sccm

*For preparation of XAFS samples $TiCl_4$ gas was NOT flowed.

2.2. *Measurements*

X-ray Absorption spectra for Fe-K and Cu-K absorption edge were obtained at the beamline 12C of the Photon Factory [1]. Fluorescence yield mode was used because of the very low concentration, and the X-ray beam was incident on the sample at grazing angle in order to cut down diffraction lines from the silicon substrate. Lytle type detector was used. One of the obtained spectra is shown in Fig. 1. It is found that the quality of these spectra is very good even if the contamination level is of the order of 1×10^{11} atoms/cm^2.

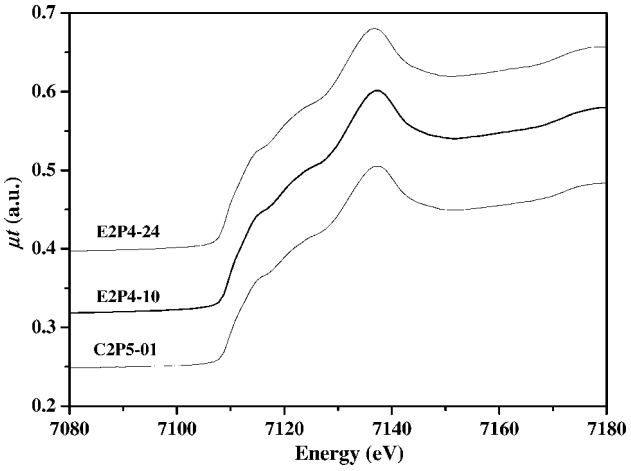

Fig. 2. Fe-K XANES spectra of various samples with different contamination levels.

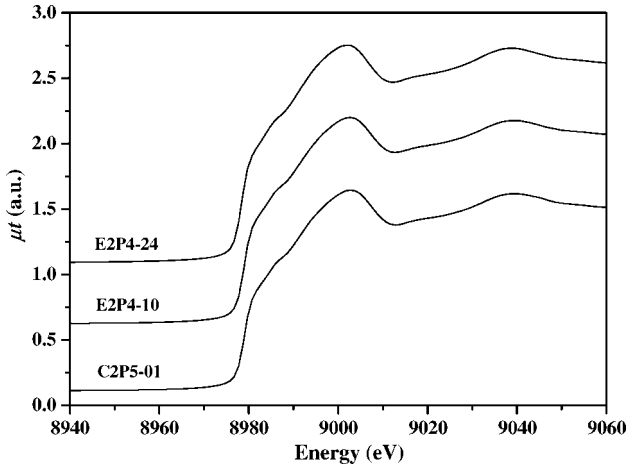

Fig. 3. Cu-K XANES spectra of various samples with different contamination levels.

3. Results and discussion

3.1. *Experimental results*

Fe-K XANES spectra and Cu-K XANES spectra of the samples with various contamination levels are shown in Fig. 2 and Fig. 3. For all contamination levels, no differences in the Fe or Cu-K XANES spectra are found.

The chemical structures of Fe contaminations turned out to be neither metal nor oxide from the features of the XANES spectra. In the case of Cu contaminations, the same results were derived from XANES.

3.2. *Curve fitting results and discussion*

Figure 4 shows the results of Fourier transform for Fe, and Table II the structure parameters and each error range obtained by curve

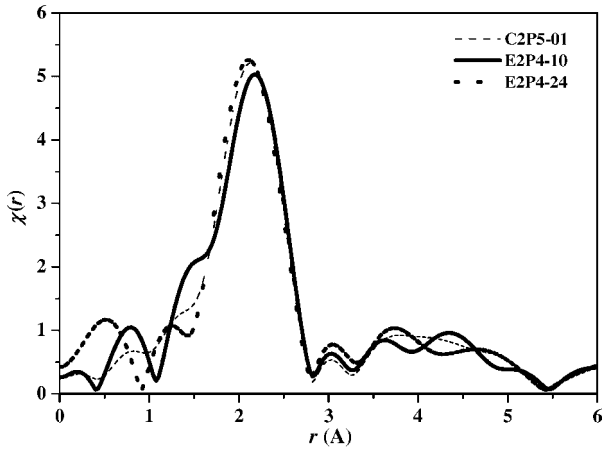

Fig. 4. Results of Fourier transform and curve fitting for Fe.

fitting. Fourier transform was carried out for the k^3-weighted spectrum in the range of $k = 2$ to $9\,\mathrm{A}^{-1}$. Table II indicates the coordination number of Fe-Cl of each sample as 5.4 to 5.9, and the distance between Fe and Cl is about 2.48 A. In contrast the coordination number of Fe-F is only 0.3. The same results are derived from every contamination level. In consequence, it was found that almost all Fe atoms on the silicon wafer bond with Cl atoms regardless of Fe concentration. It is inferred that the Cl atoms are originated in ClF_3 dry etching gas.

The results of Fourier transform for Cu are shown in Fig. 5, and the structure parameters and each error range obtained by curve fitting are shown in Table III. In Table III, the coordination number of Cu-Cl is about 0.6 while that of Cu-F is about 5.4, and the distance between Cu and F is about 2.60 A. These results do not change with the contamination level as well as in the case of Fe. It turns out that Cu atoms combine with F atoms in contrast to Fe contaminations.

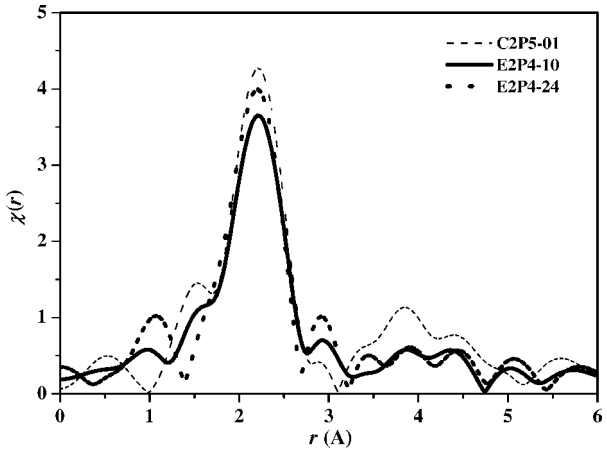

Fig. 5. Results of Fourier transform and curve fitting for Cu.

Table II. *Structure parameters of Fe obtained as the result of the curve fitting.*

	C2P5-01		E2P4-10		E2P4-24	
	n	*r* (Å)	*n*	*r* (Å)	*n*	*r* (Å)
Fe-Cl	5.7 ± 0.06	2.48 ± 0.01	5.4 ± 0.1	2.48 ± 0.02	5.9 ± 0.1	2.46 ± 0.02
Fe-F	0.3 ± 0.1	1.95 ± 0.01	0.3 ± 0.1	1.94 ± 0.02	0.2 ± 0.1	1.98 ± 0.01

*Each error range is obtained from curve fitting.

Table III. *Structure parameters of Fe obtained as a result of the curve fitting.*

	C2P5-01		E2P4-10		E2P4-24	
	n	*r* (Å)	*n*	*r* (Å)	*n*	*r* (Å)
Cu-Cl	0.5 ± 0.1	2.55 ± 0.09	0.6 ± 0.3	2.54 ± 0.06	0.7 ± 0.3	2.54 ± 0.05
Cu-F	5.5 ± 0.2	2.60 ± 0.03	5.4 ± 0.15	2.60 ± 0.07	5.3 ± 0.2	2.60 ± 0.07

*Each error range is obtained from curve fitting.

The contamination metals on the silicon wafer proved to form compounds bonded with atoms dissolved from ClF_3 dry etching gas. ClF_3 dissociate into Cl and F atoms or ions, and Cl atoms bond with Fe atoms. On the other hand F atoms combine with Cu atoms. In spite of richness of ClF_3 gas in the chamber, Cl and F atoms bond selectively. The reasons of the selectivity were not made clear in the present work.

4. Conclusion

In order to investigate the chemical bonding state of the metallic contamination on the silicon wafer, Fe and Cu-K EXAFS spectra were measured. The EXAFS spectra were clearly obtained even though the contamination level of the copper or iron was of the order of 1×10^{11} atoms/cm^2. No differences in the points in each spectrum for different contamination levels were detected. From results of the Fourier transform and curve fitting, it was proved that Fe-Cl and Cu-F are the main chemical states in the contamination. However, the reason for that selectivity of bonding was not identified.

Received June 26, 2003; revised October 31, 2003; accepted February 6, 2004

Abstract

XAS provides clear evidences that the tetravalent cations are not incorporated within Layered Double Hydroxide (LDH) sheets. The cations are segregated, presenting a local order close to that of SnO_2 rutile. However, the nature of the LDH influences slightly the local order probably due to some surface effect microtexture. Variation of the cell parameters for the LDH materials are explained by a substitution of Al cations by divalent cations M(II).

1. Introduction

The Layered Double Hydroxide (LDH) structure is referred to as the natural hydrotalcite, and described with the ideal formula, $[M^{II}_{x}M_{1-x}{}^{III}(OH)_2]_{intra}[A^{m-}_{x/m}\cdot nH_2O]_{inter}$, where M^{II} and M^{III} are metal cations, A the anions and *intra* and *inter* denote the intralayer domain and the interlayer space, respectively. The structure consists of brucite-like layers constituted of edge-sharing $M(OH)_6$ octahedra [1]. Partial M^{II} to M^{III} substitution induces a positive charge for the layers, balanced with the presence of the interlayered anions.

Some authors have reported the possibility to incorporate tetravalent cations into LDH-type layers, M(IV) = Zr and Sn over a large composition range [2], and claimed that up to 30% of Al could be isomorphously substituted by Sn(IV) to form a new MgAlSn ternary LDH. However, no detailed structural local picture has been supplied to ascertain the substitution process so far. In the present study, the question whether Sn^{4+} is incorporated into two LDHs, MgAlSn and CoAlSn, is investigated by XAS spectroscopy at Co and Sn K-edge.

2. Experimental

2.1. *Preparation of the samples*

$SnCl_4.5H_2O$ (Acros), $Mg(NO_3)_2.6H_2O$ (Acros, 99%), $Co(NO_3)_2.6H_2O$ (Aldrich, 99%), $Al(NO_3)_3.9H_2O$ (Acros, 99%), NaOH (Acros, 97%), $Na_2CO_3.10H_2O$ (Acros, 99%) were used as received.

All the hydrotalcite-like materials were prepared by the co-precipitation method according to Miyata [3]. Experimentally, 250 ml solution of the salts $M^{II}(3\cdot10^{-2}\,M)$ Al $(4(0.25-y)\cdot10^{-2}\,M)$ and M^{IV} $(4y\cdot10^{-2}\,M)$ of desired cation ratio was added dropwise to a solution of mixed NaOH (2 M) and Na_2CO_3 (0.3 M), as described by Velu *et al.* [2]. The pH is kept constant during the addition, pH of 10 ± 0.1 for the system $Mg_{0.75}Al_{0.25-y}Sn_y$ and 9 ± 0.1 for $Co_{0.75}Al_{0.25-y}Sn_y$. The slurry is aged overnight, centrifuged, and then washed several times with distilled water and finally dried at room temperature.

2.2. *Techniques of Characterization*

Powder X-ray diffraction profiles (PXRD) were obtained with a Siemens D500 X-ray diffractometer with a diffracted beam monochromator Cu K_α source.

2.3. *X-ray absorption spectroscopy*

2.3.1. *Co and Sn K-edges.* XAS studies were performed at LURE (Orsay, France) using X-ray synchrotron radiation emitted by the DCI storage ring at the D44 beam line. Data were collected at 77 K in transmission mode at Co and Sn K-edges (7708.9 and 29200.0 eV, respectively) using a double-crystal monochromator Si (111) and Ge (400), respectively. The energy was scanned in 2 (or 4) eV-steps from 100 eV below to 900 eV above each K-edge, and three spectra were recorded for each sample. An accumulation time of 2 s was used per point.

Extraction and analysis of EXAFS data was performed following standard procedures [4]. The $\chi(k)$ signal was fitted by using the classical single scattering approximation: $\chi(k) = S_0{}^2\Sigma A_i(k)\sin[2k\cdot r_i+\phi_i(k)]$, with $A_i(k)$ amplitude equal to $(N_i/k\cdot r_i{}^2)F_i(k)\exp(-2k^2\sigma_i{}^2)\exp(-2r_i/\Gamma)$, where r_i is the interatomic distance, ϕ_i the total phase shift of the ith shell, N_i the effective coordination number, σ_i the Debye-Waller factor, $F_i(k)$ the backscattering amplitude and Γ the mean-free path. To estimate the relative part of the cations contributing to the metal-metal correlation, the number of backscattering atoms was free to move during the refinement. This guarantees all possible cation ratios for the second shell. Phase and amplitude were taken from Mac Kale files and the validity for the refinements was tested against different reference compounds SnO_2, Co_2SnO_4, Mg_2SnO_4, $CoAl_2O_4$, $Co(OH)_2$. All results were similar using phase and amplitude extracted from FEFF 8 for MAC.

3. Results and discussion

Two hypotheses are possible: the cations Sn^{IV} are incorporated into the LDH sheets or they are segregated and form a coating. In the first case, the LDH composition is a function of the cations Sn^{IV} content, y in $M^{II}{}_{0.75}Al_{0.25-y}Sn^{IV}{}_y(OH)_2(CO_3)_{(y+0.25)/2}\cdot nH_2O$, in the second, it involves merely a change in the cation ratio M^{II}-Al^{III}, and the composition is a function of x, Al^{III} content and the formula becomes $M^{II}{}_{1-x}Al_x(OH)_2(CO_3)_{x/2}\cdot nH_2O$.

The ratio between cations are close to the expected values, indicating that the reaction was complete. The X-ray patterns for the two LDH systems are displayed in Figure 1. Diffraction peaks are typical of the layered double hydroxide structure, and the reflections were indexed in a hexagonal lattice with a R-3m rhombohedral symmetry, commonly used for the description of the LDH structure. For all the studied systems, the apparent incorporation of tetravalent cations induces a decrease in crystallinity, as the diffraction lines become wider, (110) and (113) are lumped together.

Concerning the local order, we surmise that cations Sn(IV) located inside LDH sheets must fulfil at least two conditions:

- no short Sn-Sn correlation. This would imply the presence of a segregation between LDH and Sn-based entities.
- Sn-M(II) correlation at a distance of ***a***, as expected for LDH.

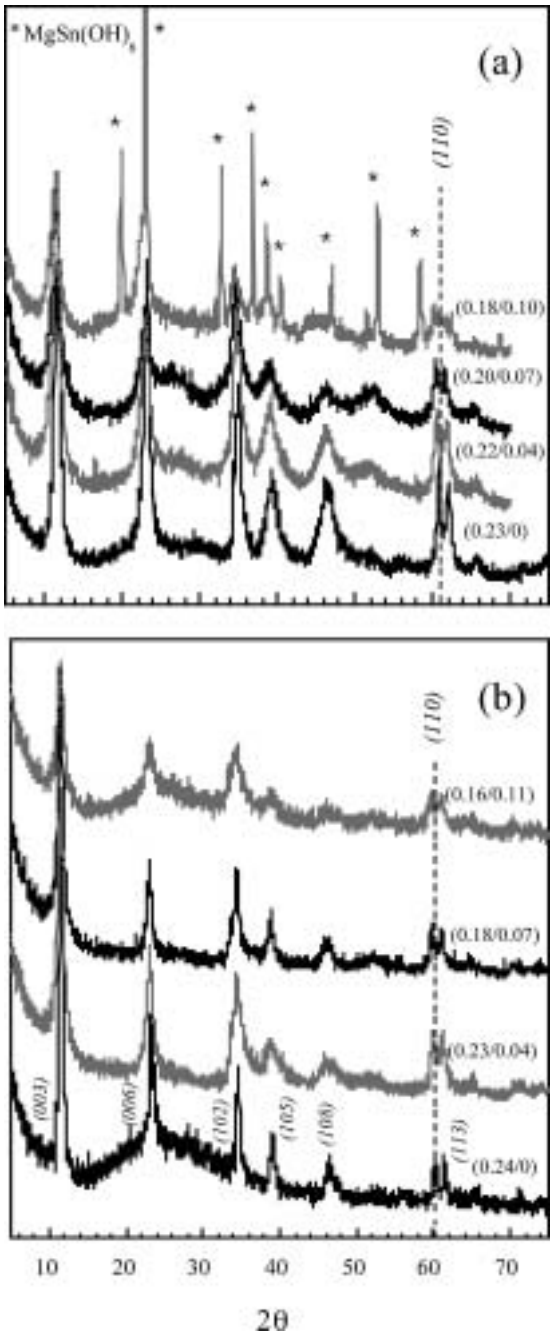

Fig. 1. X-ray patterns of the synthesized LDH materials of cation composition a) MgAlSn, and b) CoAlSn. Given the two hypotheses for the substitution, M^{II}-M^{III} ($M^{II}{}_{1-x}Al_x$) or M^{III}–M^{IV} ($Al_{1-y}M^{IV}{}_y$), the values of (x, y) are reported.

The features of the FT moduli at Co K-edge are characteristic of a LDH phase (Figure 2), namely the peak P1 represents the contribution Co-O, the contributions at longer distances arisen from multiple scattering effects and are attributed to metallic neighbors, P2 at a distance of $\boldsymbol{a}$, P3 of $\boldsymbol{a}\sqrt{3}$, and P4 of $2\boldsymbol{a}$. The latter is largely enhanced by the so- called focusing effect due to three atoms lying linearly to each other [5]. The observation of P4 implies the presence of flat inorganic sheets [6], inversely their absence would have been explained by the presence of corrugated layers. Rather small offsets in the linearity are enough to detune and lose the P4 amplification. The result of the refinements is displayed in Table I.

At the Sn K-edge, the structural local picture is different and the two contributions P3 and P4 are not observed (Figure 3).

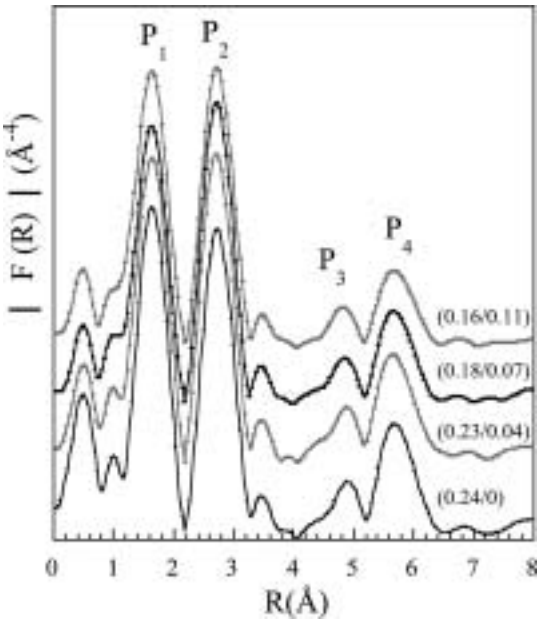

Fig. 2. Moduli of the Fourier transform for CoAlSn LDH system at Co K-edge. The distances are not corrected for phase shifts.

	Sn-Sn	2.35	3.73	7.5	9

[a] The residual ρ factor is defined as $\rho = [\Sigma(k^3\chi_{exp}(k) - k^3\chi_{theo}(k))^2 / \Sigma(k^3\chi_{exp}(k))^2]^{1/2}$. The commonly accepted fitting accuracy is about 0.02 Å for the distance and 15 to 20% for the number of neighbors.

[b] From structural data. SnO_2 crystallizes in space group P42/m n m (136) with tetragonal symmetry, lattice parameters $\boldsymbol{a} = 4.736$, $\boldsymbol{c} = 3.185$ Å. Distance in SnO_2: Sn-O = 2.045 (2), 2.058 (4) Å, and Sn-Sn = 3.185 (2) and 3.708 (8) Å.

[c] Given the two hypotheses for the substitution, M^{II}–M^{III} ($M^{II}{}_{1-x}Al_x$) or M^{III}–M^{IV} ($Al_{1-y}M^{IV}_y$), the values of (x, y) are reported.

Consequently, it suggests that there is no Sn-surrounding atom lying linearly to each other, and this whatever the values of y. For P2, a double structure is observed with two distinct Sn-Sn refined distances (Table I). The contributions look like those encountered

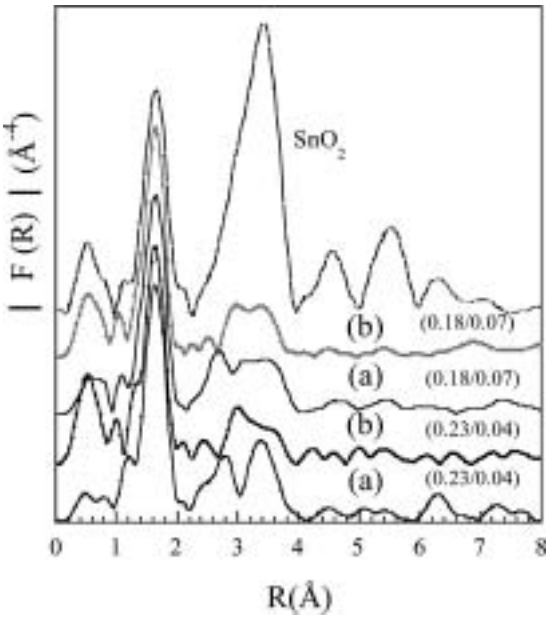

Fig. 3. Moduli of the Fourier transform at Sn K edge for (a) CoAlSn, and (b) MgAlSn LDH system. The distances are not corrected for phase shifts.

for hydrogels or xerogels of SnO_2 rutile-type samples [7]. This added to the fact that there is no Sn-Co correlation at a distance of ***a*** evidences strongly that Sn atoms are not located into LDH sheets, thus dismissing the hypothesis of Al substitution by Sn cations.

Indeed, the EXAFS fit results provide unambiguous evidence that Sn(IV) substitution does not occur. The local structures around Sn resemble the one present in tin-hydrogels [7], with Sn-Sn correlation, which cannot be explained by the LDH structure (Table I). The different acido-basic properties and reducibility of the mixed oxides formed upon calcination were recently studied [8].

Using the same method as for LDH, an amorphous precipitate "SnO_2" is obtained in absence of divalent and trivalent cation

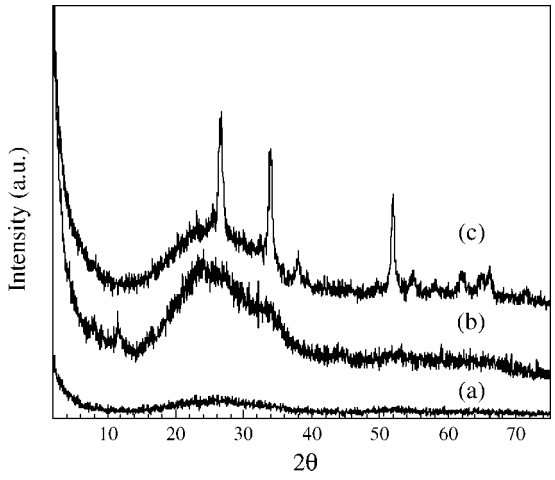

Fig. 4. XRD of SnO_2-type sample at (a) 25, (b) 800 and (c) 1000 °C.

source. It crystallizes into cassiterite-type (PDF file-41-1445) at 1000 °C (Fig. 4).

All these results were supported by additional information supplied by Mg K-edge study and ^{119}Sn Mössbauer.

Abstract

Mn(II) doped SnO_2 thin films used for shielding fluoride glasses against corrosion were investigated by X-ray absorption spectroscopy (EXAFS and XANES) at the Sn and Mn K-edges. The effect of firing treatment on the densification of the films was studied. It has been evidenced a partial change of Mn valence from 2.3 to 2.6 upon heating which is attributed to a change of ratios of two Mn sites: grafted divalent Mn ions at the surface of SnO_2 nanocrystallites and trivalent Mn ions embedded into a substitutional solid solution with Sn.

1. Introduction

Tin oxide films present numerous applications like gas sensors [1, 2], basic components in optoelectronic devices [2] or nano and ultrafiltration membranes [3]. Moreover, SnO_2 thin films prepared by sol-gel dip coating have recently been used for shielding fluoride glasses against corrosion [4]. Nevertheless, the high porosity (≈40%) of the films so-prepared limits its use as barriers against corrosion for a long period of time ($t > 50$ h). New preparative routes involving Mn(II) doping used as densifying agent [5] and Tiron® capping molecules recently reported as crystallite growth controller [6] are under study in this paper. The sintering process of SnO_2 coatings must be achieved at low temperatures due to the melting temperature of fluoride glasses (around 350 °C). Then it was achieved either by conventional heating between 120 and 530 °C or microwave-assisted treatment [7]. The poor crystallinity of the films obtained below 530 °C, as well as the low doping concentration of manganese (1 mol %) prevents the use of X-ray diffraction (XRD) for the structural analysis. Indeed X-ray Absorption Spectroscopy appears as a powerful tool to obtain structural information on the films allowing us to rationalize the effect of the firing treatment.

2. Experimental

2.1. *Film deposition and microwave treatment*

A transparent and stable colloidal suspension was prepared from the hydrolysis of $SnCl_4.5H_2O$ in presence of 1% mol $MnCl_2.4H_2O$ and 10% mol of Tiron®using the procedures previously described [4, 6]. Doped SnO_2:Mn films deposited onto cleaned Corning 7059 glass slides were prepared from this colloidal suspension by dip-coating method. The samples were either heated for 30 min at 120, 450 and 530 °C, or heated under high microwave power [7]. For microwave treatment (250 W for 45 s), the heat conduction was improved by locating the sample between two alumina susceptors. The temperature of the sample during the microwave irradiation was not measured, but it was estimated to be near the softening temperature of glass slides (550 °C). The melting of the glass slides was observed for longer time irradiation (55 s).

2.2. *XAS measurements and data analysis*

XAS measurements were carried out at LURE (Orsay, France) on the D44 station installed on the DCI storage ring (1.85 GeV and 300 mA). Sn K edge EXAFS spectra (29200 eV) were recorded in transmission mode at room temperature using a Ge(400) double crystal monochromator and ionisation chambers filled with krypton. Due to the thickness (≈0.5 μm) of the films, several slides were stacked to obtain a typical edge jump of 0.1. The EXAFS spectrum was recorded over 1200 eV with 4 eV energy step. Mn K edge XANES and EXAFS spectra were recorded in fluorescence mode using a solid-state 7-elements detector. XANES (resp. EXAFS) data were measured by using a Si(111) (resp. Ge(111)) double crystal monochromator detuned by 40% to suppress the harmonics. XANES spectra were recorded over 120 eV with 0.3 eV energy step whereas EXAFS data were obtained over 550 eV with 2 eV energy step. At both edges, the data acquisition time was typically around 5 s and several spectra (between 8 to 20) were added for each sample to improve the signal to noise ratio. For energy calibration of XANES data a metallic Mn foil was measured between each sample.

Standard methods were used to obtain normalized EXAFS $\chi(k)$ spectra as those already described for Sn K edge data [6]. The program ROUND MIDNIGHT [8] was used to fit the weighted $k^n\chi(k)$ spectra, with input from crystallographically known reference samples used to extract experimental phase and amplitude functions or to validate theoretical FeFF6 [9] phase and amplitude functions. For the XANES data analysis, the pre-edge absorption background was subtracted from the rough data using a linear function and the spectra were normalized far from the edge (≈6630 eV). The energy threshold of the Mn metal foil was determined from the first inflection point in the spectrum and set to the tabulated absorption edge energy equal to 6539 eV.

3. Results

Fast Fourier transforms (FFT) of the Sn-K edge EXAFS spectra for the films are shown in Figure 1. FFTs of films isothermally heated at 120 and 450 °C and of the film treated by microwave present a shape similar to the one of the crystalline SnO_2 reference but with a clear reduction of intensity for the contribution labelled B. This evidences the presence of nanocrystallites with the incipient cassiterite structure [1, 6]. The structural parameters determined by a least-square fitting procedure (Figure 1) are in agreement with this conclusion. The local order around Sn is characterized by a first coordination shell of 6.2 ± 0.3 oxygen atoms at 2.07 ± 0.01 Å and tin second neighbours located at 3.18 ± 0.02 and at 3.71 ± 0.02 Å as in the SnO_2 structure. From the mean number of tin second neighbours and according to the

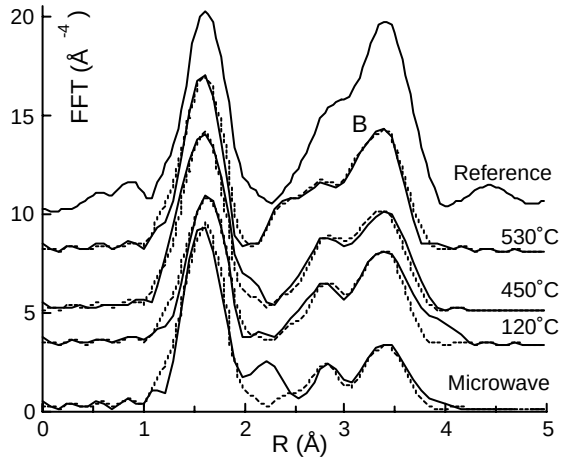

Fig. 1. Fast Fourier transforms (solid line) of the Sn-K edge $k^3\chi(k)$ EXAFS spectra of a crystalline SnO_2 reference and of the different SnO_2 : Mn films, using a Kaiser apodization window from 3.2 to 14.3 Å^{-1} with $\tau = 3$ and best fits (dashed line). The Sn-Sn coordination numbers at 3.18 and 3.71 Å are 1.6 and 5.0 for the film treated by microwave, 1.8 and 5.8 for films heated at 120 °C, 2.0 and 5.8 for those heated at 450 °C and 2.0 and 7.1 for those heated at 530 °C.

theoretical correlation published elsewhere [10] the crystallite size is determined around 4 ± 1.5 nm for the films heated below 530 °C and around 2.5 ± 0.5 nm for the film treated under microwave. For the film heated at 530 °C, the determination of the crystallite size from the EXAFS results is not yet enough accurate. The crystallite size equal to 7 ± 1 nm is determined from XRD, using the Sherrer formula. Note that the FFT of the film heated at 530 °C displays an additional pronounced shoulder on the left side of the B contribution. This shoulder has been successfully simulated by adding in the fitting procedure a Sn-Sn contribution at 2.86 Å like the one encountered for α-Sn metal.

FFTs corresponding to the Mn K-edge EXAFS spectra of the films are shown in Figure 2. The local atomic structure for Mn in the films heated at 450 and 530 °C is clearly different from that for the films treated under microwave or at 120 °C. In particular, a shift at shorter distances of the maximum of the first peak correlated to the Mn-O contribution is evidenced upon heating. The structural parameters obtained from the least-square fitting procedure dealing with the first

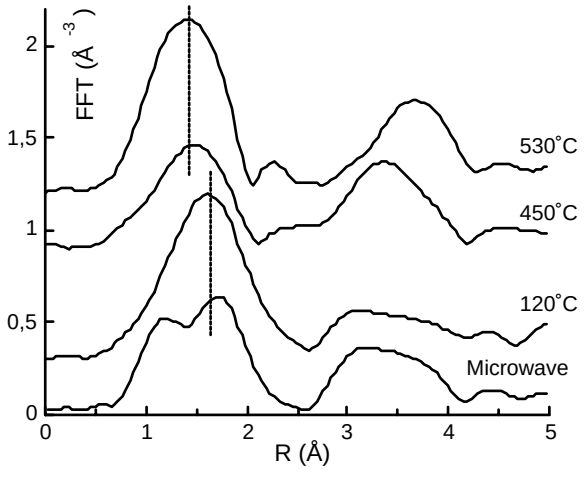

Fig. 2. Fast Fourier transforms of the Mn-K edge $k^2\chi(k)$ EXAFS spectra of the different SnO_2:Mn films, using a Kaiser apodization window from 2.7 to 10.3 Å^{-1} with $\tau = 3$. Dashed lines are a guide for eyes.

Table I. *EXAFS fit results at the Mn-K edge. The residual ρ factor is defined as* $\rho = [\Sigma(k^3\chi_{exp}(k) - k^3\chi_{theo}(k))^2 / \Sigma(k^3\chi_{exp}(k))^2]^{1/2}$. *The commonly accepted fitting accuracy is of about 0.02 Å for the distance and 15 to 20% for the number of neighbors.*

Films treated	N	R (Å)	σ (Å)	ρ (%)
By Microwave	2.9	2.16	0.06	1.8
	2.6	2.00	0.09	
At 120 °C	3.6	2.13	0.09	1.1
	1.7	1.95	0.19	
At 450 °C	1.2	2.14	0.04	1.9
	2.5	1.96	0.03	
At 530 °C	3.3	2.11	0.01	2.2
	3.2	1.93	0.01	

oxygen coordination shell are gathered in Table I. The best fits are obtained by using a two shell fitting procedure with a first Mn-O distance at 1.96 ± 0.03 Å and a second one at 2.13 ± 0.03 Å. The shortening of distances compared to the Mn-O distance found for divalent manganese (typically around 2.20 Å) suggests a change of manganese oxidation degree. This is clearly confirmed by the Mn K-edge XANES results presented in Figure 3. Everything else being equal, and by comparison with reference compounds, the rising edge position can be qualitatively used for the determination of the manganese oxidation state [11]. On one hand, the rising edges of the films treated at 120 °C (6546.1 eV) and by microwave (6546.0 eV) are almost superimposable and are in between those of Mn(II) (MnO: 6544.7 eV) and Mn(III) (Mn_2O_3: 6548.7 eV) references evidencing an intermediary average manganese valence for these films. On the other hand, the rising edge of the film treated at 530 °C (6547.1 eV) is shifted one eV above the position observed

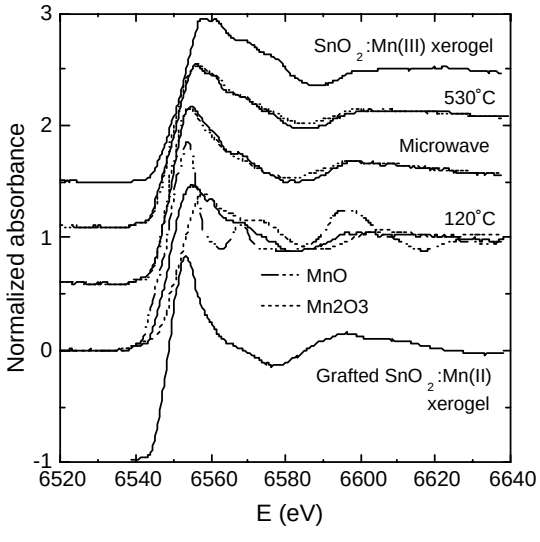

Fig. 3. Mn K-edge XANES spectra of different SnO_2:Mn films compared to divalent (MnO) and trivalent (Mn_2O_3) manganese references. The dashed line superimposed to the SnO_2:Mn film treated at 530 °C or by microwave has been obtained from the linear combination of the SnO_2 xerogel grafted by Mn(II) (site 1 at 2.13 Å) and the SnO_2:Mn(III) xerogel (site 2 at 1.96 Å), shown at the bottom and top of the figure, respectively. The ratios (site 1 : site 2) are 65% : 35% for the film treated by microwave, 55% : 45% for the film heated at 120 °C (the combination is not shown) and 38% : 62% for the film heated at 530 °C.

for the other films evidencing the increase of oxidation state upon heating at high temperature. Using a correlation between the edge energy and the Mn valence similar to the one established by Ressler *et al.* [11], the change of average Mn valence state is from ≈2.3 at 120 °C to ≈2.6 at 530 °C. In fact, the EXAFS results suggest the presence of Mn in two different sites. The site corresponding to a Mn-O distance of 1.96 Å is characteristic of trivalent manganese and is encountered alone for SnO_2 xerogels doped by Mn [12] whereas the site at longer distance is found for SnO_2 xerogels modified by Tiron® and grafted at pH = 7 by Mn(II) ions. As a matter of fact, the XANES spectra of the SnO_2:Mn films can be satisfactorily reproduced by a linear combination of the XANES spectra of the SnO_2:Mn(III) and SnO_2:Mn(II) grafted xerogels displayed in Figure 3. Note that the ratios used for the linear combinations and indicated in the caption of Figure 3 are in good agreement with the average manganese valence determined from the above correlation.

4. Discussion

Two sintering additives were introduced in the traditional route [4] to improve the densification of films and so reduce the microporosity of the SnO_2 coating. As evidenced by the EXAFS results at the Sn K edge, Tiron® grafting acts over the crystallite growth since the mean number of tin atoms as second neighbours is almost invariant when the films are heated from 120 °C to 450 °C. This effect, already reported for SnO_2 xerogels [13] and ultrafiltration membranes [6] modified by Tiron®, is ascribed to the capping coordination of Tiron® molecules at the surface of the SnO_2 crystallites. When Tiron® is burnt (i.e. above 450 °C), the crystallite growth control exercised by Tiron® disappears and the mean number of tin atoms as second nearest neighbours (3.18 and 3.71 Å) clearly increases.

Second, it is well known that suitable additives lead to the densification of the SnO_2-based ceramics during sintering. Recently we have proposed from EXAFS results [14] that the formation of a non-homogeneous solid solution between Cu(II) ions and $SnO_2$was mainly responsible for the low temperature densification (<900 °C) of Cu-doped SnO_2 xerogels. Due to the application of the coatings, we are interested in reducing the densification temperature. For MnO-doped SnO_2 xerogels [5], it has been reported faintly smaller densification temperature than those for copper doping and it is proposed that this behaviour is associated to the change of oxidation state of manganese. Indeed we have verified herein that a change of the average manganese valence from 2.3 to 2.6 occurs by heating the films from 120 to 530 °C due to a change of the proportion of sites in which manganese atoms are at the divalent and trivalent states. The oxidation of initial divalent manganese is concomitantly accompanied by a shortening of Mn-O distances from 2.13 to 1.96 Å. We propose that this process is a driving force for the bodies densification by leading to the formation of a stable substitutional solid solution Mn(III):SnO_2. Indeed for steric hindrance, the substitution of tin atom by divalent manganese is not possible (d(Mn(II)-O) = 2.13 Å and d(Sn(IV)-O) = 2.06 Å) but the decrease of ionic radius of manganese at the trivalent state is clearly a more favourable situation for stabilizing the solid solution. The formation of a substitutional solid solution has been clearly evidenced for the SnO_2:Mn(III) xerogels [12] by comparison with *ab initio* EXAFS calculations, as those already reported for Cu-doped SnO_2 xerogels [14]. Thus, the Mn-doping may have a double role in the sintering aid: *i*) the formation of Mn(III) substitutional solid solution increase the oxygen vacancy concentration improving the lattice diffusion and densifying transport mechanism; *ii*) the presence of the grafted like Mn(II) at the grain interface can act as a solute drag decreasing the grain boundary mobility. In both cases, it contributes to improve the densification of the films. Furthermore, the Sn-Sn contribution at 2.86 Å indicates the presence of a secondary phase in films fired at 530 °C that was tentatively attributed to metallic tin. The low oxygen partial pressure caused by combustion of Tiron® and reduction of Mn(II) can explain the reduction of Sn(IV)$O_2$to metallic tin. The presence of metallic tin favours liquid phase sintering explaining the fast densification rate and the amorphous-like phase observed by several research groups [5, 15].

Doped SnO_2:Mn films sintered by microwave treatment have a similar structure to those obtained from low temperature heating (120 °C), with a higher proportion of divalent manganese compared to the films heated at 450 °C. This feature can be explained by the very fast heating and short time period of firing, that reduces diffusion limited phenomena like grain growth and the Mn(II) oxidation.

5. Conclusion

A partial change of the average Mn valence degree from 2.3 to 2.6 upon conventional heating above 120 °C occurs which favours the formation of a stable substitutional solid solution Mn(III):SnO_2 in which Mn cations are surrounded by oxygen atoms at 1.96 Å. It contributes to increase the oxygen vacancy concentration improving the lattice diffusion and the densifying sintering. Both Tiron® and Mn(II) grafting are responsible for grain growth inhibition and increase of the thermal stability of the nanostructure against coarsening.

Abstract

Transmission XAFS measurements were performed on lanthanum chloride ($LaCl_3$) and $LaCl_3$-Li_2O mixture at various temperatures using La-K X-ray absorption edge. A distinct phase shift in the EXAFS oscillations was observed in going from the solid phase to the molten phase in $LaCl_3$. The results of curve fitting to the predominant peak in the structure function of $LaCl_3$ in real space, corresponding to the La^{3+}-Cl^- 1st coordination shell, reveal that both the inter-ionic distance and coordination number of chloride ions around a lanthanum ion decreased with increase in temperature to above its melting point. The short-range structure of $LaCl_3$-Li_2O ($x_{Li_2O} = 5$ mol%) mixture appears to be almost similar to that observed in pure $LaCl_3$.

1. Introduction

During the course of development of pyrochemical reprocessing of oxide nuclear fuels, several key issues need to be addressed in the uranium-plutonium co-electrodeposition process, *e.g.*, decrease of electric current efficiency due to circular current induced by either of the following redox reactions: Ce^{3+}/Ce^{4+} or Fe^{2+}/Fe^{3+}, noble metals contamination caused by their co-electrodeposition with (U, Pu)O_2, and possible composition variations in the electrodeposited material, *etc*. Additionally, and more importantly, the behaviour of rare-earth cations in molten chlorides in the presence of oxide anions is still unknown, and is bound to play a crucial role in the realization of this process. It is already reported that lanthanum chloride reacts with oxygen from either air or moisture to make compounds of oxychloride at *ca.* 620 K. Once oxychlorides are formed, they are very stable even above the melting point of pure lanthanum chloride (*ca.* 1100 K), and they will either float or precipitate in the melt bath. With the above point in view, we performed structural analysis of XAFS data on lanthanum oxychloride to elucidate the short-range distance environment around the lanthanum cation. As the first in a series of measurements planned to address the above issues, we chose the lanthanum compound, $LaCl_3$, among the several rare-earth compounds that generally exist in the fission products. The reason being that we expect $LaCl_3$ to behave most simply in its molten state in the presence of coexisting oxide anions as revealed by the E-pO^{2-} diagrams [1].

2. Experimental

2.1. *XAFS measurements*

X-ray Absorption spectra at the La K-edge (38.92 keV) were collected at various temperatures on BL19B2 and BL38B1 beam lines of SPring-8, Japan, using Si (311) double crystal monochromator. The energy range of the measurements was 38.6–40.4 keV, and stepped scan measurements were performed with an energy resolution of 1 eV. The SPring-8 storage ring was operated at 8 GeV and 100 mA. The intensities of the incident (I_0) and transmitted (I) X-rays were detected by using ionisation chambers filled with Kr + Ar (1 : 3) and Kr, respectively. For energy calibration, La K-edge of LaF_3 was used.

Chemicals of oxychloride (x $Li_2O = 5$ mol%) were prepared by adding Li_2O (Soekawa, 4N) to molten anhydrous $LaCl_3$ (AAPL Japan, 4N) in a glassy carbon cell kept in a dried argon atmosphere. The chemicals were grinded into a few micrometer particles, mixed with BN matrix powder (Goodfellow, 2N5) homogeneously (weight ratio; 1 : 2), and then pressed into pellets under 10 ton weight. The sample pellets disks were *ca.* 1 mm in thickness and 12 mm in diameter. The sample pellets were installed into a sample holder made of boron nitride fitted inside an electric furnace originally constructed by Rigaku Corporation [2]. The temperature was elevated from room temperature (RT) to a value (1173 K or 1223 K) above the melting point (*ca.* 1100 K) of pure $LaCl_3$. Sample environment of inert Ar atmosphere was maintained throughout the experiment by purging dried Ar gas continuously through the hermetically sealed furnace.

2.2. *XAFS data analysis*

XAFS data analysis was carried out using WinXAS Ver. 2.3 [3] software with the following procedure. Background subtraction and normalisation were performed by fitting the modified Victoreen equation to the pre-edge region and linear polynomial to the post-edge region, respectively. La K absorption threshold was decided from the first root in the second derivative of the near-edge region. XAFS oscillation, $\chi(k)$, was obtained by removing the atomic background smoothly using cubic spline method. The structure function $\mathrm{FT}|\chi(k) \cdot k^3|$ was obtained by Fourier transforming the k^3 weighted $\chi(k)$ function multiplied by a Bessel window function. The range of wave numbers used in the Fourier transformation was $2 < k < 12\,\mathrm{A}^{-1}$ for the solids, and $2 < k < 8\,\mathrm{A}^{-1}$ for the liquid melts. The curve fitting, including the 3rd and 4th cumulants, was done by nonlinear least square fits on the predominant La^{3+}-Cl^- 1st neighbour correlation peak in R-space using backscattering factors evaluated by FEFF 8.0 [4] code. The fitting and theoretical calculations were performed by assuming reasonable symmetric structures *e.g.*, hexahedron, octahedron and tetrahedron. Thus, the most reasonable coordination number of chloride ions around lanthanum ion was chosen by consideration of the inter-ionic distance and the sum of effective ionic radii [5].

3. Results and discussion

The extracted XAFS oscillations and their Fourier transformed structure functions of pure $LaCl_3$ in both the solid and liquid phases measured at BL19B2 and BL38B1 are depicted in Fig. 1(a, b) and Fig. 2(a, b), respectively. A comparison between the two spectra obtained on different beamlines reveals that the quality of the spectra on BL38B1 is much better than that on BL19B2. This may probably be due to some technical problems in the piezo monochromator optimization system that existed during the course of our measurements on BL19B2. Nevertheless, for our purpose of characterisation of lanthanum oxychlorides, it is not a serious problem requiring further discussion.

Similar to the observation in [6], the phase shift in the EXAFS spectra on melting $LaCl_3$ is observed, and the predominant peak corresponding to La–Cl 1st coordination shell is shifted to shorter distance upon melting. Table I shows the structural parameters obtained from the curve fitting procedure (see Section 2.2) applied to the first coordination shell. These values show a typical tendency of decreasing interionic (La^{3+}-Cl^-) distances and coordination numbers, $\bar{n}^{Cl}_{La}$, of chloride ions around a lanthanum cation on increasing the temperature. This trend is

already known from diffraction studies. However, the extent of decrease in the distance on melting is found to be much larger than that previously reported by Okamoto *et al*. [6]. The major difference between the present measurements and those reported previously [6] is in the sample confinement. While we used pellets made by mixing $LaCl_3$ in BN matrix, Okamoto *et al*. used quartz cells to contain $LaCl_3$. Although BN is not expected to react at all with lanthanum chloride, it is probable that at the high operating temperatures the sample may get oxidized by quartz/silica. The above results simply highlight the already well-accepted view that special concern should be focused on each step of the entire experimental procedure. While even the most advanced experimental techniques cannot rectify the problems generated by complicated sample preparation, the step between the points at which the analytical materials are transferred from the pure sample matrix to a form suitable for analysis is often overlooked. The sample confinement is another issue where the effects of the container material or the dilution matrix (BN or graphite powder) material used to prepare the pellets, as in the present measurements, should be addressed. Other steps, such as the sample environment, the design and construction of the furnace, the temperature control, and the whole suite of XAFS experimental procedures also need attention. To address one of our main concerns on the sample catching up the moisture even during quick transportation of the pelleted samples from the sealed polyethylene bags to the furnace in an open environment, the procedure that we adopted in the present measurements has already been revised for future studies.

Figure 3 shows a comparison between the structure factors of pure $LaCl_3$ and $LaCl_3$-Li_2O ($x_{Li_2O} = 5$ mol%) mixture obtained in this study. The structural parameters obtained by curve fitting to the 1st coordination shell of $LaCl_3$-Li_2O ($x_{Li_2O} = 5$ mol%) are also listed in Table I. It is difficult to find a recognisable difference (see Fig. 3) between the two radial structure factors at 1173 K. This observation may also imply that some problems probably existed in either the sample quality itself or the measurement procedure adopted. For a detailed quantitative discussion of the effect of the oxide ion on the structure of molten rare-earth chlorides, further similar experiments by varying the oxide ion concentrations, using the hydrated samples, revising the sample environment, i.e. the cell and furnace constructions, would be required. Some successful modifications to the above procedures have already been made, and further work is in progress.

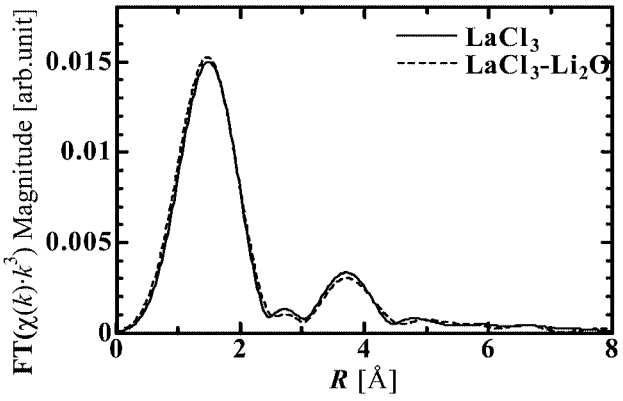

Fig. 3. Comparison between the structure functions of pure $LaCl_3$ and $LaCl_3$–Li_2O mixture ($x_{Li_2O} = 5$ mol%) at 1173 K.

4. Conclusions

XAFS measurements on $LaCl_3$ and $LaCl_3$–Li_2O ($x_{Li_2O} = 5$ mol%) were carried out over a wide temperature range from RT to above the melting point of $LaCl_3$. The structural parameters in the solid phase of pure $LaCl_3$ are in fairly good agreement with the crystallographic data. The values of the inter-ionic, La^{3+}-Cl^-, distance and the coordination number, $\bar{n}_{La}^{Cl}$, in the liquid phase are found to be lower than those in the solid phase. Further improvement and modification of the sample preparation and XAFS measurement procedures is necessary to obtain proper short-range structural parameters of rare-earth oxychlorides.

Abstract

Transmission XAFS measurements were performed on PbF_2 and LiF-PbF_2 at various temperatures using Pb-L_{III} X-ray absorption edge. Distinct phase shift of EXAFS oscillations was observed at the temperature range of superionic conductance phase transition in PbF_2. From the results of curve fitting to the predominant peak of PbF_2 in real space which is considered to be Pb^{2+}-F^- correlation, we can reveal that both inter-ionic distance and coordination number decreases with increasing temperature from β phase to liquid phase through the superionic conductance phase. Structural change in LiF-PbF_2 shows the same tendency with that of pure PbF_2.

1. Introduction

There are 2 phase transitions in lead fluoride under its melting point. At 589 K, $\alpha \rightarrow \beta$ phase transition occurs firstly. This phase transition is irreversible if temperature is controlled, however $\beta \rightarrow \alpha$ phase transition occurs under high pressure [1]. Lead fluoride in α phase is asymmetric orthorhombic crystal and that in β phase is symmetric cubic crystal. Then PbF_2 crystal at higher temperature than 710 K is known as 'superionic conductor', since its electric conductivity is comparable with that in the liquid phase even below the melting point. Some authors reported that fluoride ions in the superionic conductance phase move like in liquid phase [2]. According to those reports, increase of structural disorder on first neighboring Pb^{2+}-F^- correlation can be observed by XAFS measurements before and after superionic conductance phase transition. Additionally, structural parameters of Pb^{2+}-Pb^{2+} correlation are considered to be unchanged in this temperature range. Various studies have been performed on superionic conductance phase of PbF_2 and mixtures [3, 4], however clear structural variations of pure PbF_2 crystal in superionic conductance phase transition have not been investigated yet.

Incidentally, we have proposed LiF-PbF_2 system as a candidate of blanket material for fusion reactors using D-T reaction, and evaluated various properties of this system, e.g. eutectic composition (PbF_2:60 mol%, 850 K) [5], suitable material for the container [6], chemical form of tritium recovered from the molten salt when thermal neutrons were irradiated [7] and tritium inventory [8], etc. Since some other properties, such as electrical and thermal conductivity, viscosity and mobility of ions, depends on the local structure of molten salt, structural information will be necessary to apply to fusion blanket. Therefore structural information of molten PbF_2 is required as fundamental information to analyze molten LiF-PbF_2 structure.

With these objectives, we have investigated temperature dependence on short range structure of PbF_2 and LiF-PbF_2 by Pb-L_{III} XAFS measurements at various temperatures in the temperature range from room temperature to above their melting point.

2. Experimental

2.1. *XAFS measurements*

X-ray Absorption spectra of Pb L_{III}-edge (13.04 keV) were collected at various temperatures in BL10B beam line of Photon Factory at High Energy Accelerator Research Organization (KEK-PF), Japan, using Si (3 1 1) channel-cut monochromator. The energy range of the measurements was 12.54–14.14 keV, and stepped scan measurements were performed with 1 eV energy resolution. The PF storage ring was operated at 2.5 GeV with 200–400 mA. The intensities of the incident (I_0) and transmitted (I) X-rays were measured by using ionization chambers filled with Ar + N_2 (1 : 1) and Ar, respectively. For energy calibration, Pb L_{III}-edge of PbF_2 was used.

Powders of PbF_2 (Soekawa Chemical Co., 5N, m.p. = 1128 K) and LiF (Wako, superpure quality)-PbF_2 with eutectic composition were mixed with BN matrix powder (Good Fellow, 2N5) homogeneously (weight ratio; 1 : 9) at dried Ar atmosphere, and then they are pressed into pellets. The size of the sample pellet disks are ca. 1 mm thickness and 12 mm diameter. Sample pellets were installed into a sample holder made by glassy carbon in an electric furnace equipped at PF. Sample temperature was controlled as follows.

PbF_2
(*i*) RT → 1174 K (liquid phase) → RT.
(*ii*) RT → 792 K (superionic conductance phase) → RT → 1178 K (liquid phase) → RT.

LiF-PbF_2
RT → 905 K (liquid phase) → RT

Sample environment was kept at Ar atmosphere throughout the experiment.

2.2. *XAFS data analysis*

XAFS data analysis was carried out using WinXAS Ver. 2.3 [9] software package in the following procedure. Background subtraction and normalization were performed by fitting the Victoreen equation to the pre-edge region and a linear polynomial to the post edge region, respectively. Pb L_{III} absorption threshold was decided from the first root in the second derivative of

*e-mail 03d31067@nr.titech.ac.jp

the near edge region. XAFS oscillation $\chi(k)$ was obtained by removing the smooth atomic background using cubic spline method. The structural function $\mathrm{FT}|\chi(k)\cdot k^3|$ was obtained by Fourier transforming the k^3 weighted $\chi(k)$ function multiplied by a Bessel window function. Since double-electron excitation channel associated with a [2p4f] excitation and triple-electron excitation [$2p4f^2$] were indicated at about 180 eV and 410 eV above the L_{III} threshold energy [10], respectively, the range of wave numbers used in Fourier transformation was $2 < k < 7.5$ Å^{-1} to avoid these multi-electron excitation effects. Fitting including 3rd and 4th cumulants was done by nonlinear least square fits on predominant Pb^{2+}-F^- correlation peak in *R*-space using backscattering factors calculated by FEFF8.0 [11] code. Fitting and theoretical calculations were performed assuming reasonable symmetric structure e.g. hexahedron, octahedron and tetrahedron. Therefore the most reasonable coordination number of fluoride ions around the lead ion was chosen by consideration of inter-ionic distance and a sum of effective ionic radii [12]. As α-PbF2 is not suitable for this fitting procedure since its structure is asymmetric, curve fittings were performed without α-phase.

3. Results and Discussions

3.1. PbF_2

XAFS oscillations extracted and their Fourier transformed magnitudes are shown in Fig. 1(a), 2(a) and 1(b), 2(b), respectively. Spectra at 676 K in fig. 1 and at 300 K in fig. 2 show typical ones of β-PbF_2 and α-PbF_2, respectively.

Main issues are:

1) Phase shifts of XAFS oscillations in heating process.
   These phase shifts are considered to indicate superionic conductance phase transition since similar phase shifts in XAFS oscillations of $SrCl_2$, which is a superionic conductor, have been reported [13]. At the same time as for the phase shifts, the intensity of the peaks correspond to the 2nd coordination shell in *R*-space decrease suddenly. As those peaks are considered to be Pb^{2+}-Pb^{2+} contributions, they should not have changed suddenly as mentioned above.
2) Phase shifts of XAFS oscillations in cooling process.
   In temperature control (*i*), we could observe distinct phase shifts of XAFS oscillations in the cooling process. However, in temperature control (*ii*), the phase of oscillation did not change while the temperature was dropped from 792 K to 313 K although this phase shift was observed again as the temperature was elevated above the melting point. Since the phase of oscillation after the phase shift in a cooling process is regarded as the same as that before heating, those phase shifts may indicate the reverse of the phase shift observed in heating process.
3) Structural change from solid to liquid phase.
   There is little difference in XAFS oscillations and structural functions before and after the melting point. However, we would observe structural disorder in melting by evaluating the structural parameters.

Next, we will discuss issues of the structural parameters obtained by curve fitting to the predominant peak in *R*-space. Table I–II show the structural parameters obtained by curve fitting. Here $r_{\mathrm{Pb\text{-}F}}$ is inter-ionic distance, $N_{\mathrm{Pb\text{-}F}}$ is coordination number of F^- ions around the Pb^{2+} ion and DW is the Debye-Waller factor. C_3 and C_4 are 3rd and 4th cumulants, respectively. The residual is defined by the following equation

$$\text{Residual} = \sum_{i=1}^{N} \left|k^3\chi_{\mathrm{exp}}(k) - k^3\chi_{\mathrm{cal}}(k)\right| \Big/ \sum_{i=1}^{N} \left|k^3\chi_{\mathrm{exp}}(k)\right|.$$

Here letters 'exp' and 'cal' correspond to experimental and calculation, respectively.

1) The phase shift of XAFS oscillations in heating process definitely indicates the superionic conductance phase transition

since the Debye-Waller factor increases abruptly. Additionally, the inter-ionic distance decreased suddenly which is considered to be owing to the effect of columbic interaction between Pb^{2+} and mobile F^-. Therefore decrease of intensity of the peak at 2nd coordination shell may be one of the properties of PbF_2 at superionic conductance phase. However, we can not discuss further since we did not use large enough k region for Fourier transformation to discuss the 2nd coordination shell. Other

experiments which can reveal long range structure (e.g. neutron diffraction or Pb K-edge XAFS in which multi-electron excitation channel has not been reported yet) will be necessary to investigate the temperature dependence of Pb^{2+}-Pb^{2+} correlation.

In order to evaluate detail local structural changes in the temperature range close to 710 K, we collected XAFS signals when temperature was controlled from 675 K to 712 K in experimental condition (*ii*). Fig. 3 shows the XAFS oscillations and structural functions, and Table III shows the structural parameters obtained from curve fitting. In these results, signals and parameters are arranged according to time evolution while temperature was controlled. Thus, temperature of each signal means only identification and numbers at left hand and right hand show the temperature at start and end of the measurement, respectively. These figures show both XAFS oscillations and structural functions changing continuously from 675 K to 712 K, and structural parameters also change continuously. Therefore these results reveal that the superionic conductance phase transition is a recognizable structural phase transition.

2) Judging only from the variation of structural parameters shown in the Tables, the structure of PbF_2 which has been cooled down is considered to depend on the temperature from which cooling was started. When PbF_2 is cooled down from liquid state, its structure becomes that of β-phase at room temperature. On the other hand, when it is cooled from superionic conductance state, its structure does not change during the cooling process. In this case, PbF_2 at room temperature may form a structure similar to the superionic conductance state.

In order to evaluate the state of PbF_2 which is cooled down from various temperatures, powder XRD measurements at room temperature have been performed on α-PbF_2, PbO, PbF_2 which have undergone some heat treatments. On the samples except for PbO, laboratory XAFS measurements have also been performed at room temperature. Powder diffraction patterns were collected by a NaI scintillation counter using an Cu-Kα line ($\lambda = 1.54046$ Å). Laboratory XAFS measurements have been carried out by using an XAFS spectrometer (Rigaku Corp.) with rotating molybdenum target and Ge(4 0 0) monochromator crystal. Some samples of PbF_2 were obtained by following heat treatments on α-PbF_2 in a globe box filled with dried Ar.

1) RT → 650 K (β-phase: keep 1 h) → RT.
2) RT → 800 K (superionic conductance phase: keep 1 h) → RT.
3) RT → 1200 K (liquid phase: keep 1 h) → RT.

According to our previous XAFS measurements, structures of samples PbF_2 2) and 3) are predicted to be superionic conductance phase and β-phase, respectively. Sample PbF_2-1) is β-phase crystal.

Figure 4 shows the diffraction pattern and XAFS oscillation of each sample. Opposite to previous results, all heat treated PbF_2 show the same diffraction pattern and XAFS oscillations. Diffraction patterns and XAFS oscillations of PbF_2 1), 2) and 3) are different from those of α-phase, and we can recognize by diffraction patterns that the lead ion was not oxidized, thus samples PbF_2 1), 2) and 3) are apparently in β-PbF_2 and the phase shift observed in the cooling process was not reproduced in these heat treatments. Since this phase shift was reproduced when temperature was elevated again to above the melting point, PbF_2

should not have changed chemically at high temperature. Then possible factors which lead to phase shift observed in cooling process are suggested to be cooling speed or mechanism of recrystallize process, and additional experiments will be required to confirm these possibilities. As the similar irreversible or temperature history dependent properties under its melting point are reported on another superionic conductor, LaF_3 [14], the irreversible property observed in this study may be one of the properties of superionic conductors.

3) After the superionic conductance phase transition, both inter-ionic distance and coordination number decrease with increasing temperature until above the melting point. As a jump of the Debye-Waller factor was recognized from 1082 K to 1174 K, the structural phase at 1174 K is definitely liquid. The structural parameters in liquid phase are considered to be reasonable since 4 coordinated structure is proposed for molten KF_{1-x}-PbF_{2x} system ($0.2 \leq x \leq 0.8$) [15] by Raman spectroscopy. Hence, superionic conductance phase is considered to have mean properties between solid and liquid phase, and those properties include electric conductance changing continuously from β-phase to liquid phase.

4. LiF-PbF_2

Figure 4(a), (b) show XAFS oscillations and structural functions of LiF-PbF_2, and Table IV shows the structural parameters obtained from curve fitting. As electron scattering by lithium ions is considered to be negligible and the first neighboring specie around a Pb^{2+} is considered to be F^-, the curve fitting procedure used on this system is the same as that used for pure PbF_2.

Phase shift of XAFS oscillations which corresponds to superionic conductance phase transition and decrease of 2nd coordination peaks were observed in this system again. Additionally, structural parameters are also similar with those of pure PbF_2 at comparable temperature even in the liquid phase of LiF-PbF_2. Therefore the effect of additive lithium ions on the local structure of this system is conjectured to be little since PbF_2 share more than 50% in this composition.

5. Conclusions

XAFS measurements on PbF_2 and eutectic LiF-PbF_2 were performed in a wide temperature range form RT to above their melting point. Structural parameters at liquid state of these systems are firstly revealed by this study. Temperature dependence of structural parameters is also investigated, and structural property of superionic conductance states of PbF_2 and LiF-PbF_2 are revealed. Additionally, the possibility that the structure of PbF_2 depends on temperature history was suggested.

Abstract

The structural parameters and the electronic structure of the complex between cerium(III) and *N*,*N*′-dimethyl-*N*,*N*′-diphenylpyridine-2,6-carboxyamide (DMD PhPDA) were studied by XAFS, and both luminescence and excitation spectroscopes. We investigated the fundamental aspects of this material as the ligand is promising for the separation of trivalent actinides and lanthanides. The Ce-K XAFS spectra were measured at the SPring-8 synchrotron facility in Japan. It was determined that the bond distances between the carbonyl oxygen and cerium, and between the pyridyl nitrogen and cerium were about 2.49 and 2.67 Å, respectively. The angle between the Ce-N bond and the p_z axis of the lone pair of the pyridyl nitrogen is 180° for the solution state, suggesting covalent interaction between cerium and the nitrogen of the DMDPhPDA ligand. Emission from this system is severely quenched, and red-shifts, and supports the presence of a strong inner sphere complexation between cerium and the nitrogen atom of the pyridyl group. From the XANES spectrum, the oxidation state of cerium was determined to be trivalent.

1. Introduction

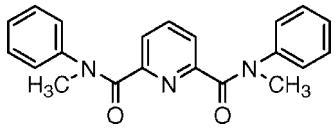
In efforts to minimize radioactive waste associated with the production of electricity via nuclear energy, research is focusing on the treatment of long half-life nuclides from the viewpoint of their geological disposal. Methods for the separation of actinide(III) from lanthanide(III) species are important for several fundamental technologies and establishing accelerator driven transmutation systems for the longer lived actinides Am and Cm. This arises as there are large quantities of lanthanides with relatively high neutron cross-sections that accompany the actinides in high level radioactive wastes.

The separation of the trivalent actinides and lanthanides is difficult given their similar chemical behaviors. From recent studies, it has been found that the required separation can be accomplished using neutral soft-donor extractants [1–4]. These separation techniques are based on the more effective and preferential complexation of actinides versus lanthanides by the soft ligands (i.e., ligands that lead to covalent bonding with the metal ion). We focus here on the *N*,*N*′-dimethyl-*N*,*N*′-diphenylpyridine-2,6-carboxyamide (DMDPhPDA) compound is a promising ligand for these separation. The structural and electronic studies conducted by XAFS, luminescence, and excitation spectroscopy are reported.

2. Experimental

2.1. *Material and synthesis*

The DMDPhPDA ligand which structure shown below was synthesized as described in reference [5]. Based on liquid chromatography analysis its purity >99.5%.



Scheme 1. Structure of *N*,*N*′-dimethyl-*N*,*N*′-diphenylpyridine-2,6-carboxyamide (DMDPhPDA).

2.2. *Sample preparation*

Hydrated cerium chlorides ($CeCl_3 \cdot 6H_2O$) were dissolved in the methanol solutions which contained DMDPhPDA at concentrations to provide the mole ratios, M : DMDPhPDA = 1 : 0, 1 : 2, 1 : 3, 1 : 4. The concentrations of the cerium was 0.05 mol/L for the samples. The methanol-solvent solution for dissolving the cerium salt was about 100 wt % MeOH. In addition, aqueous solutions of cerium ion were prepared for comparison with these methanol solutions.

2.3. *EXAFS measurements and Data analyses*

The EXAFS spectra of the Ce solutions at the K and L_{III}-edge (Ce-K edge) were measured in both the transmission and fluorescence modes at the BL11XU of SPring-8 synchrotron radiation facility, Japan. Monocromatic synchrotron radiation was obtained with a double crystal diamond (111) device.

The solutions for analysis were sealed in a polyethylene cells having a one cm path length. The data reduction and curve fitting were carried out by the WinXAS software version 2.3 [6]. The theoretical phases and amplitude were calculated by FEFF8 [7].

2.4. *Spectroscopic Studies*

The emission and excitation studies were conducted on Instrument SA's optical system, which consist of a monochromator (model 1000M) equipped with CCD, PMT and IR detectors. A 400 W xenon lamp was the light source. For absorption studies, samples were placed on quartz slides under a microscope objective and analyzed with the light from a xenon lamp delivered via a fiber optic setup. The transmitted light, collected with a second fiber, was directed into the monochromator. Emission spectra were collected at 90° from "in house" made cuvette having a diameter of 0.6 cm. Spectramax for windows software was used for data acquisition, while Grams 32 (Galactic Industries) software for data analyses.

3. Results and Discussion

is also shown in the figure for comparison. It has been reported that only water coordinates to lanthanides in this concentration range [8]. The RSF of the Ce-DMDPhPDA samples consist mainly of peaks at 2.0 and 2.7 Å. The largest peaks at 2.0 Å (in RSF) are assigned to the interaction between cerium and oxygen of the water and/or the DMDPhPDA, and the nitrogen of the DMDPhPDA molecule. This peak's position gradually shifts to lower R (Å) values with increased ratios of DMDPhPDA in the solution, suggesting interactions between cerium and the ligand.

Figure 2 shows the relationship between the bond distances and the fitting quality (Residual %) for the 1 : 4 mole ratio of the Ce : DMDPhPDA system. The first peaks of the complex systems consist of two interactions. Furthermore, the combination of the bond distances at 2.49 Å and 2.68 Å are most probable, based on the fitting quality, and are attributed to the oxygens of water, and DMDPhPDA and the nitrogen of DMDPhPDA, respectively. The small second peaks at 2.7 Å (in RSF) for the complexes are assigned to the carbon of the DMDPhPDA. The bond distances obtained by the fits are listed in Table 1.

On the basis of these results, a complex structure for the 1 : 4 complex is given in Figure 3. The crystal structure of La-DMDPhPDA complex [15] is also shown for comparison. The two oxygens of the DMDPhPDA ligand are the nearest neighbors of the Ce atom, and are located symmetrically at a distance of 2.49 Å on the axis consisting of the central nitrogen atom (Scheme 1). The angle consisting of the Ce-N bond and the p_z axis of the lone pair of the pyridyl nitrogen is probably linear in the solution, since the bond distance between Ce and 4 carbons of DMDPhPDA are almost same. However, it typical bends to 150° in the solid crystal [15]. The bend angle is important for characterizing the

This cluster is cut from $La(NO_3)_3(DMDPhPDA)_2$ complex [15].

chemical bond between the metal and ligand, as the coincidence of lobe direction of the lone electron pair of the donor atom and the bond angle has been experimentally regarded to be a measure of covalency [9, 10]. From the data, the chemical bond between the nitrogen of pyridyl group and cerium in solution appears slightly covalent. This occurs because the lobe of the lone pair of pyridyl nitrogen is about 180° degree toward the pyridine ring [11]. In the primary coordination sphere of the solid lanthanum complex, the two oxygens of the DMDPhPDA ligand coordinate to the metal asymmetrically, while in the Ce complex in the solution state, the oxygens coordinate symmetrically to the cerium.

3.2. *Photoluminescence and XANES Studies*

Cerium(III) luminescence results from 5d→4f transitions, and involves the lowest ^{2}D excited state and the two spin-orbit components of the ground term, $^2F_{7/2}$ and $^2F_{5/2}$. The accessibility and environmental sensitivity of the ^{2}D electronic state makes luminescence a useful technique to probe Ce(III) interactions with organic ligands. Except for the difference in pyridyl and the ether groups, the ligands DMDPhPDA and DMDPhDGA have similar structural motifs, and their coordination mode with lanthanide ions should be similar. However, as described below, the cerium complexes show distinctly different luminescence behavior.

In Figure 4a and b are shown the emission and excitation spectra of Ce-DMDPhPDA and DMDPhDGA systems, respectively. The Ce-DMDPhDGA system emits strongly at 370 nm (Fig. 4a) with a full width at half-maximum (FWHM) of 59 nm. In contrast, under identical experimental conditions the emission from the Ce-DMDPhPDA system is hardly detectable as it's emission intensity decreases by more than fifty-fold. Additionally, the center of mass for the emission band of the latter system is slightly red-shifted (∼376 nm) compared to the former species. The red-shifting exhibited in the emission band of the Ce-DMDPhPDA system is typical of covalent interaction between the ligand and the metal ion leading to an increase in the extent of splitting the cerium 5d levels. A larger splitting of the 5d levels reduces the energy gap between the lowest emitting state and the ground 4f level [12]. In this regard the optical property is consistent with the conclusion inferred from the bend angle analysis. The excitation spectrum for the Ce-DMDPhDGA system (fig. 4b) also shows a strong peak at 315 nm, as compared to the weak band at ∼308 nm from the Ce-DMDPhPDA system. The blue-shift (∼720 cm^{-1}) observed ffrom the Ce-DMDPhPDA system is as expected since the larger splitting of the 5d level raises the energy position of the higher excited levels, while simultaneously lowering the position of the lowest emitting level. Hence, red-shift in emission and blue shift in the excitation bands signifies the larger 5d splitting caused by the more covalent interaction between cerium and the DMDPhPDA ligand, compared to the DMDPhDGA ligand.

The quenching of the emission from the Ce-DMDPhPDA system was initially thought to indicate partial oxidation of cerium to the tetravalent state, as Ce(IV) is known [13] to be a non-luminescent species. In addition, the Ce-DMDPhPDA solution has a distinctively yellow-orange color, which was thought to provide an additional evidence for the partial oxidation. This postulate was tested by conducting the Ce-K XANES analyses. The XANES spectra of several cerium compounds and complexes

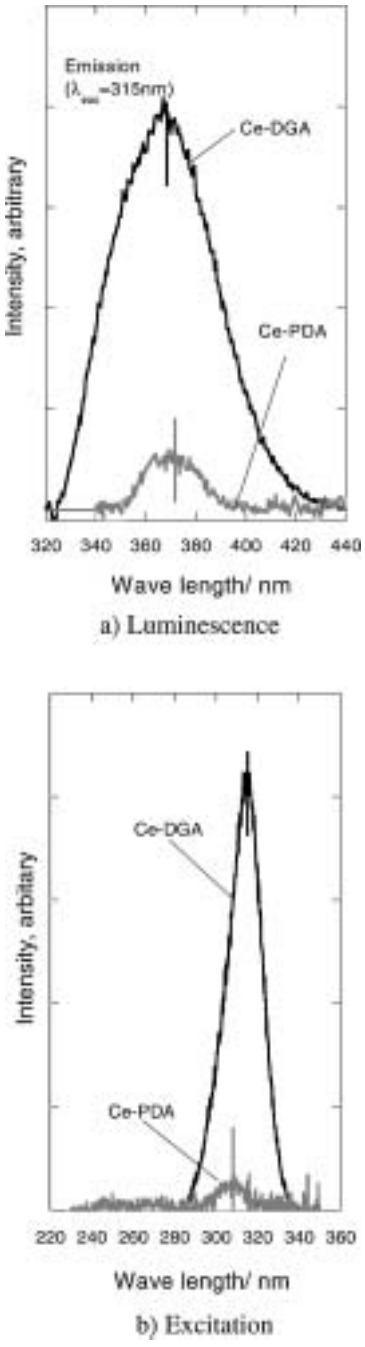

Fig. 4. The (a) luminescence and (b)excitation spectra of Ce-DMDPhPDA and –DMDPhDGA in methanol.

having different valence of cerium are shown in Figure 5. With the the Ce(IV) compounds, shift to higher energies by 7 ∼ 9 eV are observed as compared to the Ce(III) compounds. This comparison clearly indicates that the valence state of cerium in the DMDPhPDA complex is trivalent, as is the DMDPhDGA system. Hence, the quenching of emission from the former species is attributable to a strong interaction between cerium and the nitrogen of the pyridyl group of the ligand. An enhanced inner-sphere complexation with this ligand appears to affect the emission, as has been noted previously in several other chelating ligands [14].

4. Summary and Conclusions

The structural parameters of Ce-DMDPhPDA in methanol-aqueous mixtures were determined by using Ce-K EXAFS

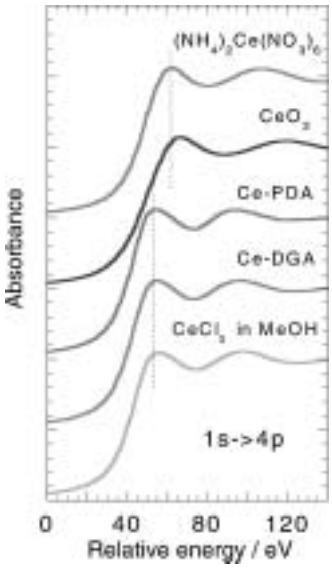

Fig. 5. The Ce-K XANES spectra of several Ce compounds. *PDA : DMDPhPDA; DGA : DMDPhDGA. (*The ratios in this figure denote Ce : DMDPhPDA(M/M).

studies. The bend angle between the Ce-N bond and the p_z axis of the lone pair of the pyridyl nitrogen for the solutions of the Ce-DMDPhPDA complex were found to be 180 degrees, which probably suggests a covalent bond property between the nitrogen and cerium. The luminescence and excitation spectra arising from the 4f-5d transition showed significant quenching, and red-shifts indicating a strong interaction between cerium and the nitrogen of the pyridyl group of the DMDPhPDA ligand. From the XANES data, the oxidation state of Ce was determined as trivalent in both the Ce-DMDPhPDA and Ce-DMDPhDGA complexes.

Abstract

The structural parameters of technetium(VII)-uranium(VI)-tri-butyl phosphate (TBP) were determined by EXAFS to elucidate the mechanism of co-extraction of technetium in the presence of uranium(VI). Sample solutions were prepared by solvent extraction methods. The bond distance between uranium and oxygen of TcO_4^- is 2.97 Å; the that of U-Tc is also observed at about 3.5 Å, suggesting that a TcO_4^- molecule exchanges with nitrate ion in the $UO_2(NO_3)_2(TBP)_2$ complex. However, the interaction of zirconium-rhenium of $Zr(NO_3)_x(ReO_4)_{4-x}(TBP)_2$ complex could not be observed. Although the rhenium also co-extracted like technetium by TBP in the presence of U(VI) and Zr(IV), this result indicates that ReO_4^- interact with Zr through water.

1. Introduction

On the behavior of technetium in the nuclear fuel re-processing, there are many reports [1–5]. In the nitric acid solution in the process, Tc exists as per-technetate ion. The pertechnetate ion is a comparatively large tetrahedral structure which consists of four oxygen, while the effective charge is comparatively smaller than that of the other anion [6]. Therefore, it is extracted in ion pair as a pertechnetic acid by TBP easily. Furthermore, the per-technetate ion is co-extracted with counter ions such as UO_2^{2+}, Pu^{4+} and Zr^{4+} with TBP [4, 5, 7]. Due to the difference this solvation, $UO_2(TcO_4)_2$ is extracted twice better on the distribution ratio of uranium than $UO_2(NO_3)_2$ by 30% TBP-n-dodecane [5]. However, there is little reported about structural analysis of these co-extracted complexes. In this study, a structural analysis of the co-extracted complexes were performed about Tc-complexes: $UO_2(NO_3)(TcO_4^-)_{2-x}(TBP)_2$ and Re-complex: $Zr(NO_3)_x(ReO_4)_{4-x}(TBP)_2$.

2. Experimental

2.1. *Sample Preparation*

The technetium samples were made as follows. 1 ml of n-dodecane as an organic solvent containing 30% tri-butyl phosphate was shaken with the same volume of nitric acid containing 40 mM of UO_2^{2+} with about 0.7 M of TcO_4^-. After centrifugation, 0.45 ml of the organic solution was separated to use as a sample.

The rhenium-zirconium sample was also made by the solvent extraction method. 1 ml of the organic solvent containing 30 % tri-butyl phosphate in n-dodecane was shaken with the same volume of 5.0 M of nitric acid containing 0.2 M of Zr^{4+} with 0.2 M ReO_4^-. After centrifugation, 0.7 ml of the organic solution was separated to use as a sample.

2.2. *Sample measurements*

0.45 ml of Tc-U-ligand complex solution was enclosed in a polyethylene tube. 0.7 ml of Re and Mn complex samples were enclosed in a polyethylene bag with 1 mm thickness adjusted by a Teflon spacer in the measurement.

EXAFS measurement were carried out at the beam line BL27B of the Photon Factory (2.5 GeV) of the high-energy accelerator research organization (KEK) in transmission mode under the condition of beam current 250–380 mA. The absorption edges were 17.16 keV for U(L_{III}), 21.05 keV for Tc(K), 10.53 keV for Re(L_{III}) and 6.54 keV for Mn(K).

The extraction of EXAFS oscillation from the absorption spectra were carried out by WinXAS V.2.3. [8]. A linear function was used for pre-edge extrapolation. Atomic absorption was modeled using cubic spline function. Normalization was achieved using the victoreen method. The Fourier transform [$k^3\chi(k)$] was calculated with Gaussian windows function in the range of 2.50–11.4 $Å^{-1}$ for Tc complexes, 2.65–14.1 $Å^{-1}$ for U complexes, 2.70–13.7 $Å^{-1}$ for Re complexes and 2.7–14.0 $Å^{-1}$ for Mn complexes. Back-Fourier transforms were performed in the ranges 0.5–4.0 Å for Tc complexes, 0.4–4.1 Å for U complexes, 0.8–1.9 Å for Re complexes and 0.77–2.0 Å for Mn complexes.

The theoretical parameters for curve fittings of the EXAFS spectra were calculated using FEFF7 [9].

3. Results and Discussion

The radial structural functions of Tc-K XAFS for Tc-U-TBP complex in dodecane prepared by the solvent extraction method are shown in Fig. 1. The first peak in the sample is attributed to the four oxygen atoms of the TcO_4^- ion. The bond distance of Tc-O, i.e. about 1.74 Å, agrees well with the previous data [10]. Generally, technetium is further extracted in the presence of U(VI) ion in the solvent extraction with TBP. Therefore, technetium is regarded to behave as a counter ion in the extraction of uranium. Accordingly, the peaks around 3.2 Å (in RSF) can be attributed to the Tc-U interaction. The curve fitting for the UO_2-TcO_4-NO_3-TBP complexes of Tc-K EXAFS is also shown in Fig. 1. The bond distance of Tc-O and Tc-U are about 1.74 Å and 3.59 Å, respectively. These structural analysis data suggest that TcO_4^- ion coordinates to uranium with bidentate fashion instead of a nitrate ion in the Tc co-extraction system. The comparison of radial structural functions of U-L_{III} XAFS for $UO_2(TcO_4)(NO_3)\cdot 2TBP$, $UO_2(NO_3)_2\cdot 2TBP$ and $UO_2(NO_3)_2\cdot 2H_2O$ are shown in Fig. 2. The U-O(-Tc) and U-Tc of $UO_2(TcO_4)(NO_3)\cdot 2TBP$ are also confirmed, and significant evidence of TcO_4^- for direct coordination to UO_2^{2+}. The distance U-Tc is 3.60 Å, which agrees well with the Tc-K XAFS result. The curve fitting results of U-L_{III} EXAFS spectra for $UO_2(TcO_4)\cdot(NO_3)2TBP$ are listed in Table I. The interaction of uranium are mainly 5, U=O_{axial}, U-O_{eq1} (O = P), U-O_{eq2} (O_2-NO), U-O_{eq3} (O-Tc), and U-Tc. The bond distance of U-O_{eq3}: 2.97 Å is longer than for U-O_{eq2}: 2.51 Å and U-O_{eq1}: 2.31 Å. Therefore, TcO_4^- would show weaker interaction than the other oxygens. For clarification of these results, we need to do experiments.

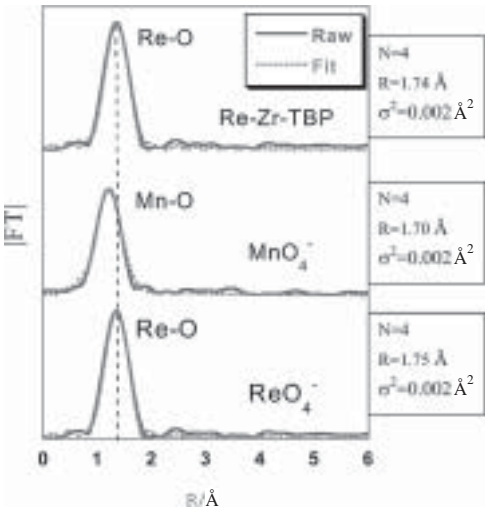

Fig. 3. Comparison of radial structural functions and curve fittings of ReO_4^- MnO_4^- in aqueous solution (3M HNO_3) and the extracted Re-Zr-TBP complex in dodecane. *N, R, σ^2 present the coordination number, bond distance, and Debye-Waller factor, respectively. **The phase shifts were not corrected.

The radial structural functions of ReO_4^-, and MnO_4^- in solution are shown in Fig. 3. The bond distance of Mn-O is about 1.70 Å, and slightly shorter than that of Re-O (1.75 Å). The radial structural function of Re-Zr-TBP complex in dodecane is also shown in Fig. 3. Although Re is also co-extracted by TBP in the presence of Zr^{4+} like UO_2^{2+}, there are no interactions around Re expect for the interaction for the Re-O of ReO_4^-. This result suggests that Zr^{4+} would exist beyond 4.0 Å and the ReO_4^- seems to interact with Zr^{4+} through water.

Abstract

Silicon carbide polytipes 6H-SiC and 3C-SiC were characterized by optical absorption at the C K edge in the near edge absorption region.

3C-SiC and 6H-SiC showed similarities for energies about 15 eV above the edge.

Marked differences were found in the near edge region. A picture based on the p distribution of empty states was suitable to describe the main features of 3C-SiC. 6H-SiC showed important absorption anisotropies traceable to the anisotropies of the scattering paths as shown by full multiple scattering calculation performed by MXAN code. The role of self consistency is also discussed.

1. Introduction

The interest in silicon carbide is increasing due to its promising properties in high power, high frequency and high temperature electronic applications [1]. Silicon Carbide is one of the compounds that show the most pronounced polytypism, with more than 200 SiC polytypes existing in nature. The existence of so many different polytypes is due to the many possible stacking sequences of the basic structural elements: the $\{111\}$ Si-C bilayers of the cubic (zincblende) structure or $\{0001\}$ layers of the hexagonal structure [2].

All SiC polytypes have the same nearest neighbor configuration, and differ in the long-range structure. The long range order influences deeply the electronic properties, which depend on the joint density of states between valence and conduction band. For example the band gap energy increases with increasing hexagonal character of the polytype: 2.2 eV in 3C-SiC, 3.0 eV in 6H-SiC and 3.5 eV in 2H-SiC. Experimental results [3] and theoretical calculations [4] show that the differences in the electronic properties are a consequence of the differences in the electronic structure of empty states. It is crucial to understand the long-range properties of the different polytypes, and significant efforts were made to characterize these systems [3, 4, 5, 6]. Nevertheless, a detailed knowledge of the correlation between electronic and structural properties is still lacking in literature. X-ray absorption spectroscopy gives insights on both aspects at the same time, giving information on the local density of the empty states, and providing the local atomic geometry around the absorbing atom.

This work reports on a C K-edge X-ray absorption study of 6H-SiC monocrystal and 3C-SiC ordered film. The sample orientations were (0001) for the 6H and (100) for the 3C system. The C K-edge NEXAFS spectra of the two systems showed similarities for energy above 295 eV (i.e. 15 eV above the absorption edge), while marked differences were found in the near edge region (within 10–15 eV above the edge). These differences are related both to the particular polytype and to the measurement geometry and light polarization used. Full multiple scattering self-consistent calculations were performed on these systems by using MXAN code.

For the C K-edge NEXAFS of 3C-SiC the assignment of the structures was made on the basis of the character of the empty electronic states and by using the full multiple scattering simulations. The C K-edge of the absorption spectra of 6H-SiC monocrystal showed a strong dependence on the polarization direction of the photon electric field that is explained in terms of the anisotropy of the electronic structure of the hexagonal 6H systems and also by the anisotropies of the scattering paths, as analyzed by the simulations. The role of self-consistency is also discussed.

2. Experimental

The cubic SiC sample was growth *ex-situ* by co-deposition of Fullerene and Silicon on Si(100) substrate at high temperature (about 1100 K). The thickness of the SiC film was 8000 Å. This growth procedure leads to 3C-SiC films that can show a good degree of order, without the presence of other polytypes [7]. The quality of the film was *ex-situ* evaluated by X-ray diffraction and by Low Electron Energy Diffraction (appearance of the (3×2) pattern) after a cycle of sputtering (Ar^+, 500 eV, 0.1 μA) and annealing (1000 K) in ultra high vacuum. Photoemission from the C 1s, Si 2p core levels and from the valence band were measured in order to characterize the system. 6H-SiC was a commercial CREE crystal, with a thickness of about 1 mm. Optical absorption measurements at the C K-edge were performed in a UHV chamber at the BEAR beamline of the ELETTRA synchrotron radiation facility in Trieste, Italy [8]. The light was linearly polarised with a photon flux of the order of 10^{10} ph/s. The energy resolution was 80 meV. The sample could be rotated along an axis normal to the synchrotron orbit plane, allowing switching from normal incidence (photon Electric field in the surface plane, p incidence conditions) to grazing incidence (photon Electric field almost normal to the surface plane).

The absorption of 3C-SiC thin ordered film was obtained in total electron yield (TY), by measuring the current drained by the sample; the dark current was stable and typically of the order of 0.1 pA. For the insulating 6H-SiC monocrystal the absorption was obtained by measuring the total fluorescence yield obtained from a calibrated photodiode (IRD AXUV100). Also in this case the dark current was stable, and typically of the order of 0.01 pA. The sample was biased at +1000 V in order to avoid any signal due to

*e-mail: pedio@tasc.infm.it

the electrons excited by the photon beam reaching the photodiode detector. The use of fluorescence yield guarantees that spectra are relative to bulk properties and unaffected by the surface condition. The photodiode surface normal formed an angle of 90° with the direction of the incident beam. Fluorescence yield (FY) spectra of concentrated samples can be distorted due to self-absorption [9]. The FY spectra were corrected for self-absorption as described in ref. [10].

Absorption signals were normalized to the incident flux, obtained by measuring the current drained by a tungsten grid inserted in the beam path. The grid was flashed in order to remove the contaminants, typically C and O.

3. Results and Discussion

The absorption spectrum (measured by TY) at the C K edge of 3C-SiC, taken at normal incidence, is shown in Fig. 1(a). In Fig. 1(b) the absorption at the same edge, taken by FY, is reported for 6H-SiC for two different grazing angles, 75° and 15°, respectively.

For 3C-SiC, the spectrum region above the C K edge shows a rich fine structure characterized by a group of peaks with prominent features at about 290 eV. The spectra did not show any dependence on the incidence direction of light, confirming the good crystal quality of the thin film with zinc-blend structure.

The 6H-SiC spectra show a similar fine structure, but with a dependence on the direction of the electric field with respect to the surface normal.

The following discussion is concentrated on the electronic and structural information that can be extracted from the analysis of the near edge spectra. The discussion will concern the first 15 eV above the edge, where marked differences occur. No significant differences are present above about 295 eV, where the NEXAFS spectra show similar features (indicated by the A and B labels of Fig. 1). The above experimental evidences are in agreement with inverse photoemission (IPES) measurements [6] and theoretical calculations [4], which show that the density of empty states of the conduction band extend significantly up to about 15 eV. In a framework based on the electronic states, the contribution to the K edge is related to the p character of the empty states. Band structure calculations [4] and cluster calculations performed by Xα molecular orbital [11] show that the unoccupied density of states of SiC both in cubic (3C-SiC) and hexagonal polytypes (applicable to the 6H-SiC in present case) is dominated by C 2p and C 2s empty electronic states. In particular the C 2p character is spread up to about 20 eV above the edge. In this framework the group of features in the IPES spectrum of 1×1 6H at 8 eV above the Fermi level has been attributed to the intrinsic bulk band of 6H-SiC due mainly to C 2p empty states. On this basis, the feature at 292 eV (present in the 6H-SiC, missing in the 3C-SiC) can be related to the bulk state at 8 eV detected by IPES, confirming the carbon origin of this state. Moreover the behavior of the 6H-SiC states as a function of the light incidence angle can be put into relation with the bond direction. In particular the most intense state at 290 eV suggests the presence of a state almost prominent from the basal plane of p character. This analysis is not able to assign the origin of the final state.

Information on both geometrical and electronic structure can be extracted by analyzing the experimental spectra with full multiple scattering calculations. Full multiple scattering simulations have been performed by MXAN [12] code. The code can provide fits of the experimental data by the absorption cross section calculation depending on the choice of structure and potential parameters. Preliminary non self consistent results will be shown here. Results obtained by using a self consistent

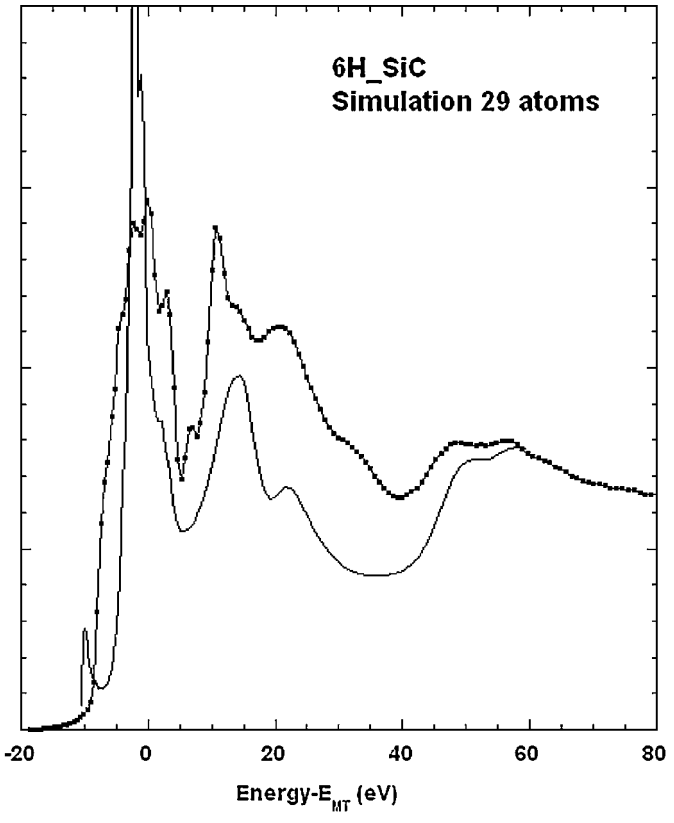

Fig. 1. (a) C K-edge NEXAFS of 3C SiC 8000 Å ordered film taken at normal incidence in total yield detection mode (b) 6H SiC monocrystal taken at nearly normal (75°) and grazing incidence (15°) in fluorescence yield mode.

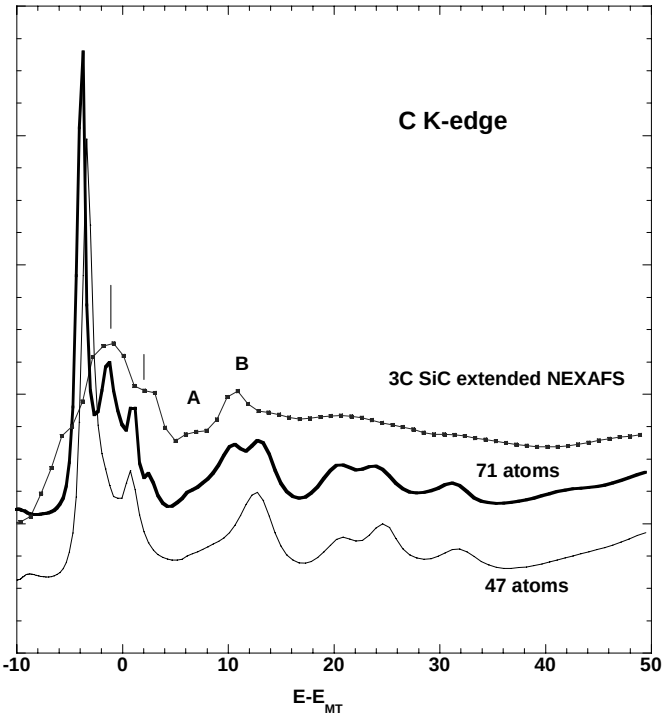

Fig. 2. Experimental spectrum (dots) of the C K-edge extended NEXAFS of 3C SiC compared with MXAN simulation performed with a cluster of 47 and 71 atoms around the central C atom. A and B indicate the features showing up in all the spectra of the SiC polytypes.

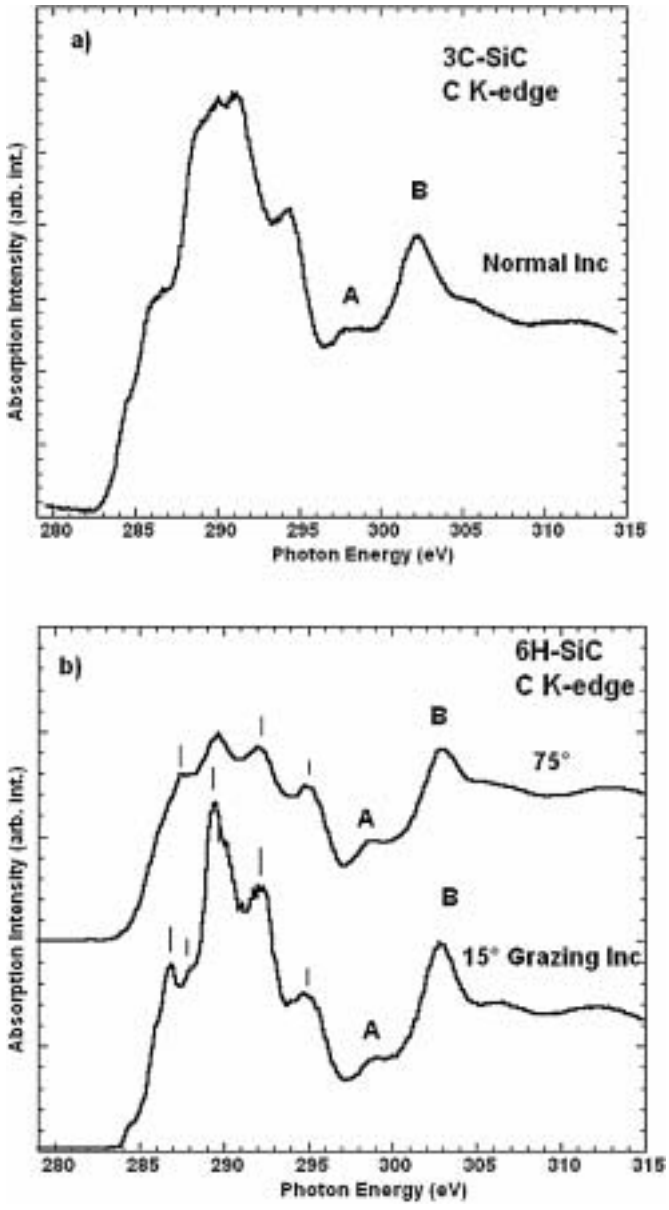

Fig. 3. Experimental spectrum (dots) of the C K-edge extended NEXAFS of 6H SiC taken at nearly normal incidence (75°) compared with MXAN simulation performed with a cluster of 29 atoms around the central C atom.

potential will be presented in a forthcoming paper. A Hedin-Lundqvist energy dependent potential was used to take into account the exchange and correlation. The atoms coordinates were fixed, while some potential parameters (e.g. interstitial potential values, overlap fraction between contiguous atoms and the Fermi energy) were treated as fitting parameters. The results are shown in Fig. 2 for 3C-SiC and in Fig. 3 for 6H-SiC.

Fig. 2 shows our results obtained with two 3C clusters of 47 atoms (cluster radius of about 4.7 Å) and of 71 atoms (cluster radius of about 5.3 Å) around the central C atom. The dependence of the simulation on the cluster dimension shows that to reproduce the high energy part of the spectrum it is enough to use a cluster of 3.6 Å. The NEXAFS part within 20 eV above the edge is reproduced only by using 71 atoms, and convergence in the simulations was achieved only at this cluster dimension. Apart from the over-estimation of the intensity at the very edge, the simulation gives a good account of the overall lineshape.

As in the case of the 3C polytype, in the case of 6H-SiC a simulation with 29 atoms (corresponding to a radius of 3.6 Å) is able to reproduce the spectrum at energies above the feature A of Fig. 1(b). The result is shown in Fig. 3 for the case of 75° of grazing incidence and compared with the experimental results reported in Fig. 1(b). The simulation gives a good account of the overall features of the spectrum though it overestimates the intensity in the near edge region.

The simulations (not shown here) performed with a larger cluster (56 atoms corresponding to a radius of 5.3 Å) gave a good account of the dependence of the intensities of the two features at about 293 eV and 295.5 eV on the direction of the electric field of light, as reported in Fig. 1(b). This is in agreement with the picture reported by Vvedensky [13] that demonstrates that the maxima of the absorption cross section correspond to those scattering paths involving atoms in a direction parallel to the direction of the electric field of the light. Closer to the edge the details of potential are more critical requiring the use of a self consistent approach mainly for low Z elements. In the case of low Z elements further difficulties arise from the effects due to the long e-h recombination life time. Moreover theoretical calculations in the case of carbon silicides [14] indicate that there is a large accumulation of electronic charge around the carbon atom generating a situation similar to that of ionic materials where, as discussed in ref. [15], self consistency is required to take into account the critical details of potentials. In order to test the possibility to correctly simulate the near edge part of NEXAFS corresponding to conduction band contribution of the local density of C electronic states, further calculations are in progress.

4. Conclusions

Silicon carbide polytipes 6H-SiC and 3C-SiC were characterized by optical absorption at the C K edge in the near edge absorption region. The NEXAFS spectra of both systems show important differences related to the peculiarities of the electronic and structural properties of the two systems well evident in the 0–20 eV photon energy region above the edge. Less evident differences were detected for higher energies.

The assignment of spectral features can be made on the basis of the partial empty density of states mainly of 2p character originating from C. This is further substantiated by the observation in the near edge region of the strong dependence of the absorption spectra, only for 6H poly-type, on the polarization direction of the photon electric field related to the anisotropy of the stacking sequence of the hexagonal structure.

Non self consistent multiple scattering analysis is able to describe the region close to the absorption edge; on the other side its failure in the about first 10 eV is in agreement with the critical dependence of the electronic potential substantiated by the possibility of interpretation on the basis of the density of empty states. The above point requires particular attention in the description of the potential. To this aim a self consistent analysis by the MXAN code is in progress.

Abstract

Anti-bixbyite-type zinc oxynitride powders $Zn_3(N_{1-x}O_x)_{2-y}$ could be prepared by directly nitriding zinc powder under ammonia gas flow. $Zn_3(N_{0.91}O_{0.09})_{1.98}$ could be obtained after 168 hours of nitridation at 500 °C. X-ray absorption spectra near N and O K-edges for some zinc oxynitrides were recorded in both total electron yield and fluorescence modes. The two spectra provide complementary information on the near surface, and on what can be considered as the bulk of the powdered zinc oxynitride. O K-edge spectra clearly appeared for all the measured oxynitrides in both the total electron yield and fluorescence modes. However, only the N K-edge fluorescence yield spectrum was detected even for the nitrogen-richest oxynitride $Zn_3(N_{0.91}O_{0.09})_{1.98}$. These results imply that the prepared zinc oxynitrides were covered with some ten nanometers of oxide layers and that nitridation of zinc powders would proceed by thinning down the oxide layers.

1. Introduction

Various zinc compounds are actively investigated because of their significant properties. For example, impurity doped ZnO is a promising material for transparent conducting oxides [1, 2]. Recently, zinc ternary oxides such as Zn-In-O [3, 4] and Zn-Sn-O [5] systems have also drawn much attention as new transparent conducting oxides. However, Zn-O-N system has been scarcely studied. The anti-bixbyite-type Zn_3N_2 has been reported to show n-type conduction with a direct band gap of 1.23 eV [6] whereas the optical band gap of the wurtzite-type ZnO is determined to be around 3.2 eV. Futsuhara *et al*. tried to alter the optical band gap from 1.23 to 3.2 eV by varying the composition of Zn-O-N films, and showed that the gap decreased from 3.26 eV to 2.3 eV with increasing nitrogen concentration in the films [7].

In preparing such metal oxynitrides, ammonia gas is preferentially used as a nitrogen source. We have reported that the anti-bixbyite-type zinc oxynitrides $Zn_3(N_{1-x}O_x)_{2-y}$ could be prepared by directly nitriding zinc powder under ammonia gas flow [8]. The oxygen content x and amount of anion deficiency y decreased with increasing nitriding period at 500 °C. The nitrogen richest $Zn_3(N_{0.91}O_{0.09})_{1.98}$ could be obtained after 168 hours of nitridation at 500 °C. During the nitridation of zinc powder by ammonia gas flow, entire zinc oxide layers of a few millimeters covered forming oxynitrides and the oxynitrides enriched their nitrogen content in proportion to the nitriding period. Though these oxynitrides were detected as a single phase by X-ray diffraction, it is necessary to prove the microstructures by using methods which are sensitive to the local environment around the nitrogen and oxygen centers.

In this study, X-ray absorption spectra near N and O K-edge for the zinc oxynitrides were recorded in both total electron yield and fluorescence modes. The two spectra provide complementary information on the near surface, and on what can be considered as the bulk of powdered zinc oxynitride.

2. Experimental Procedures

Metallic zinc powder (analytical grade, particle size less than 45 μm, purchased from Merck) was used as a starting material. The zinc powder was laid in an alumina boat placed in an alumina tube of a horizontal Siliconit tube furnace. After evacuating the system, argon gas was introduced. The furnace temperature raised to the nitriding temperature of 400–600 °C in 1 hour, the gas was switched to ammonia flowing at a rate of 50 ml/min. Both the argon and ammonia gases were dried by passing through a soda lime cylinder and a coiled coolant trap (−30 °C). The product was cooled in the furnace down to room temperature.

Phase identification was performed by powder X-ray diffractometry (Rigaku RINT-2500VHF+) using monochromatized CuKα radiation with a source power of 40 kV and 100 mA. The oxygen and nitrogen contents of each oxynitride were analyzed using a Horiba EMGA-2800 device. The samples mixed with a Ni-Sn flux were reduced in a carbon crucible to convert the oxygen and nitrogen into carbon monoxide and N_2 in helium as a carrier gas, respectively. The amount of carbon monoxide was determined by measuring the IR absorbance and that of N_2 was detected by the thermal conductance. In calculations of composition of oxynitrides, the ratio of zinc to anion components (nitrogen and oxygen) was normalized to be "3". Hereafter, the composition of oxynitride is expressed as $Zn_3(N_{1-x}O_x)_{2-y}$, where x represents oxygen amount and y represents the anion deficiency in the oxynitride.

X-ray absorption spectroscopy was carried out at the Canadian Synchrotron Radiation Facility (CSRF) located at the Aladdin storage ring at the Synchrotron radiation Centre, University of Wisconsin, Madison, USA. The ring operated at 1 GeV and the average ring current was 190 mA. N K-edge and O K-edge spectra were recorded on the Spherical Grating Monochromator beamline, in both total electron yield (TEY) and fluorescence yield (FLY) modes [9]. The grating used on the spherical grating monochromator has 600 lines/mm, giving an energy range of 240–700 eV. The resolution of this beamline has been demonstrated to be around 70 meV in gas phase spectroscopy [10]. The photon beam is incident along the surface normal and the energy was typically scanned across 395 to 420 eV and 510 to 560 eV windows to collect the nitrogen and oxygen spectra, respectively. The beam on the sample has a size of 1 mm horizontal times 1 mm vertical. Spectra were normalized by division by the photon flux measured by a 90% transmission gold mesh.

3. Results and Discussion

The X-ray diffraction patterns showed that nitridation of metallic zinc under ammonia gas flow at 500 °C led to the formation of pure anti-bixbyite-type zinc oxynitrides. Interestingly, the zinc oxynitrides were covered with ZnO in the alumina boat. After removing the oxide cover carefully, the oxynitrides were examined. When the nitriding temperature was set at 500 °C, $Zn_3(N_{0.81}O_{0.19})_{1.97}$ and $Zn_3(N_{0.91}O_{0.09})_{1.98}$ was formed for 48 and 168 hours, respectively. The compositional analysis of the products suggested that the oxygen content x in $Zn_3(N_{1-x}O_x)_{2-y}$ fundamentally decreased with increasing nitriding period. The lattice constant a of the respective product was 9.762 Å after the 48-hour nitridation and 9.764 Å after the 144-hour nitridation, both of which were slight smaller than 9.769 Å of the reported one for Zn_3N_2. This trend in increased lattice constants agrees well with the results reported by Futsuhara *et al*. [7, 11], and these facts mean that the oxygen should be occluded in the zinc oxynitrides.

Figure 1 shows O K-edge TEY and FLY spectra observed for $Zn_3(N_{0.81}O_{0.19})_{1.97}$ and $Zn_3(N_{0.91}O_{0.09})_{1.98}$ at room temperature. No significant differences were observed between the spectra except that the edge jump height corresponding to the so-called white line, just after the absorption threshold, was smaller in the FLY spectra than that in the TEY spectra. Figure 2 shows N K-edge TEY and FLY spectra. No signals were detected in the TEY mode whereas definitive spectra were presented in the FLY mode for both specimens.

Kasrai *et al*. considered the electron mean free path and thus information depth in TEY and FLY modes, in the analysis of oxide films on silicon [9]. For the Si L-edge at around 100 eV the maximum sampling depth in TEY mode is found to be around 5 nm, while that of the fluorescence spectrum is around 70 nm. While sampling depths will be somewhat greater for the N and O K-edges at 400–550 eV due to the increased range of the primary Auger electrons which give rise to the TEY signal, the factor of >10 in the relative information depth will be retained. These results imply that the prepared zinc oxynitrides were covered with some ten nanometers of oxide layers where nitrogen scarcely existed. Note that the S/N (signal to noise) ratio was improved for the sample of nitrogen-rich $Zn_3(N_{0.91}O_{0.09})_{1.98}$. This fact would be mainly attributable to a decrease of thickness of the oxide layers, suggesting that nitridation of zinc powders would proceed by thinning down the oxide layers. The zinc nitrides will contain less amount of oxygen than detected by the compositional analysis.

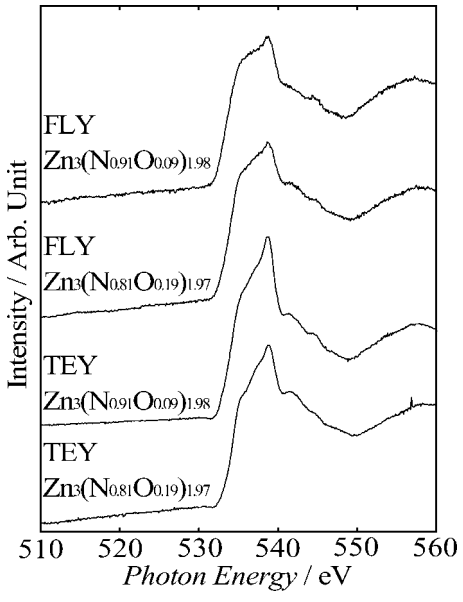

Fig. 1. O K-edge TEY (total electron yield) and FLY (fluorescence yield) spectra observed for $Zn_3(N_{0.81}O_{0.19})_{1.97}$ and $Zn_3(N_{0.91}O_{0.09})_{1.98}$.

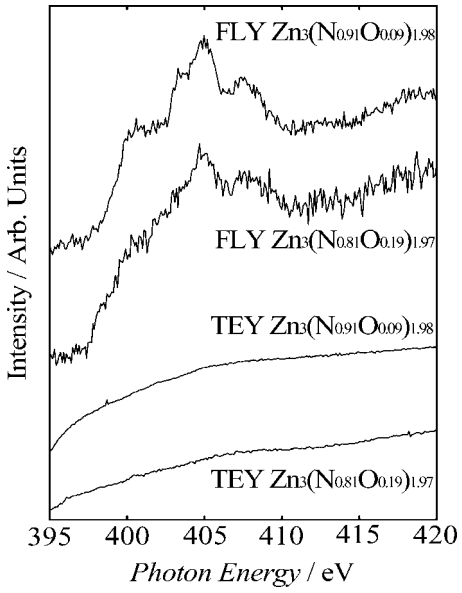

Fig. 2. N K-edge TEY (total electron yield) and FLY (fluorescence yield) spectra observed for $Zn_3(N_{0.81}O_{0.19})_{1.97}$ and $Zn_3(N_{0.91}O_{0.09})_{1.98}$.

Concerning the feature of N K-edge FLY spectrum of $Zn_3(N_{0.91}O_{0.09})_{1.98}$, a dominant peak observed at 405 eV and a shoulder peak at around 400 eV are consistent with that of the N K-edge FLY spectrum of crystalline GaN. In line with other works, including studies of BN, the sharp feature at around 400 eV and the broader peak at 405 eV can be correlated with nitrogen in sp^2 and sp^3 hybridization, respectively [12, 13]. Based on this model, the zinc oxynitride shows greater sp^3 character in the bonding of nitrogen. It is not clear how this should be interpreted, as it is apparent that the nitrogen will be in an octahedral environment in the anti-bixbyite-type zinc oxynitrides. Though early first transition metal nitrides such as TiN and VN possess metallic characters, they tend to show stronger covalent characters as their atomic number increases. Covalent nitrides refer to compounds containing heavier metals than copper in the periodic table. The greater sp^3 character, however, presumably relates to the greater p character, resulting from strong covalency between Zn-N bonds.

Abstract

Six-coordinated silicon [6]Si was observed by Si and P K-edge XAFS measurements in $x$$Li_2O$-$y$$SiO_2$-(100-$y$)$P_2O_5$ glasses (x = 25 and 33, y = 40, 45, 50, 55, and 60). Si K-edge EXAFS spectra of the glasses indicated the co-existence of [6]Si and four-coordinated silicon [4]Si. The proportion of octahedral [SiO_6^{6-}] to [6]Si depends upon the alkali content and the [SiO_6^{6-}]/[SiO_4^{4-}] tetrahedral ratios were estimated by Si K-edge XANES spectra. The interatomic distances were 1.88–1.90 Å for Si-O and 1.5 5–1.61 Å for P-O and the amounts of [SiO_6^{6-}] were 11.8–46.9%.

1. Introduction

It is thought that local structure of silicon in silicate glasses has usually a SiO_4 tetrahedral structure, but in case of SiO_2-P_2O_5 glasses and crystals with high phosphorus concentration, it was reported by NMR [1] and XANES [2] that six oxygen atoms bind with silicon. Moreover, the proportion of six-coordinated silicon [6]Si depends upon the alkali content [3]. XAFS spectra of Si and P K-edge were collected in the soft X-ray region under vacuum conditions, and usually measured by total electron yield [TEY]. However, TEY is very sensitive to the near surface structure of the sample. Therefore, it is not suitable to know the real network in structure formed glasses.

In the present study, we report the experimental method of transmission XAFS under atmospheric pressure and the local structure of [6]Si in octahedral [SiO_6^{6-}] in Li_2O-SiO_2-P_2O_5 glasses.

2. Experimental

$x$$Li_2O$-$y$$SiO_2$-(100-$y$)$P_2O_5$ (x = 25, 33, y = 40, 45, 50, 55, 60) glasses were prepared from extra-reagent grade SiO_2, P_2O_5 and Li_2CO_3. The glasses were melted in Pt crucibles in the range 1573–1673 K depending on the stoichiometry and then quenched by squashing between two stainless-steel plates. The Si and P K-edge XAFS spectra of glasses were obtained by transmission mode at BL-4 in the Ritsumeikan Synchrotron Radiation Center using InSb(111) double monochromater crystals and two ionization chambers filled with helium gas.

3. Results and discussion

Fig. 1 depicts Si K-edge XANES spectra of the glasses. It was reported by Li and Fleet *et al.* [2, 4, 5] that the white peak at the Si K-edge of [SiO_4^{4-}] and [SiO_6^{6-}] were observed at 1868 and 1840 eV, respectively. Each obtained spectrum was fitted by Gaussian components for [4]Si and [6]Si. This estimation method for [6]Si through deconvolution of the Si K-edge XANES spectra was first addressed by Li *et al.* [4] and subsequently revised by Fleet *et al.* [2, 6]. As shown in Fig. 2, the Si K-edge EXAFS spectra of the glasses are very similar for all glasses in the composition range investigated. On the other hand, the EXAFS oscillation of these glasses differs from the Si K-edge EXAFS of standard samples, such as Leucite and amorphous SiO_2. Coordination numbers obtained by XANES fitting analysis were used in the EXAFS curve fittings as an initial value. Results of the curve fitting procedure indicate that the Si-O interatomic distances of

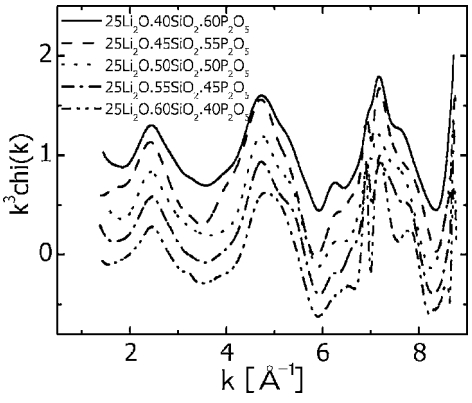

Fig. 1. Transmission mode Si K-edge XANES spectra of Li_2O-SiO_2-P_2O_5 glasses. The absorption edge peak of the glasses are observed at 1848.0 eV, and the shoulder peak by six-coordinated silicon are 1850.0 eV.

Table I. *EXAFS structure parameters for $Li_2O.SiO_2.P_2O_5$ glasses.*

Samples	$N_{Si\text{-}O}/N_{P\text{-}O}$ [atoms]	$R_{Si\text{-}O}/R_{P\text{-}O}$ [Å]	SiO_6^{-6}/SiO_4^{-4} [%]
$25Li_2O.40SiO_2.60P_2O_5$	$4.5 \pm 0.3/3.8 \pm 0.2$	$1.89 \pm 0.04/1.61 \pm 0.03$	25.3/74.7
$25Li_2O.45SiO_2.55P_2O_5$	$4.7 \pm 0.3/4.0 \pm 0.2$	$1.88 \pm 0.04/1.55 \pm 0.03$	32.5/67.5
$25Li_2O.50SiO_2.50P_2O_5$	$4.5 \pm 0.3/4.0 \pm 0.2$	$1.89 \pm 0.04/1.57 \pm 0.03$	25.3/74.7
$25Li_2O.55SiO_2.45P_2O_5$	$4.4 \pm 0.3/3.8 \pm 0.2$	$1.88 \pm 0.04/1.57 \pm 0.03$	18.2/81.8
$25Li_2O.60SiO_2.40P_2O_5$	$4.3 \pm 0.3/4.0 \pm 0.2$	$1.88 \pm 0.04/1.58 \pm 0.03$	11.8/88.2
$33Li_2O.40SiO_2.60P_2O_5$	$4.6 \pm 0.3/4.0 \pm 0.2$	$1.90 \pm 0.04/1.58 \pm 0.03$	46.9/53.1
$33Li_2O.55SiO_2.45P_2O_5$	$4.4 \pm 0.3/3.8 \pm 0.2$	$1.90 \pm 0.04/1.58 \pm 0.03$	26.7/73.3
$33Li_2O.50SiO_2.50P_2O_5$	$4.3 \pm 0.3/3.8 \pm 0.2$	$1.90 \pm 0.04/1.58 \pm 0.03$	16.7/83.3
Leucite [$KAI(Si_2O_6)$]	4.0 ± 0.1/	1.64 ± 0.01/	
TEP	$/4.0 \pm 0.1$	$/1.58 \pm 0.01$	

the glasses are 1.88–1.90 Å, while the Si-O interatomic distance of tetrahedral [SiO_4^{4-}] in Leucite was 1.64 Å. The obtained structural parameters by EXAFS and XANES are summarized in Table I. The coordination numbers $N_{Si\text{-}O}$ and $N_{P\text{-}O}$ and the interatomic distances $R_{Si\text{-}O}$ and $R_{P\text{-}O}$ were estimated by EXAFS, and the ratio [SiO_6^{6-}]/[SiO_4^{4-}] by XANES fitting. Moreover, the Si-O distance of [SiO_6^{6-}] in a SiP_2O_7 crystal in which silicon is octahedrally coordinated to oxygen is 1.7345 Å [6]. Therefore, Si-O distances in Li_2O-SiO_2-P_2O_5 glasses are much larger than in the crystal composed of [SiO_6^{6-}] octahedral structure.

On the other hand, the P K-edge EXAFS spectra of Li_2O-SiO_2-P_2O_5 glasses can be divided roughly into two types, and the P-O distance in $25Li_2O$-$40SiO_2$-$60P_2O_5$ glass are larger than the other glasses as shown in Table I.

4. Conclusion

Six-coordinated silicon [6]Si was observed by Si K-edge EXAFS spectra in $x$$Li_2O$-$y$$SiO_2$-(100-$y$)$P_2O_5$ glasses ($x = 25$ and 33, $y = 40$, 45, 50, 55, and 60). The results indicate the co-existence of tetrahedral [SiO_4^{4-}] and octahedral [SiO_6^{6-}]. The proportion of [SiO_6^{6-}] octahedra depends upon the alkali content and the [SiO_6^{6-}]/[SiO_4^{4-}] ratios were estimated by Si K-edge XANES spectra and analysis of EXAFS. While the Si-O interatomic distance of [SiO_4^{4-}] in Leucite was 1.64 Å, the Si-O distance containing [SiO_6^{6-}] octahedral were 1.88 to 1.90 Å. Moreover, the Si-O distance in a SiP_2O_7 crystal in which Si atom is octahedrally coordinated to oxygen is 1.7345 Å [1], therefore, Si-O distances in Li_2O-SiO_2-P_2O_5 glasses are much larger than in the crystal composed of [SiO_6^{6-}] octahedral. On the other hand, P-O interatomic distances in the glasses were observed at 1.55–1.61 Å, while the distance in TEP was 1.58 Å.

Abstract

X-ray absorption near edge structure (XANES) spectra, at the Na and Al K-edge, have been measured for Ca-Na aluminosilicate glasses. This allows a determination of the local cationic sites corresponding to 6–8 oxygen neighbours in a distorted first shell for Na and to 4 oxygen neighbours for Al. The Al XANES spectra show a strong dependence on the medium range organisation of the polymeric network.

1. Introduction

Soda lime aluminosilicate glasses are important glasses in glass industry or for geological melts but there have been relatively few structural studies of glasses in this system. Alkali and alkaline earth content are strongly affecting the physical properties (viscosity, electrical conductivity and heat capacity) and the microstructure of the glasses. Calcium and sodium in aluminosilicate glasses have a double structural role either as modifier, participating to the network depolymerization, or as charge compensator, near the $(AlO_4)^-$ tetrahedra. The local and medium range environment may be affected by the structural role played in the network by these cations. However, a detailed analysis of the cationic environment is lacking, which is important to understand the structural role of the alkali. Previous studies have mainly concentrated on the aluminosilicate network by NMR [1] or Raman [2] spectroscopies, indicating that Al and Si are present in tetrahedral coordination but the polymerization nature (rings, Si/Al ordering...) of the aluminosilicate network is still poorly understood.

In this paper, we present an extensive study on a wide range of composition of aluminosilicate glasses containing Ca and Na. The environment of Na and Al are investigated by X-ray Absorption Spectroscopy (XAS) to highlight the influence of the substitution Ca/Na or Si/Al and to determine the possible usefulness of this technique to investigate the cationic environment in complex multicomponent glasses.

2. Experimental

Soda lime aluminosilicate glasses (NCAS glasses) were synthesized by melting at 1900 K for 4 hours and then quenched by immersion of the bottom of the Pt crucible in water. Chemical compositions were obtained by electron microprobe analyses (with a Camebax SX50 at the Université Paris 7). We use the notation NCAx.y.z, where x, y and z refer to the molar percent of SiO_2, Al_2O_3 and Na_2O respectively, and 1-x-y-z is the CaO molar content.

We obtained XANES spectra at Na K-edge (1070.8 eV) and Al K-edge (1559 eV) on the SA32 beam line at the Super ACO storage ring at the LURE (Orsay, France). The spectra were collected at room temperature using a double-crystal monochromator equipped with beryl (10$\underline{1}$0) for the Na K edge and quartz (10$\underline{1}$0) for the Al K edge. The total yield of photoelectrons (TEY) was measured using the sample current for two or three scans with 0.1 eV step and 1 s integration time. Spectra were calibrated using the inflection point of the absorption edge of metallic Ge (1217 eV) and Al (1559 eV) foils for the Na and Al XANES spectra, respectively. The energy calibration was periodically checked during the measurements. A Victoreen pre-edge was removed for each spectrum and the data were normalized.

3. Results

Na K edge XANES spectra are shown in Figure 1 for NCA glasses and compared with crystalline references (albite $NaAlSi_3O_8$, nepheline $NaAlSiO_4$ and jadeite $NaAlSi_2O_6$). The quality of the XANES spectra for the crystalline references is significantly improved compared to a previous study [3] and in agreement with a more recent study for jadeite [4]. A weak pre-edge (peak *a*) at about 1074.4 eV is apparent on some samples. Absorption spectra present sharp features near threshold (1077.4 and 1082.4 eV) and broader resonances extending 60–90 eV above the threshold. The sharp lines close to the threshold can be attributed to core-level excitons, i.e., an excitation of a core-level electron into an unoccupied bound level. The first sharp feature in the absorption spectra, peak *b*, can be associated with a localized transition from the 1s core level to the 3p state of Na^+ [5]. Although the detailed interpretation of some peaks energetically close to the strong peak *b* is under discussion, there is a consensus that broad peaks above 1085 eV are due to photoelectron scattering resonances, i.e. the outgoing photoelectron wave from the absorbing atom and the single- or multiple-scattering from the surrounding atoms.

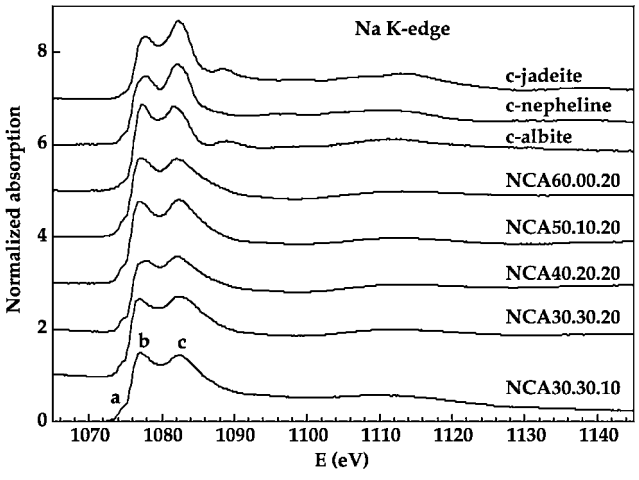

Fig. 1. Na K-edge XANES spectra for the NCA glasses compared with crystalline references.

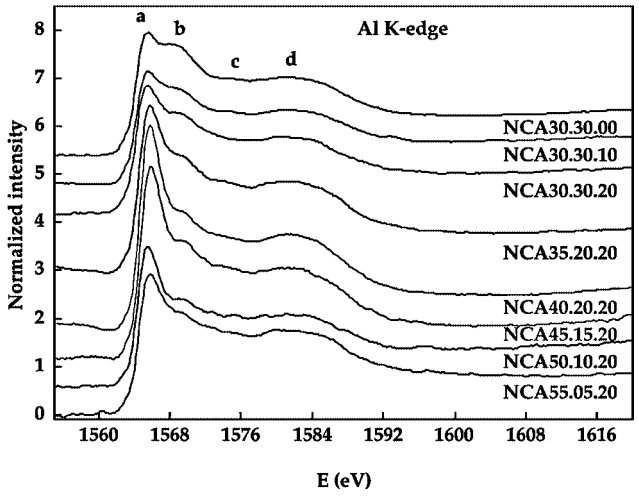

Fig. 2. Al K-edge XANES spectra for the NCA glasses.

The positions of peaks *b* and *c* are the same for the glasses and the references. Yet, the relative intensities of peak *b* and *c* change from jadeite to nepheline and albite. Peak *c* is more intense in jadeite than peak *b* and the reverse is observed for albite. XANES spectra for nepheline and albite have greater similitude with XANES spectra of glasses than the spectra of jadeite, in particular for the relative intensities of peaks *b* and *c*. The coordination number of Na in albite and nepheline corresponds to 8 oxygen neighbours with a wide range of Na-O distances between 2.5 and 3.15 Å. The Na site in jadeite is more regular with six oxygen neighbours at a mean Na-O distance of 2.391 Å and two further oxygen neighbours at 2.803 Å.

Al K-edge XANES spectra are presented in Figure 2 for the NCA glasses. A white line at 1565.6 eV is observed, followed by three ill-defined features a about 1568.1, 1574.5 and 1581 eV. These absorption features arise from transitions of core electrons to the first empty electronic bound states as well as from multiple scattering resonances inside the nearest neighbour coordination shell or among the first neighbours [6].

4. Discussion and conclusion

The Na K-edge XANES spectra of the NCA glasses are compared in Figure 1 with several Na- aluminosilicate crystals. Peaks *b* and *c* in glasses are broader which is likely due to a more disordered Na environment. Peak *c* in glasses present a broad tail at high energy which may overlap the feature present at 1088 eV in albite. In the crystalline references, the Na environment corresponds to 5 (albite) or 6 (jadeite and nepheline) oxygen neighbours at distances of 2.3–2.7 Å with two more oxygen neighbours at longer distances (2.8–3 Å). The similitude between the spectra of crystals and glasses indicate a similar distorted environment around Na in aluminosilicate glasses. This coordination number is close to that determined by EXAFS in sodium aluminosilicate glasses [3]. Similarly, computational simulation studies indicate a distorted environment around Na with 5 or more oxygen neighbours [7, 8].

As Si is replaced by Al, the structural role of Na is changing from a modifying position which depolymerises the glassy network to a charge compensating position near the $(AlO_4)^-$ tetrahedra. Such change in structural role implies small modification in the cation environment [9] but no clear modification of the Na XANES spectra are discernible which suggests that XANES spectra are not sensitive to such changes. Similarly, at constant content of SiO_2 and Al_2O_3 of 30 mol% (two lower curves in Figure 1), the effect of substituting one cation (Na) by another (Ca) does not modify the positions, the relative intensities and the widths of peaks *b* and *c*. This again suggests that the Na environment is poorly affected by such substitution or that such changes are too subtle to be observed in the Na XANES spectra.

The position and the shape of the white line in the Al XANES spectra indicate that Al is tetrahedrally coordinated for all glass compositions [6]. Among the various glasses, variation in the relative energy intensity of peaks *a* and *b* are observed on the Al K-edge XANES spectra. The intensity of peak *a* is the most intense for the NCA45.15.20 and NCA40.20.20 samples and becomes less intense as Si is replaced by Al (NCA30.30.20). With the Si/Al substitution, there is a repolymerization of the glassy network. The observed changes in the Al XANES spectra indicate that XANES spectra are highly sensitive to the degree of polymerization of the glassy network and to the number of Si and/or Al neighbours in the second coordinated shell. For a constant ratio of Si/Al, the intensities of peak *b* slightly increases when Na is replaced by Ca (three top curves in Figure 2). The origin of this contribution is still uncertain without simulations and multiple scattering calculations. This feature is not necessarily associated with the cations. Indeed, Ca atoms favour the microsegregation of Al due to the double charge of Ca^{2+} ions which requires two $(AlO_4)^-$ tetrahedra in their environment compared to one in the case of Na^+ ions. Therefore, peak *b* could be an indication of this Al distribution. This is confirmed by the low intensity of peak *b* in the glasses with low Al_2O_3 content, where a heterogeneous distribution of Al atoms is unlikely (NCA55.05.20).

In conclusion, Al and Na XANES spectra can give valuable structural information on the structure of complex disordered materials but theoretical analysis is required. Few changes are observed in the Na XANES spectra with Si/Al or Ca/Na substitution. By contrast, the Al XANES spectra present important changes upon these substitutions in relation with the nature of the aluminosilicate network.

Abstract

BI*ME*VOX ceramics with different molar fraction of *ME* = Mg, Si, Zr, Zn have been investigated. X-ray absorption spectra have been measured for K edges of vanadium and zinc. The XANES at the vanadium K edge undergoes a conspicuous change for the metal dopant concentrations exceeding dopant solubility limits. Position of the pre-edge peak indicates the valence state of vanadium to be 5+ in all studied BI*ME*VOX'es. Vanadium coordination, as inferred from the EXAFS data, shows similarity for all dopants used, with two characteristic distances to oxygen atoms. An estimate of oxygen occupation numbers is given. Local environment of zinc atoms has an average coordination number *ca.* 4, and exhibits shorter interatomic distances to oxygen atoms than vanadium.

1. Introduction

Fast oxide ion conductors have found use in devices such as fuel cells, oxygen sensors and gas separation membranes. In last years interest has been focused on a family of oxide ion conductors based on bismuth vanadate, $Bi_4V_2O_{11}$, which have high conductivities at relatively low temperatures (*ca.* 10^{-3} Scm^{-1} at 500 °C). The structure of the parent compound, $Bi_4V_2O_{11}$ consists of alternating layers of $[Bi_2O_2]_n^{2n+}$ and $[VO_{3.5}]_n^{2n-}$. Three main polymorphs have been identified and are associated with various ordering in the vanadate layer. The high oxide ion conductivity is found only in the high temperature γ-phase. Substitutional doping of vanadium by lower valency cations (in most cases divalent metals) leads to a stabilisation of the γ-phase at room temperature. This family of solid electrolytes has become known as the BI*ME*VOX system [1, 2].

Most of structural data concerning BI*ME*VOX'es comes from diffraction measurements, which do not distinguish between the sites of the vanadium and the dopant cation. In contrast, EXAFS spectroscopy is a local probe, which examines structure around a specific atom. Till now, two papers on EXAFS studies in BI*ME*VOX system concerning only few compositions have been published [3, 4].

In this work we studied X-ray absorption fine structure in BI*ME*VOX materials with bivalent and tetravalent dopants.

2. Experimental

BI*ME*VOX samples with *ME* = Si, Mg, Zr, Zn have been prepared from high-purity oxides by conventional solid state interdiffusion procedures. XAFS measurements have been carried out at HASYLAB (Hamburg) at the A1 station by the transmission method. Most measurements have been performed on vanadium K edge. Considering a local structure around a metal dopant, only the zinc K edge was experimentally attainable in this study.

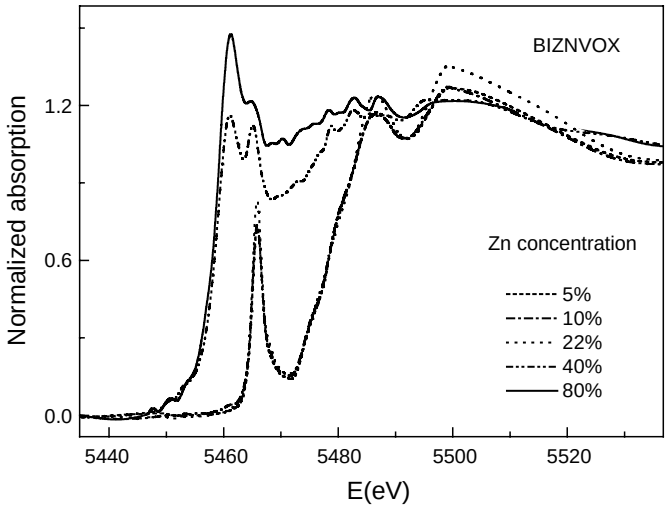

Fig. 1. XANES for BIZNVOX for different Zn content.

3. Results and Discussion

Fig. 1. presents the normalised XANES spectra for BIZNVOX with different zinc content. It shows quite dramatic change of the spectra between two compositions with 22% and 40% of zinc. This corresponds to crossing the zinc solubility limit and formation of polyphasic system. In the further analysis we will limit ourselves only to the single phase (γ-phase) compositions, which correspond to a dopant content well below 30% for all studied BI*ME*VOX materials. The distinct pre-edge peak has practically the same position for all studied BI*ME*VOX'es (Fig. 2). A comparison with V_2O_5 standard indicates that vanadium is almost exclusively in 5+ charge state [5]. The strength of the pre-edge feature indicates highly non-centrosymmetric position of vanadium atoms. As has been shown for V_2O_5 [6], the strength of this peak comes about almost exclusively from the short V-O bond and its asymmetry to the opposite bond. This suggests that "apical" oxygens in BI*ME*VOX materials are far from ideal octahedral positions. When two oxygen vacancies are present in equatorial positions, local environment of vanadium atom is effectively tetrahedral-like for which strong pre-edge feature is usually observed.

The EXAFS data in the k range 3–14 Å^{-1} have been extracted and analysed in a standard way, using the VIPER programme and ATHENA-ARTHEMIS package. The scattering amplitudes and phases have been calculated by the FEFF8 programme. Fig. 3. shows the Fourier transform of the EXAFS function measured at the vanadium K edge for all studied BI*ME*VOX'es and for the zinc K edge. The range of the useful data is limited to the nearest neighbour shell, because of disorder in higher shells. The data has been analysed, taking into account results of the combined X-ray and neutron powder diffraction [7, 8]. In particular they

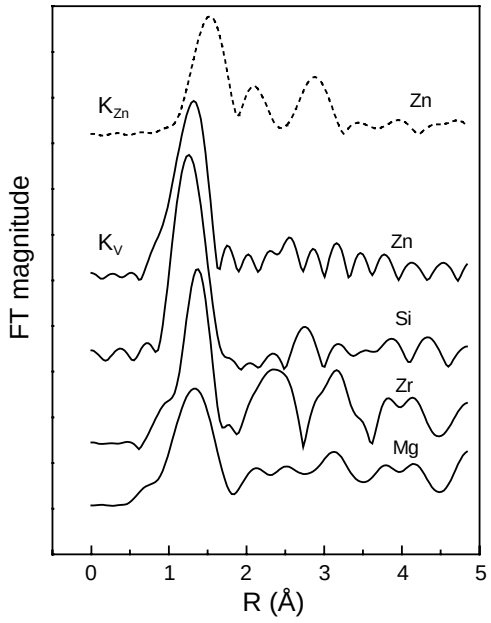

Fig. 2. Pre-edge peak for BI*ME*VOX with different *ME* dopants.

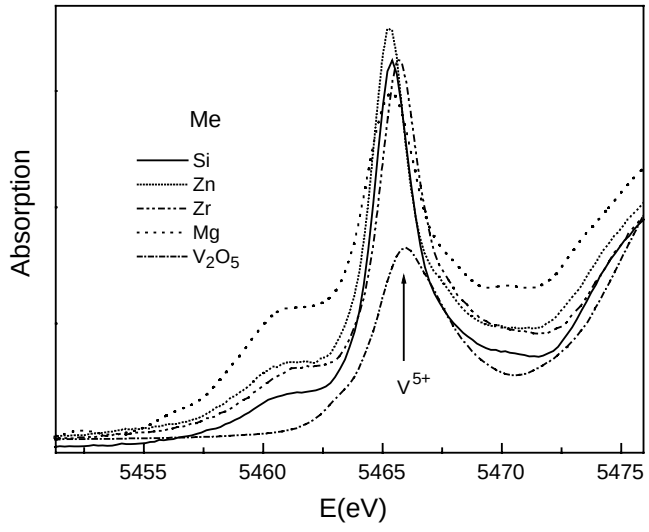

Fig. 3. Fourier transforms of $k^2\chi(k)$ for K edge of vanadium and K edge of zinc.

have revealed two main types of vanadium/dopant coordination viz. distorted octahedral and distorted tetrahedral. In a distorted "octahedral-like" coordination vanadium has 2 apical oxygen atoms at *ca.* 1.6 Å distance and 2 to 4 (depending on number of vacancies) equatorial oxygens at *ca.* 2.1 Å. For this reason, we performed two-shell fitting. The results are presented in Table 1. The parameter errors were estimated from comparison of the results from several scans and different fitting procedures. The shorter interatomic V-O distances (R_1) can be identified with the apical oxygen atoms and longer ones (R_2) with equatorial oxygen

Table I. *Fitting parameters for BIMEVOX with different dopants.*

ME	R_1 (Å)	N_1	R_2 (Å)	N_2
Mg	1.74	1.4	2.07	2.61
Si	1.7	1.5	2.13	3.4
Zn	1.73	2	2.13	3
Zr	1.67	1.7	2.08	2.8
error	0.03	0.4	0.03	0.4

atoms. The obtained coordination numbers bear a quite high uncertainty. Still, the EXAFS results indicate, shorter vanadium bonds with 1 or 2 oxygen atoms and longer bonds with 2 or 3 oxygen atoms. Analysis of zinc K edge EXAFS indicates, that the Zn-O distances are shorter than the V-O distances. The shorter bonds have 1.5 Å length and longer 1.95 Å. The total coordination number is for zinc closer to 4, what is expected in the equatorial vacancy model [2].

4. Conclusions

Vanadium K-edge XANES of the studied BI*ME*VOX materials appears to be a sensitive probe of their crystallographic phase. The high intensity of the pre-edge peak is associated with a strongly non-centrosymmetric environment of V atoms. Position of the pre-edge peak in the XANES spectra of vanadium indicates its valence state close to 5+ in all studied BI*ME*VOX'es. Vanadium coordination, as inferred from EXAFS data, shows also similarity for all BI*ME*VOX'es with two V-O bond lengths. It is, however difficult to determine exact occupation numbers for oxygen atoms from our data and to judge dominant location of oxygen vacancies (apical or equatorial positions). Zinc coordination number in BIZNVOX is close to 4, the interatomic distances to oxygen atoms are shorter than for vanadium.

Abstract

By evaporation on a clean native or thermal silica film, sodium atoms incorporate into the silica network and Na becomes surrounded by a well defined local structure. Exposure to oxygen transforms this ($Na + SiO_2$) glassy system to a crystallized compound close to Na_2SiO_3. Higher Na coverage of the clean silica surface leads to a metallic sodium multilayer, which transforms after the same oxygen dosing to pure Na_2O.

1. Introduction

In previous papers [1, 2], we have studied by XAFS at the sodium K-edge the behaviour of this alkali metal deposited under UHV conditions on thin native or thermal silica layers. It has been shown that the sodium incorporates into the silica network and appears surrounded by a well defined local structure made of oxygen and silicon atoms at definite interatomic distances. After sodium deposition, the silica layer presents therefore a strong analogy with soda-silicate glasses of the (Na_2O - SiO_2) composition and a first conclusion is that sodium plays an active role in building the structure of these glasses. For moderate sodium evaporation conditions, the amount of sodium left on the sample, as measured by the absorption jump at the Na K-edge, presents a saturation behaviour which corresponds approximately to 35 at. % of sodium.

Nevertheless some definite differences exist between the glass and $Na + SiO_2$: since sodium is deposited as neutral atoms, while in the glass, the incorporation takes place through the oxide, the silica layer is oxygen-defective. This incorporation of sodium is thermally reversible since a 600 °C heating in vacuum removes the sodium from the SiO_2. Because of the oxygen stoichiometry of the final compound, it is likely that a dosing of oxygen could change the chemical composition of the mixed $Na + SiO_2$ layer. In this paper we then present results on the exposure of two samples to oxygen: the first one corresponds to a 'moderate' deposit with a local structure close to that of the previous experiments, and the second one is the result of a very long sodium evaporation beyond the saturation limit.

2. Experimental

XAS experiments have been done on the SA32 beam line at LURE-Super-ACO, running typically at 800 MeV with an average current of 300 mA. For sodium K-edge spectra, the line is equipped with a beryl ($10\underline{1}0$) double-crystal monochromator, allowing an energy resolution of about 0.5 eV at 1 keV. The incident flux is monitored by the total electron yield (TEY) from a 2 µm polyethylene film covered by 700 Å of titanium. The absorption signal is also measured by TEY inside the UHV chamber, the vacuum level being kept always, even during the Na evaporation, in the low 10^{-10} Torr range.

The data analysis follows the now classical scheme: the atomic background is modelled by a spline function and the normalization uses the Heitler formalism. Then the filtered Fourier transform of the $k.X(k)$ EXAFS data, weighted by an Hanning window spanning from 2.3 to 7.5 $Å^{-1}$ is fitted in k and R spaces by the FEFFIT code [3]. The phase shift parameters are *ab-initio* calculated by FEFF7 [4] and checked on the experimental results for the model compound Na_2SiO_3. This procedure has been detailed in the previous papers.

3. Results

3.1. *'Moderate' deposits*

In this case the SAES-getter cell was set to 4.8 A and the evaporation time was 45 min. The structural result is perfectly in line with previously published analysis and sodium is found surrounded by about 3 oxygen atoms at 2.30 Å and 2 silicon atoms at 3.80 Å. Moreover the Fourier transform exhibits the presence of other sodium atoms in the surroudings of one Na, at a distance close to 3 Å. These sodium neighbours have been shown to appear only at high sodium contents.

This sample is then exposed to oxygen at a pressure of 10^{-6} Torr for 20 min at room temperature. The local structure around Na appears definitely different, as indicated in Fig. 1 through a comparison between the near edge structures, while the similarity between the Fourier transforms immediately shows

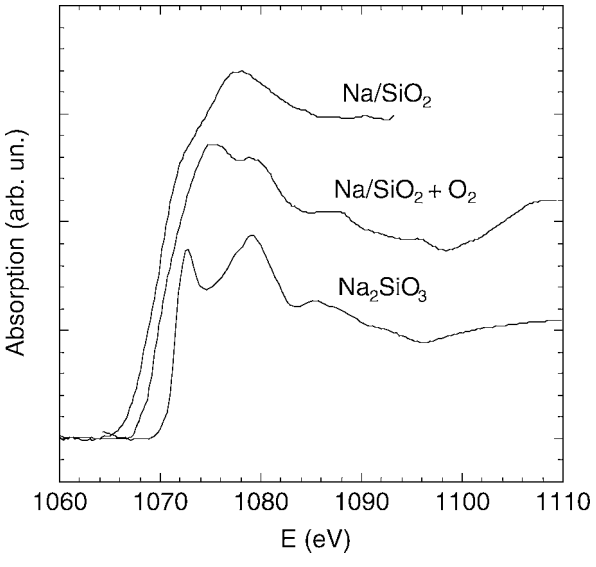

Fig. 1. Comparison of the near K-edge structure of sodium incorporated into silica (top), after exposition to oxygen (center) and in Na_2SiO_3 compound (bottom). The curves have been scaled for clarity.

*e-mail: pierre.lagarde@lure.u-psud.fr

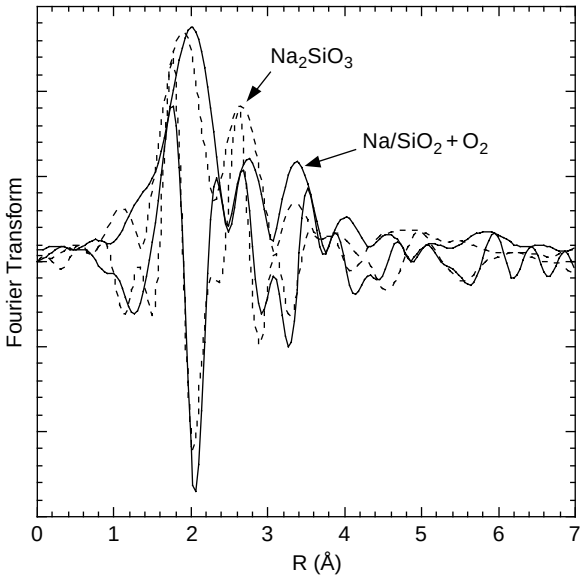

Fig. 2. Comparison between the Fourier transforms of $Na/SiO_2 + O_2$ (solid line) and Na_2SiO_3 (dotted line).

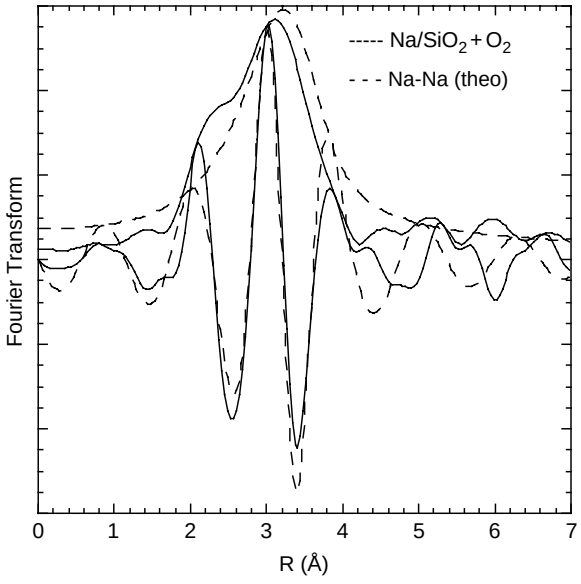

Fig. 3. Fourier transform of the 'large' sodium coverage EXAFS data (solid line) compared to the theoretical contribution from Na-Na pairs in pure sodium metal (dotted line).

that the sodium environment is very close to that of the crystalline Na_2SiO_3 compound (Fig. 2). Conclusions of this first experiment are then the following:

a) pure silica incorporates sodium atoms, leading to a still amorphous structure where the sodium presents a well defined environment. By increasing the evaporation time, the sodium cooncentration can reach about 35 at. %.
b) upon exposure to oxygen, the Na-SiO_2 layer absorbs oxygen, generating a compound with a local structure very close to that of crystalline Na_2SiO_3.

This behavior could explain why fused silica halogen lamps should not be touched by bare fingers: the hands bring sodium, which, with the oxygen of the air, transforms the pure silica (melting point of 1713 °C) into Na_2SiO_3 which has a much lower melting point at about 1089 °C, leading to the destruction of the fused quartz enveloppe.

3.2. *'Heavy' coverages*

Increasing the current of the sodium cell leads to, for the same time of deposit, a totally different structural result. The EXAFS Fourier transform is now dominated by a component at about 3 Å. This peak can be interpreted as a contribution from the first shell of metallic sodium. In Fig. 3, are superimposed the experimental result and the theoretical contribution of Na-Na at 3.76 Å calculated by FEFF7. On the lower *R* side of this main peak appears the sodium-oxygen contribution analoguous to the preceding result. Therefore, by a more intense sodium deposit, a pure metallic sodium multilayer is obtained once the saturation limit of the silica substrate has been reached. The energy position of the edge is found now about 3 eV lower than in the case of Na_2SiO_3 which is in line with an atomic Na (compared to Na+) electronic configuration of the sodium.

The same oxygen treatment as the one used for the first sample changes drastically the absorption spectrum at the sodium edge, which becomes characteristic of a crystallized compound. The modelling by FEFF8 shown in Fig. 4 indicates that the metallic sodium multilayer has been fully transformed into pure sodium oxide Na_2O. An analysis of the EXAFS data leads to the same conclusion.

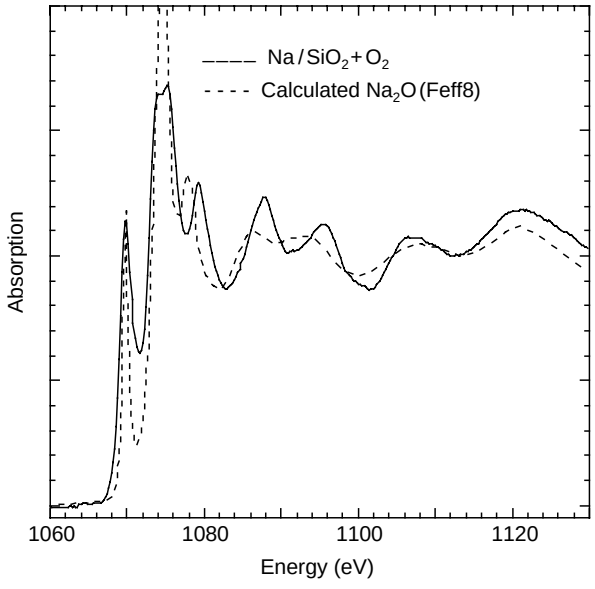

Fig. 4. The near edge spectrum of the 'large' deposit after an O_2 exposition compared to a FEFF8 calculation of Na_2O.

4. Conclusions

When exposed to oxygen the amorphous system made by the native or thermal silica layer incorporated with sodium in UHV conditions transforms into a compound which has a local structure around the sodium atom close to that of Na_2SiO_3. Because of the low melting temperature of Na_2SiO_3 compared to that of pure silicon oxide this behaviour could explain the sensitivity of pure fused silica used in high temperature halogen lamps to contact with fingers, which bring sodium atoms.

When the rate of sodium evaporation on the silica layer is strongly increased, it sticks on the substrate and forms a pure metallic multilayer. This behavior on silica differs from that of sodium on most clean crystalline surfaces, like silicon. An exposure to oxygen of this metal overlayer gives rise to pure sodium oxide, Na_2O. It is worth to point out that this experimental procedure is the only way to prepare a sample

of metallic sodium or sodium oxide for X-ray absorption experiments.

Abstract

The distributions of unoccupied electronic states in the conduction bands of MgS and CaS have been determined. It has been found that the bottom of the conduction band of MgS is formed by Mg s and S s states, and of CaS by S d, s and p states. The partial electronic densities of S p and Fe d states in the conduction band of FeS (B8 phase) have been calculated. Interaction between these states in the bottom part of the conduction band of iron sulfide has been studied. A special kind of hybridization has been found: it has been shown that the sulfur p states are "squeezed out" of the energy region of the iron d states.

1. Introduction

The monosulfides of Ca and Mg have the rocksalt (B1) structure and occur in EH enstatite chondrite meteorites, where they appear to result from metamorphism under very reduced conditions [1]. Iron monosulfide has a hexagonal NiAs-type (B8) structure under ambient pressure and temperature. FeS is a nearly ubiquitous phase in most meteorites and is the iron sulfide of lunar rocks. It occurs also, albeit sparingly, in magmatic sulfide assemblages of mafic/ultramafic rocks.

One of the most fruitful methods allowing study of the local arrangement of atoms and electronic structure of the presently investigated compounds is X-ray absorption near-edge structure (XANES) spectroscopy [2]. But, in order to extract the necessary information from the experimental spectra, one needs to perform theoretical analysis.

Some of the physical properties of the studied sulfides cannot be explained without a detailed study of their electronic structure. The electronic structure of the valence band of many monosulfides has been widely investigated. In contrast, the electronic structure of the conduction band has received much less attention due to limitations of theoretical calculations and experimental approaches. Some experimental measurements carried out by different methods [3–7] have yielded information on aspects of the electronic structure of the investigated sulfides; for example, the experimental estimation of band gaps. But only theoretical methods yield a complete description of the electronic energy band structure. Attempts to understand the electronic structure of the metal sulfides were made earlier by different theoretical methods. Analysis of the electronic band structure of magnesium sulfide predicts an indirect (Γ-X) band gap [8–10]. In materials with an indirect band gap the bottom of the conduction band and the top of the valence band lie at different wavevectors. The band gap in MgS is bounded by S p states in the upper part of the valence band [8–10] and Mg s states [9, 10] (and to a less extent, S d) in the conduction band. Different estimates of the band gap width of MgS are given in the literature. Stepanyuk *et al.* [9] using the totally self-consistent linear augmented plane wave method have found that the value of band gap width is 2.69 eV. This result is in a good agreement with that calculated by Kalpana *et al.* [10] (2.7 eV) using the tight binding linear muffintin orbital (TBLMTO) method. But the Hartree-Fock calculation performed by Pandey *et al.* [8] has resulted in band gap value of 6.48 eV. Ching *et al.* [11] based on the MOLCAO method have determined that the gap width of MgS is equal to 4.59 eV.

In CaS the band gap (estimated variously as 2.143 eV [12], 3.2 eV [11] or 7.6 eV [8]) lies between the S p states [8, 12] in the valence band and Ca d states [12] in the conduction band. Pandey *et al.* [8] disagree with the view of Stepanyuk *et al.* [12] and Ching *et al.* [11] that CaS is an indirect (Γ-X) band dielectric. It is claimed [8] that CaS is a direct-band-gap material.

Moreover, several experimental measurements of band gaps in magnesium and calcium sulfides have been carried out. XPS measurements on bulk MgS and ZnSe/MgS supperlattice made by Suzuki *et al.* [3] indicate that the band gap width of MgS is 5.27–5.47 eV. Investigation of CaS single crystals by optical reflectivity and luminescence [4–5] resulted in an estimated indirect band gap width of 4.434 eV, a direct gap (X) of 5.343 eV, and a direct gap (Γ) of 5.80 eV. Optical absorption measurements in CaS evaporated thin film [6] yielded a band gap width equal to 5.38 eV. CaS : Eu2+ : Sm^{3+} thin films were studied by Zhang *et al.* [7], and a band gap equal to 4.48 eV was obtained. Thus, we can conclude that the experimental measurements of band gap width differ from the theoretical estimations. Overall, the experimental band gaps are significantly larger than the theoretical ones.

The above-mentioned theoretical results were obtained by analysing the band structure calculations and densities of states of studied compounds. But in the literature we can find only total DOS calculations for occupied [8, 10, 12, 13] or unoccupied states [10, 12] of MgS and CaS. The projected DOS of investigated sulfides has not been computed earlier.

In this paper we present the curves proportional to the projected electronic densities of unoccupied states in the conduction band of MgS, CaS, FeS calculated for the first time.

2. Method of calculation

For the calculation, the computer code G4XANES [14] was used. The algorithm of the full multiple scattering method was described earlier [14]. Atomic charge densities were obtained with the help of a self-consistent Dirac method. Phase shifts of the photoelectron were calculated in the framework of the crystal muffin-tin (MT) potential scheme with touching MT spheres. The MT radii and the MT constants were obtained according to an

*e-mail: soldatov@rsu.ru

established procedure of MT potential construction [14]. The MT approximation according to the Mattheiss prescription [15] with Slater exchange ($\alpha = 1.0$) was used while constructing the crystal potential.

3. Results and discussion

Some initial investigations of metal sulfides have been performed previously by X-ray absorption near edge structure (XANES) spectroscopy [16–18]. Sulfur K- and L-edge XANES spectra of MgS, CaS, FeS were collected at the Canadian Synchrotron Radiation Facility (CSRF), Aladdin storage ring (University of Wisconsin at Madison, Wisconsin) [16–17]. The theoretical analysis of experimental data was made by full multiple scattering method [17–18]. It has been found that the S K- and $L_{2,3}$-XANES spectra results from the multiple scattering of an excited photoelectron inside a large cluster of 13 shells (251 atoms) for MgS and CaS (B1 phase), although a cluster size of 4 shells (37 atoms) appears sufficient for FeS (B8 phase). A good agreement between theoretical and experimental spectra was obtained for all studied sulfides. For example, in Fig. 1(a) the comparison of experimental S K-XANES spectrum of magnesium sulfide with theoretical one is presented. Experimental and theoretical S $L_{2,3}$-XANES spectra of MgS are shown in Fig. 1(b). In order to compare the theoretical S K- and $L_{2,3}$-XANES spectra of MgS with experimental XANES, the Fermi distribution function and three main factors that cause the broadening of the spectra were taken into account. These factors were: 1.) the width of the core hole states, which is 0.59 eV for the S K-edge XANES and

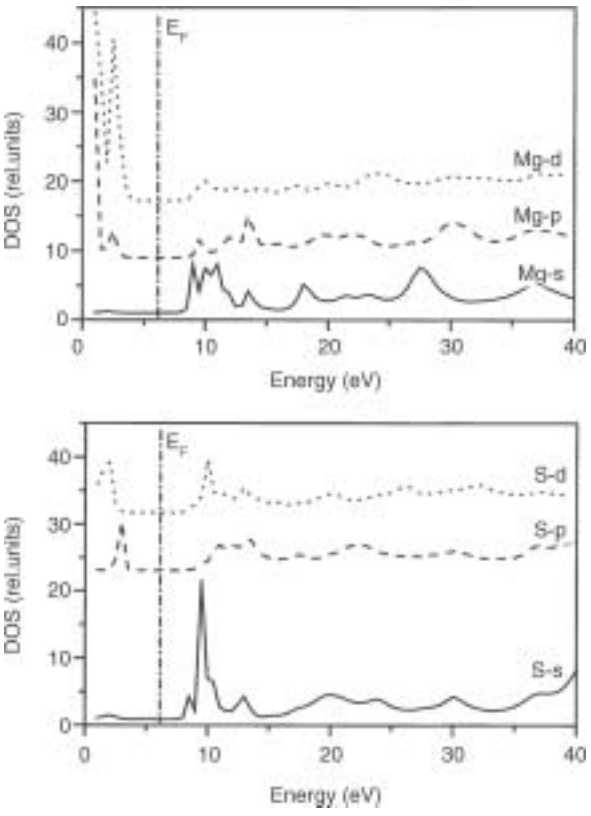

Fig. 2. Partial densities of unoccupied states in the conduction band of MgS, using a cluster of 13 shells (251 atoms). Origin of the energy scale corresponds to the zero of the MT potential. Vertical dotted line conforms to the location of Fermi level.

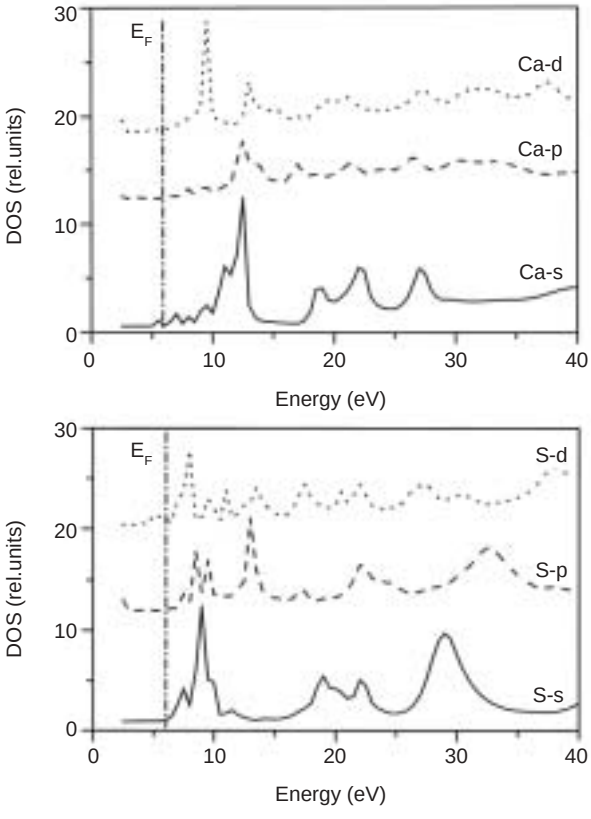

Fig. 3. Partial densities of unoccupied states in the conduction band of CaS, using a cluster of 13 shells (251 atoms). Origin of the energy scale corresponds to the zero of the MT potential. Vertical dotted line conforms to the location of Fermi level.

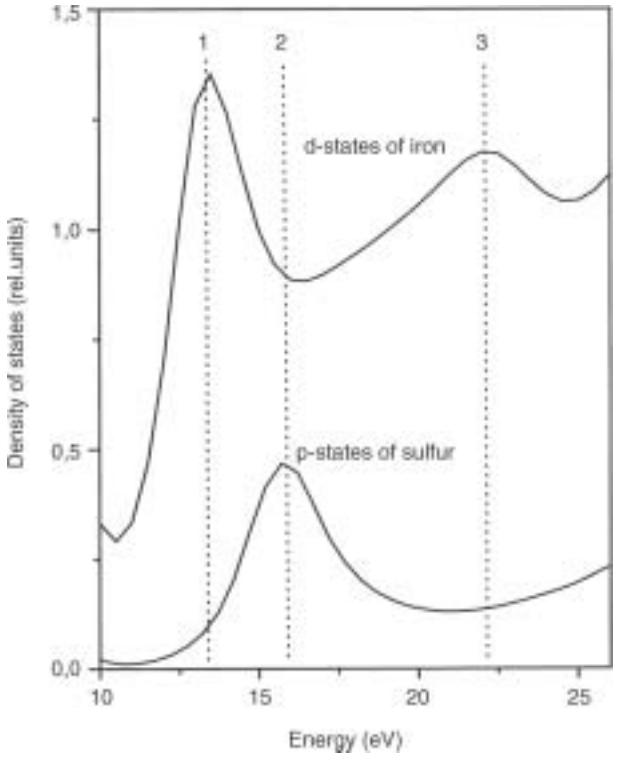

Fig. 4. Part of the densities of unoccupied states of FeS (B8 phase) where a repulsive hybridization is observed. Cluster of 4 shells (37 atoms) was taken into account. Origin of the energy scale corresponds to the zero of the MT potential.

0.05 eV for the S $L_{2,3}$-edge XANES; 2.) the mean free path of the photoelectron function [19]; and 3.) the experimental energy resolution, which is 0.9 eV for the S K-edge XANES and ∼0.1 eV for the S $L_{2,3}$-edge XANES. From Fig. 1 (a,b) one can see that theoretical spectra are in good agreement with correspondent experimental spectra in both shape and energy peaks positions. These results indicate that the present theoretical approach works well and calculations for partial densities of states can be done using the same MT potential.

In Fig. 2 the partial DOS in the conduction band of MgS are shown. It is seen that S p states lie at the top of the valence band of MgS. The bottom of conduction band is formed by Mg s states and S s states. Our calculations give an estimation of the band gap width for MgS to be about 4.6 ± 0.3 eV.

In Figure 3 the partial densities of states in the conduction band of CaS are presented. It shows that the bottom of the conduction band is mainly formed by sulfur states (S d and s states and, in lower degree, S p states). We estimate that the band gap width of CaS is about 3.5 ± 0.3 eV.

In the present work an interesting effect was found for electronic density of states of B8 phase iron sulfide. In Fig. 4 the unoccupied electronic p states of sulfur and d states of iron in the conduction band of FeS (B8) are shown. It can be seen that line 1 corresponds to the position of maximum of iron d states as well as to a minimum in the sulfur p states. At the position of line 2 there is a maximum of S p states. This feature aligns well with the minimum of d states of iron. Line 3 marks the next maximum of Fe d states. Note also that this line matches a minimum in the sulfur p states plot. Thus, the S p states in the conduction band of FeS (B8) have minima at the position of maxima in Fe d states. In these cases the S p states are "squeezed out" of the energy positions of Fe d states, as a result of the specific interaction between iron and sulfur states. For the unoccupied states such specific interaction between electronic states has been previously found for rare earth sulfides [20], CeO_2 [21], orthoferrites [22] and stishovite [23]. Thus, we can conclude that the interaction between S p states and Fe d states in the conduction band of FeS (B8) is a special kind of repulsive hybridization.

Abstract

Further understanding of the electrochromic mechanism taking place in anodically colored nickel oxide was achieved by XAS. From EXAFS simulation we were able to determine the percentages of electrochemically active phases and confirm the dissolution of the oxidized one, which was previously assumed by electrochemical characterization.

1. Introduction

Since the early eighties, Nickel Oxide has received a great interest due to its brownish coloration associated to the presence of trivalent nickel ions when anodically oxidized. NiO thin films switch reversibly to a transparent state on reduction. Further interest comes from its association to the blue coloration of tungsten trioxide, yielding a neutral gray color of a complete device. However despite a large number of studies, many aspects of NiO electrochromic behavior remain poorly understood. To throw some light on the mechanism, NiO thin films were grown using Pulsed Laser Deposition (PLD). Among a wide range of growth parameters, good electrochromic properties were determined to be a 10^{-1} mbar oxygen pressure and a Room Temperature (RT) substrate [1]. Preliminary understanding of the electrochromic mechanism was deduced from the coupling of electrochemical test and X-ray diffraction, Scanning and Transmission Electron Microscopies. However, if the X-ray diffractogramms of the as-deposited film exhibit well defined peaks confirming the NiO cubic structure (SG: Fm-3m) with a [111] preferred orientation, on cycling the loss in resolution limits the benefit of this long range order technique. This paper presents further insights into the understanding of the electrochromic mechanism involved in NiO thin films, grown by PLD, using X-ray Absorption Spectroscopy (XAFS).

2. Experimental and Data Analysis

NiO thin films were deposited on SnO_2:F coated glass substrates in optimized conditions, namely a 10^{-1} mbar oxygen pressure and a RT substrate, by PLD using a KrF excimer laser (Lambda Physik, Compex 102, $\lambda = 248$ nm) and a laser fluence of 1–2 J · cm^{-2}. The duration of depositions last from few minutes to few hours, leading to thickness in the 10 to 500 nm range. The electrochemical properties of the films were characterized by cyclic voltammetry performed on an AUTOLAB PGSTAT 30 system with a NiO|KOH 1 M|Pt *versus* Hg/HgO cell configuration.

The XAS spectra were recorded at the Ni K edge at LURE (Laboratoire pour l'Utilisation du Rayonnement Electromagnétique) on the EXAFS13 (DCI D42) workstation in total electron yield mode. The monochromator was a channel-cut silicon with reflecting (331) faces. EXAFS data analysis was performed with "EXAFS 98" programs [2] using the Lengeler-Eisenberger standard procedure to normalize EXAFS function $\chi(k)$ [3]. The Fourier transform (FT) of $\chi(k)$ was performed with a k^3 weight and a Kaiser-Bessel apodization window function (the smoothness coefficient $\tau = 3$) in the range $1.5\,\text{Å}^{-1} < k < 12.52\,\text{Å}^{-1}$.

3. Results

Electrochromic performances (i.e. capacity, contrast) of PLD NiO thin films increase with decreasing film thickness [4]. Unfortunately, due to the very small amount of material ($\approx 10^{-6}$ g) EXAFS data could not be recorded on very thin films whereas the spectrum resolution increases with film thickness. Therefore, despite a lower electrochromic activity, the XAS study was focused on the thicker films knowing that a similar mechanism takes place whatever the film thickness.

3.1. *Cyclic Voltammetry*

Figure 1a shows the Cyclic Voltammogram (CV) of NiO | KOH 1 M|Pt *versus* Hg/HgO cell with 465 nm thick film. The CV is characterized by a set of reversible peaks, located at about 0.60 V in oxidation and 0.38 V in reduction, which is associated to a faradic process involving the Ni^{3+}/Ni^{2+} ions. The strong increase in current observed at the end of the anodic sweep corresponds to the oxygen evolution. The evolution of the relative capacity (deduced from the surface area below the CV shape) is plotted in Fig. 1b. The capacity curve can be separated in three domains, (I) the activation period, during which the capacity increases, (II) the steady state, and (III) the degradation period.

3.2. *XANES*

In this paper, we do not show any XANES spectrum but we observe that during the oxidation process, the inflection point of the edge shifts from 8344.97 eV to 8345.65 eV due to the transformation of Ni^{2+} to Ni^{3+}. As described in the following, the shift intensity is correlated to the amount of oxidized phase, which varies on cycling.

3.3. *EXAFS*

The evolution of the EXAFS spectra on coloration (recorded after the film was maintained in the oxidized state $V = 0.60$ V for 10

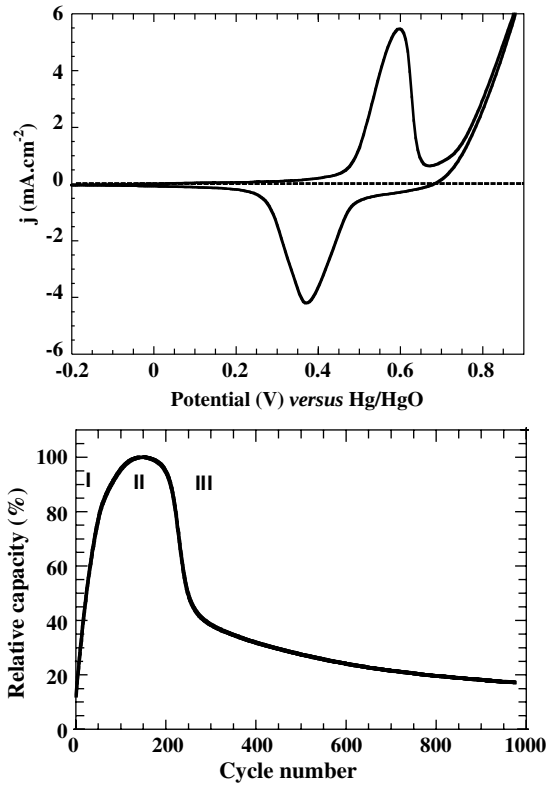

Fig. 1. (a) 50th Cyclic Voltammogram of NiO | KOH 1 M | Pt *versus* Hg/HgO cells of NiO 465 nm thick film. Cycling is performed between −0.20 V and 0.90 V at a sweep rate of 10 mV · s^{-1}. (b) Evolution of the relative capacity ($100 * Q/Q_{\max.}$) versus the number of cycles for NiO|KOH 1 M|Pt *versus* Hg/HgO cells of NiO 465 nm thick films. I, II, III represent the activation period, the steady state and the degradation period, respectively.

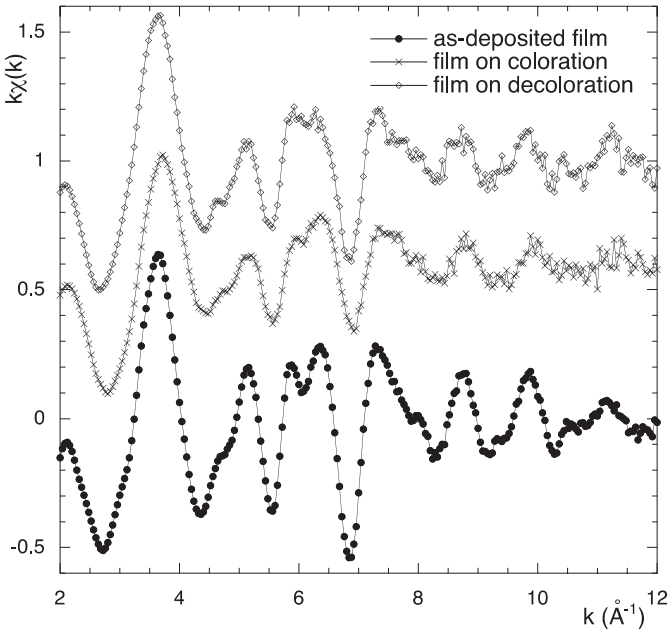

Fig. 2. Comparison between the EXAFS spectra of the as-deposited film, after coloration and decoloration. Both coloration and decoloration were performed after the film went through 100 cycles.

minutes) and decoloration (after the film was maintained in the reduced state $V = 0.2$ V for 10 minutes) is presented in Fig. 2 in comparison with the one of the as-deposited NiO film.

Based on the mechanism, previously deduced from electrochemical data, one may assume that the coloration/decoloration

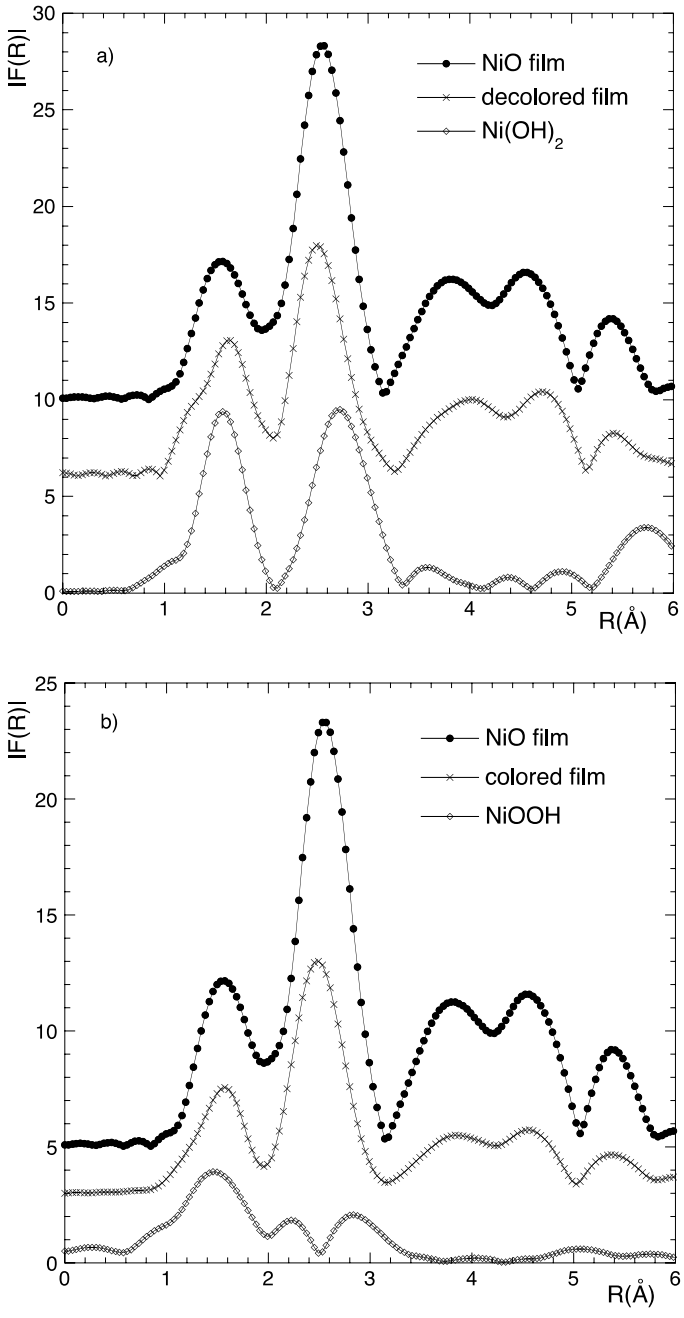

Fig. 3. (a) Comparison of the Fourier Transform of NiO film in the bleached state with NiO and β(II)Ni(OH)$_2$ and (b) in the colored state with NiO and β(III) NiOOH.

process involves electrochemically (oxy)-hydroxides phases, whereas NiO acts as a reservoir [4]. Therefore, the EXAFS spectra of the colored and bleached state correspond to the superimposition of nickel oxide and hydroxide phases. In this regard, EXAFS spectrum of the bleached state was compared to β(II)Ni(OH)$_2$ whereas EXAFS spectrum in the colored state was compared to β(III)NiOOH. The corresponding FT are presented in Fig. 3a,b. FT of NiO is decomposed in 5 shells of which meaning and amplitude are well described in the literature [5–6]. The loss in amplitude for region higher than 3.5 Å, observed for cycled films or hydroxides, is not surprising as multiple scattering phenomenon is enhanced in cubic symmetry in comparison to the hexagonal one (i.e. higher number of direct Ni-ONi paths). The evolution of the FT of the EXAFS spectra recorded on cycling at V_0 ($V_0 \approx 0.1$ V corresponds to the equilibrium state) is shown in Fig. 4. In first approximation, the FT of the film after 1000 cycles

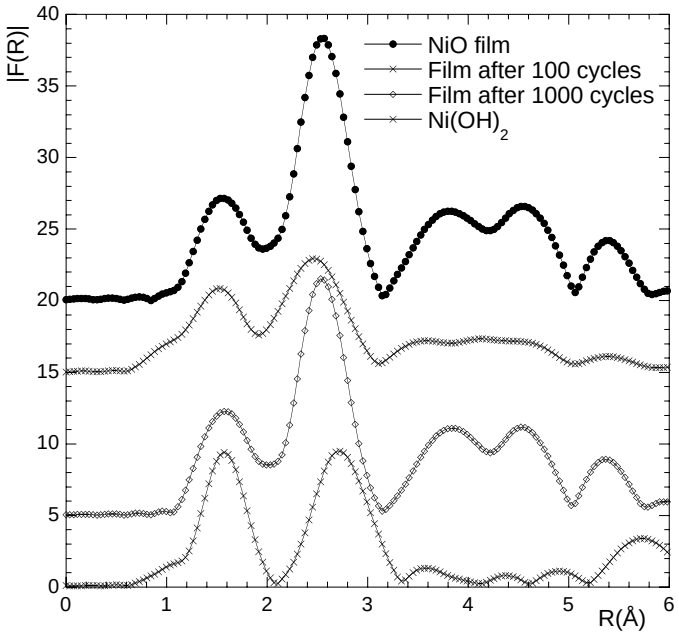

Fig. 4. Comparison of the Fourier Transform of films cycled 100 and 1000 times at V_0 with NiO and $Ni(OH)_2$.

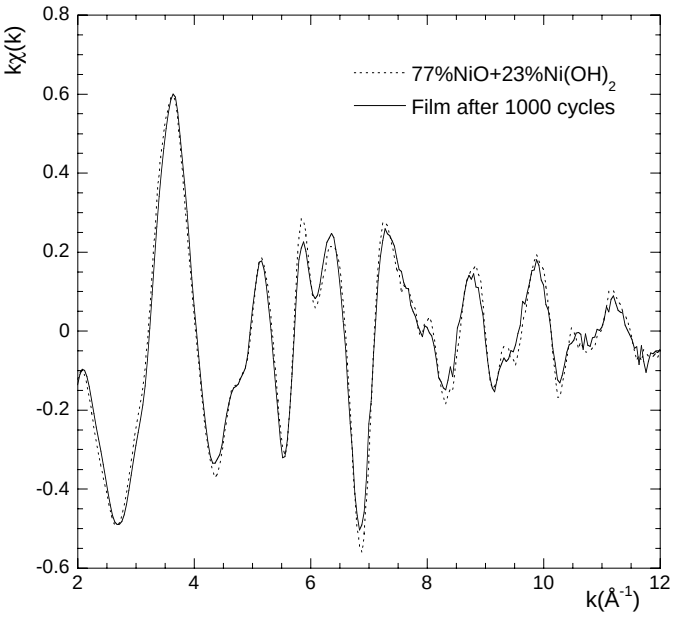

Fig. 5. EXAFS simulation of a 100 cycled films and $x\text{NiO} + (1 - x)$ $\beta\text{(II)Ni(OH)}_2$, $x = 77\%$.

exhibits similar features of the as-deposited film whereas the film cycled 100 times shows a rather different FT, associated to similar amplitudes for the first two shells and quasi no amplitude for the further shells. This trend would suggest that the film on cycling undergoes modifications, of which are not completely reversible, and tends to return to its initial state.

4. Discussion

Whatever the cycling stage, EXAFS spectra correspond to the superimposition of NiO and an (oxy)-hydroxide phase, namely $\beta\text{(II)Ni(OH)}_2$ in reduction and at V_0, or $\beta\text{(III)NiOOH}$ in oxidation. The proportion of the second phase was estimated from basic simulation performed by comparing the experimental EXAFS spectrum with the calculated sum of $x\text{(NiO)} + (1 - x)$ [$\beta\text{(II)Ni(OH)}_2$ or $\beta\text{(III)NiOOH}$] EXAFS spectra. The x values are evaluated by linear least squares fitting and the error bars are calculated using the statistical standard deviation (2σ). The various percentages are gathered in Table I whereas an example of simulation is given in Fig. 5 for the film cycled 100 times. For the colored phase, we have calculated the figure of merit with $\beta\text{(II)Ni(OH)}_2$ instead of $\beta\text{(III)NiOOH}$, the best fit is largely in favor of $\beta\text{(III)NiOOH}$ ($\chi^2 = 0.43$) compared to $\beta\text{(II)Ni(OH)}_2$ ($\chi^2 = 2.48$).

Table I. *Percentages of the (oxy)-hydroxide active phases, namely β(II)Ni(OH)$_2$ in reduction and β(III)NiOOH in oxidation, deduced from the simulation of the EXAFS spectra.*

Cycle Number	$(1 - x)$ % (EXAFS)
0	0% (100% NiO)
100 (V_0)	48% ± 4 $Ni(OH)_2$
1000 (V_0)	23% ± 2 $Ni(OH)_2$
100 on coloration	66% ± 1 NiOOH
100 on decoloration	39% ± 1 $Ni(OH)_2$

Table I shows two major trends: (*i*) a decrease in the amount of $\beta\text{(II)Ni(OH)}_2$ on cycling in good agreement with the decrease in capacity observed in Fig. 1b and (*ii*) a larger quantity of oxidized phase in coloration than of the reduced phase in the bleached state for the same cycle number. The presence of a higher amount of $\beta\text{(III)NiOOH}$ than of $\beta\text{(II)Ni(OH)}_2$ confirms that the capacity results from the addition of a reversible phenomenon associated to the $Ni(OH)_2/\text{NiOOH}$ reaction (39% in the case of the film cycled 100 times) to which is added an irreversible phenomenon previously identified as being due to the instability of the oxidized phase [4]. Moreover the existence of the dissolution mechanism is emphasized on cycling with a decrease in the $Ni(OH)_2$ percentage down to 23% for the film cycled 1000 times.

5. Conclusion

In this paper, we demonstrate the benefit of the XAS characterization in the understanding of the electrochromic mechanism involved in NiO thin films deposited by Pulsed Laser Deposition, which was simply assumed based on electrochemical tests. Simulation of the EXAFS spectra leads to the determination of the percentage of the various electrochemically (oxy)-hydroxide active phases, namely $\beta\text{(II)Ni(OH)}_2$ in reduction and $\beta\text{(III)NiOOH}$ in oxidation. Moreover the smaller percentage of the β(II) phase in the bleaching process compared to the β(III) phase proves the dissolution of the oxidized phase, which is thermodynamically less stable.

Abstract

SnO_2 and doped Sb:SnO_2 sol, prepared by a precipitation-peptization sol-gel process, has been used as a host for the incorporation of an organic semiconductor, the perylene dye (PTCDA). The structure of the SnO_2 gel host together with the effect of inorganic (Sb) and organic (PTCDA) doping is studied with EXAFS at the Sn and Sb K-edge. Distinct neighbor shells are resolved only up to 4 Å. The corresponding radii are the same as in a cassiterite crystal structure with a 60% reduction in the Sn neighbor population. In the spectra at the Sn edge, the doping with Sb and/or a small concentration of PTCDA produces no detectable effect. At higher content of PTCDA, however, the number of the first oxygen neighbors is diminished by ∼30% indicating that the disordered organic groups from the dye molecule reach right into the Sn neighborhood. In the weaker Sb EXAFS spectra only the first shell of oxygen neighbors is resolved: again the static disorder is higher in the presence of the organic dopant.

1. Introduction

The sol-gel processing has been developed into an appropriate technique for producing inorganic and organic-inorganic glasslike materials [1]. Owing to mild processing conditions, organic molecules can be introduced into inorganic polymeric matrices. The inorganic matrix in this study is tin-oxide gel derived by alkaline aqueous sol-gel route [2]. For comparison, SnO_2 matrix was made also according to a peroxo route [3]. Pure or Sb-doped SnO_2 in thin film form is a promising material for transparent conductive electrodes, ion-storage electrodes or low-emitting coatings for advanced glazings [3–8].

In addition to inorganic doping, perylene tetracarboxylic acid dianhydride (PTCDA) as an organic semiconductor with attractive optical properties has also been introduced into the SnO_2 gel matrix. Generally, the photochemical and mechanical stability of the dye is increased by using inorganic host systems [9, 10]. PTCDA is highly insoluble in common solvents used for sol-gel synthesis (alcohol, water) so that a homogeneous dispersion in the sol-gel host is not easy to achieve. However, good solubility and distribution of perylene derivatives was found in alkaline medium of SnO_2 sol that was prepared by the aqueous precipitation-peptization sol-gel process.

From the structural point of view, SnO_2 can serve as an insertion compound (to be used for example as an optically passive counter electrode in electrochromic devices) since it has the rutile structure with existing tunnels expanding along the 001 direction, which enable the intercalation/deintercalation of small ions (Li^+) through the thin film. The ion-insertion properties can be additionally improved by: (*i*) decreasing electronic resistivity and the particle grain size with doping; and (*ii*) increasing the porosity and the number of redox centres [7]. The induced disorder of the rutile structure through doping can be investigated by EXAFS. Thus, EXAFS of various SnO_2 xerogel samples is used to study the structural environment around tin atom and the disordering effect of Sb and PTCDA guest species.

2. Synthesis

SnO_2 aqueous sol (*a*) was made according to ref. [2] from $SnCl_4 \cdot 5H_2O$ precursor (Table I). Doping with Sb was achieved by adding $SbCl_3$ (7 mol% vs. Sn) in the initial aqueous solution acidified with HCl to dissolve Sb-salt. A precipitate was formed with the addition of ammonia up to pH 3. After repeated washing with water the precipitate was peptised with 8 mL of concentrated aqueous ammonia, which resulted in a basic aqueous sol (pH ∼ 10). To this sol (undoped and Sb-doped) various amounts of PTCDA (0.5–5 mol%), previously dissolved in 9% KOH, were introduced. The gelling time of the sol in a closed vessel was a few days at room temperature.

SnO_2 peroxo sol (*p*) was made for comparison purposes according to ref. [3]. Conc. H_2O_2 was added dropwise to $SnCl_2 \cdot 2H_2O$ precursor leading to the strong exothermic reaction. The formed solution was evaporated at 70 °C to get a viscous opaque gel, which was diluted with ethanol. To this sol a small amount of bis end-capped triethoxysilane with a covalently linked mid polyether chain (ICS-PPG4000 [11], 1 mol%) was added to enhance the porosity of the oxide samples in order to improve ion-storage characteristics.

Xerogel powders were made from gels by drying them at ambient conditions.

3. Experiment

Samples of xerogel powders were prepared on multiple layers of adhesive tape to gain sufficient absorption jump: 0.2–0.6 at Sn K edge (29200 eV) and ∼0.2 at Sb K edge (30491 eV). Standard Sn and Sb K-edge EXAFS spectra were measured at the X1 station of HASYLAB synchrotron facility at DESY (Hamburg, Germany) using a two-crystal Si 311 monochromator with energy resolution of about 6 eV. Owing to the high photon energy, the incident beam is free of harmonic contamination. The energy scale at Sn edge was calibrated by a simultaneous absorption measurement of a thin Sn foil, while at Sb edge only the stability of the monochromator scale was monitoring by a simultaneous measurement of both Sb doped samples. Spectra were analysed by FEFF6 code [12, 13].

4. Results

The XANES spectra of all samples are very similar showing no detectable valence shift.

By EXAFS, the structure of pure inorganic SnO_2 gel host derived from aqueous sol (*a*) is compared to that of hybrid organic-inorganic xerogel made by peroxo sol-gel route (*p*). In both r-space spectra, a coherent signal is found only up to $r \sim 4$ Å indicating a short-range order. Obviously, the preparation route influences the local structure: a sharp first peak observed in the *a* spectrum is split into two smaller peaks in the *p* spectrum (Fig. 1).

For *a* spectrum, a very good fit of the first peak can be obtained with a model of 6 oxygen neighbors at 2.06 Å as in the cassiterite crystal [14]. With two subsequent shells of Sn neighbors the entire *a* spectrum is roughly described: the distances agree with crystal data but the occupation number is reduced to ∼40% due to disorder in the structure (Table II). The signal of farther oxygen neighbors in the cassiterite structure is small and their parameters cannot be reliably extracted from the xerogel data.

The nearest neighborhood of Sn in the hybrid organic-inorganic xerogel can be modeled with a combined model of a reduced number (∼4.5) of oxygen atoms at distances as in the cassiterite structure and of approximately 1.5 chlorine atoms at 2.40 Å as in a $SnCl_4$ structure [15]. Thus, a relatively large fraction of Sn atoms in the xerogel made by peroxo route remains as chloride while in the xerogel made by aqueous precipitation-peptization route no Sn-Cl bonds are detected, confirming that Cl from starting materials is efficiently washed out.

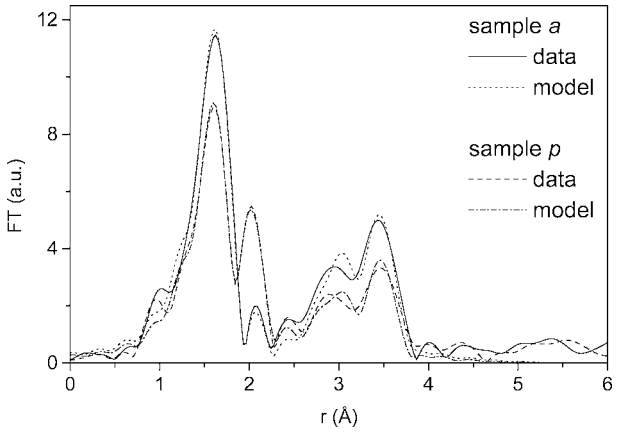

Fig. 1. Fourier transform of the Sn K edge EXAFS of the SnO_2 xerogel and its 3-path model in comparison with SnO_2 xerogel made by peroxo route and its 4-path model (k^3-weighted, 3–14 $Å^{-1}$).

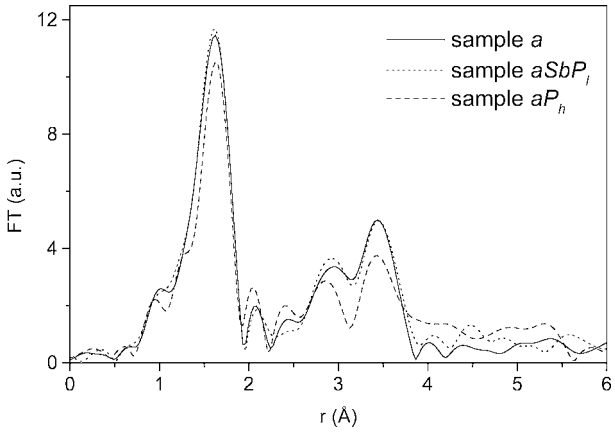

Fig. 2. The effect of doping the SnO_2 xerogel with Sb and low concentration of PTCDA in comparison with doping with high concentration of PTCDA (k^3-weighted, 3–14 $Å^{-1}$).

It can be seen from Fig. 2 that doping with Sb (7 mol% vs. Sn) and a small concentration of PTCDA (0,5 mol%) produces no detectable effect in the spectra at the Sn edge. Doping with high concentration of PTCDA (5 mol%), however, results in a lower signal of the first neighbors. A single-shell model differs from that of the *a* spectrum only in a lower occupation number while the distance and the Debye-Waller factor remain practically the same. The missing oxygen neighbors are not replaced with another species indicating that the disordered organic groups from the dye reach right into the Sn neighborhood.

The spectra at Sb K edge exhibit a higher level of noise due to the relatively small concentration of Sb atoms and a strong background absorption limiting the scope of modeling. Nevertheless, some information can be extracted: both Fourier spectra exhibit only one prominent peak indicating highly disordered Sb-sites (Fig. 3). The first shell around Sb consists of ∼5 oxygen atoms at ∼1.95 Å. In Sb-doped xerogels, the additional doping with PTCDA even at low concentration results in higher static disorder around Sb atoms (Table III).

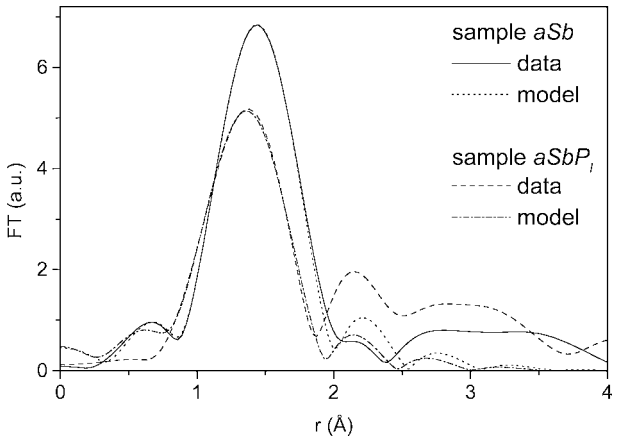

Fig. 3. Fourier transform of the Sb K edge EXAFS of the Sb-doped SnO_2 xerogel in comparison with Sb- and low concentration PTCDA-doped xerogel. Single-path models (k^3-weighted, 2.7–9.1 $Å^{-1}$) are also shown.

Table III. *Model parameters for spectra at the Sb K-edge, k range 2.7–9.1Å^{-1}, r range 1.0–1.8Å, k^3-weighted, the numbers in parentheses indicate uncertainties of the last digit.*

	sample *aSb*	sample *aSbP$_1$*
r_{fit}	0.001	0.002
N_1 (**O**)	4.9(5)	5.0(8)
r_1 [Å]	1.98(1)	1.93(1)
σ_1^2 [Å^2]	0.003(1)	0.006(2)

5. Conclusions

Tin-oxide gel was doped with Sb and/or PTCDA to tailor the electrochemical and optical properties of the final material, keeping the host structure nearly unchanged with evenly dispersed dopant in it. Indeed, all Sn EXAFS spectra are adequately modeled by the structure of SnO_2 cassiterite with reduced occupation numbers.

The disorder increases with the content of the organic dopant. Higher concentration induces a drop of the first neighbor signal indicating a homogeneous distribution of the organic dye.

Abstract

We have studied the chemistry of S species in tribofilms generated on steel blocks from belt-drive continuously variable transmission fluids using X-ray absorption near-edge structure (XANES) spectroscopy. First, we examined S K-edge XANES spectra of tribofilms generated using a friction tester from four kinds of fluid which have different friction properties. It is suggested that sulphides such as FeS, alkyl sulphide and ZnS in the tribofilms might increase the friction coefficients of the tribofilms. Second, we examined the XANES spectra of tribofilms collected in both fluorescent yield (FY) and conversion electron yield (CEY) modes. FY and CEY spectra of a fluid were compared and it is found that ZnS content in the surface region might be higher than that in the bulk. On the other hand, the chemistry of the S species in the other three tribofilms might be almost uniform as far as the near surface and the bulk are concerned.

1. Introduction

The fuel efficiency of vehicles will continuously be an important issue in order to conserve natural resources and protect the global environment. Under those circumstances, belt-drive continuously variable transmissions (B-CVTs) have attracted attention because B-CVTs give better fuel efficiency than conventional automatic transmissions (ATs), and they also enable the torque converter, if applied, to lock up at a slower vehicle speed than with ATs. Recently, B-CVTs have been adopted for some vehicles by automobile manufacturers, and it has become very important for oil manufacturers to develop transmission fluids suitable for B-CVTs, that is, belt-drive continuously variable transmission fluids (B-CVTFs) [1]. B-CVTFs are required to have not only the properties of conventional automatic transmission fluids (ATFs), such as good oxidation stability and antiwear performance, but also a high friction coefficient between metal surfaces.

In order to develop high-performance B-CVTFs, it is necessary to investigate the nature of the tribofilms that are generated on metal surfaces by lubrication and govern the lubrication performance. Although conventional surface analysis methods such as EPMA and XPS have been employed to investigate the tribofilms, the nature of the tribofilms has not been well elucidated yet. Therefore, we employed XANES spectroscopy which is more sensitive to the chemical environments of elements such as P and S contained in the tribofilms than other analytical techniques, in order to investigate the nature of the tribofilms.

In this paper, we report the chemistry of the S species of the tribofilms generated on steel blocks using a friction tester, from four B-CVTFs which include different additives such as antioxidant and antiware additives and have different friction properties. The S K-edge XANES spectroscopy in both the fluorescence yield (FY) and the conversion electron yield (CEY) modes was employed to characterize the S species in the tribofilms.

2. Experimental

2.1. *Tribofilm preparation*

The block-on-ring test [2], which is one of friction tests and a convenient method for surveying B-CVTF performance, was employed both to prepare tribofilms and to measure the friction coefficients for four test fluids: three designed for vehicles with high torque-capacity B-CVT units and one designed for vehicles with medium torque-capacity B-CVT units, which is also used as AT fluid as shown in Table I. A schematic diagram of the friction test is shown in Fig. 1. The load is applied on the rotating test ring, so the friction force is produced along a line contact between the block and the ring. The test fluid reaches a level over halfway above the test ring. The test conditions are summarized in Table II. The tribofilms generated on the test blocks were used for the XANES measurements.

2.2. *XANES measurement*

S K-edge XANES measurements were carried out on BL-9A [3] at the Photon Factory, High Energy Accelerator Research

Organization, Tsukuba, Japan. X-rays were monochromatized with a Si(111) double crystal monochromator and higher orders were reduced by a pair of mirrors. The spectra were collected in both the FY and the CEY modes using a Lytle detector.

3. Results and Discussion

The test time dependences of the friction coefficients for the test fluids are very different: the friction coefficient of Fluid-1 barely varies with test time, while those for the other fluids vary with test time, as shown in Fig. 2. At the 30-minute point in the test, the fluids can be classified into two groups: fluids designed only for B-CVTs, which show high friction coefficients (Fluids-1 to 3), and fluid designed for both B-CVTs and ATs, which shows a medium friction coefficient (Fluid-4). Therefore, as the first step, we examined the S K-edge XANES spectra of the tribofilms generated at the test time of 30 min in the FY mode which indicates the chemistry of the bulk of the tribofilms, in order to understand the differences in the chemical nature of the tribofilms generated from B-CVTFs between the above-mentioned two groups.

The S K-edge XANES spectra of four tribofilms in the FY mode show different patterns (Fig. 3), suggesting that S species in the tribofilms are different, but each spectrum has four characteristic peaks (marked a, b, c and d). In order to identify

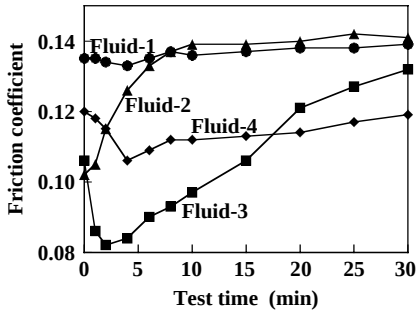

Fig. 2. Test time dependence of friction coefficient for test fluids.

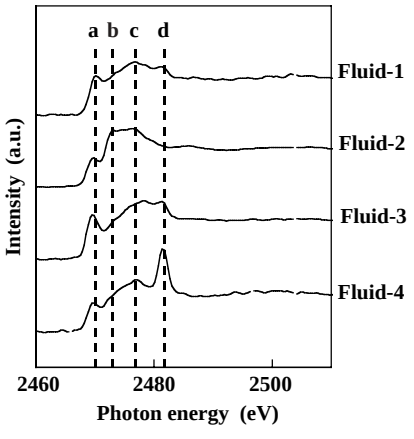

Fig. 3. S K-edge XANES spectra of B-CVT and AT/B-CVT tribofilms (at the 30-minute point).

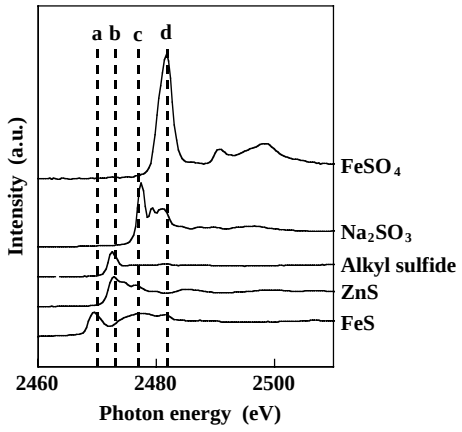

Fig. 4. S K-edge XANES spectra of model compounds of S species.

the nature of these peaks, we examined the S K-edge XANES spectra of several model compounds of S species that are supposed to be contained in the tribofilms. Comparison of the spectra of the tribofilms (shown in Fig. 3) with those of model compounds (shown in Fig. 4) suggests that peaks a and b are related to reduced forms of sulphur such as FeS, ZnS or alkyl sulphide [4]. On the other hand, peaks c and d are likely to be related to oxidized forms of sulphur such as sulphite (Na_2SO_3 as a typical example) and sulphate ($FeSO_4$ as a typical example). These results suggest that the bulks of tribofilms generated from B-CVTFs are composed of sulphide, sulphite and sulphate.

It is found that the sulphide peaks a and b in the XANES spectra of tribofilms generated from fluids designed only for B-CVTs use (hereafter referred to as B-CVT tribofilms, Fluids-1 to 3) are stronger than those in the spectrum of tribofilm of the fluid designed for both ATs and B-CVTs use (hereafter referred as AT/B-CVT tribofilm, Fluid-4) and the sulphate peak d in the spectrum of the AT/B-CVT tribofilm is stronger than those in the spectra of the B-CVT tribofilms. These results suggest that the bulks of B-CVT tribofilms are composed of more sulphides than are that of the AT/B-CVT tribofilm, while the bulk of the AT/B-CVT tribofilm is composed of more sulphate than are those of the B-CVT tribofilms.

In order to understand the chemical nature of tribofilms in detail, we estimated the composition of S species in the tribofilms by the following method. The S K-edge XANES spectra of the tribofilms were deconvoluted with four or five spectra of model compounds, that is, sulphides, a sulphite and a sulphate, by fitting the spectra of the tribofilms with those of model compounds using least squares method. In the deconvolutions of the XANES spectra of tribofilms generated from fluids containing Zn species (Fluids-2, 4), the spectra of FeS, ZnS and alkyl sulphide as sulphides were employed, while in the deconvolutions of the spectra of tribofilms from fluids not containing Zn species (Fluids-1, 3), the spectra of FeS and alkyl sulphide as sulphides were employed. As a result of the deconvolutions, it is found that the bulks of the B-CVT tribofilms are composed of over about 95% sulphides such as FeS, ZnS and alkyl sulphide, while the bulk of the AT/B-CVT tribofilm is composed of about 85% sulphides and 15% sulphite and sulphate as shown in Fig. 5.

Because the B-CVT tribofilms show high friction coefficients and the AT/B-CVT tribofilm shows a medium friction coefficient, it is suggested that the friction coefficients of the tribofilms might be governed by the type of S species contained in the tribofilms, that is, sulphides might increase the friction coefficients.

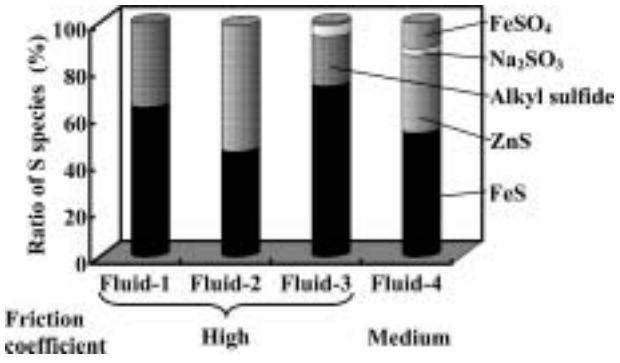

Fig. 5. Ratio of S species in the bulk of tribofilms (at the 30-minute point).

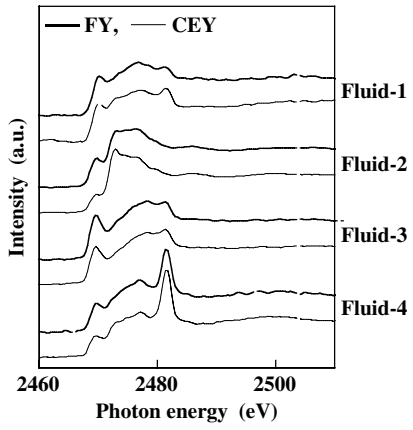

Fig. 6. S K-edge XANES in FY and CEY modes spectra of B-CVT and AT/B-CVT tribofilms (at the 30-minute point).

Further, in order to understand the uniformity of the chemistry of the S species in tribofilms, we compared the S K-edge XANES spectra of tribofilms collected in the FY mode and those collected in the CEY mode which indicates the chemistry in the near surface region of the tribofilms. Almost no significant differences in the XANES spectra of the tribofilms are observed between the two modes, except the spectra of the B-CVT tribofilm generated from Fluid-2, which gives a high friction coefficient and contains Zn species, as shown in Fig. 6. Fig. 6 suggests that the ZnS content in the near surface region of the B-CVT tribofilm generated from Fluid-2 might be higher than that in the bulk. On the other hand the chemistry of the S species in the other tribofilms might be almost uniform as far as the near surface and the bulk are concerned. In another report, the tribofilm prepared from Fluid-2 using another type of friction tester, that is a reciprocating type friction tester, showed no significant difference between the XANES spectra in both the FY and the CEY modes [5]. This suggests that the friction test conditions might affect the uniformity of the chemistry of the S species in tribofilms.

4. Conclusion

The following are suggested by the examination of the S K-edge XANES spectra of four tribofilms generated from B-CVTFs:

1. XANES spectroscopy is a useful analytical method to characterize the S species in the tribofilms in detail.
2. Sulphides such as FeS, alkyl sulphide and ZnS in the tribofilms might increase the friction coefficients of the tribofilms.
3. ZnS content in the near surface region of the tribofilm generated from Fluid-2, which gives a high friction coefficient and contain Zn species, might be higher than that in the bulk. On the other hand, the chemistry of the S species in the other three tribofilms might be almost uniform as far as the near surface and the bulk are concerned.

Abstract

Spectroscopic studies of transition metal (Tm) and rare earth (Re) oxides, combined with *ab initio* theory identify the band edge electronic structure of alternative high-K dielectrics. The lowest conduction band states are derived from anti-bonding transition metal d*-states with a π symmetry and show strong final state effects. Applied to the complex Tm/Re mixed oxides of the general form $ReTmO_3$, this approach identifies a novel way for obtaining separate and independent control of band gap energies and dielectric constants through local bonding arrangements in which Tm and Re atoms are nearest neighbors to the same oxygen atom.

1. Introduction

The band edge electronic structure of the group IVB Tm oxides, TiO_2, ZrO_2, and HfO_2, has been obtained by X-ray absorption spectroscopy (XAS) and vacuum ultra-violet spectroscopic ellipsometry (VUV SE), coupled with *ab initio* calculations and provides the basis for a quantitative understanding of empirically-determined scaling of band gaps and band offset energies with respect to Si as function of the atomic d-state energies of the respective Tm/Re atoms. Based on this scaling, and confirmed by experiment, elemental oxides, and silicate and aluminate alloys containing Sc, Ti, Ta and Nb have band offset energies too small for reducing direct tunneling to levels required for advanced devices in spite of high dielectric constants and film thickness increases of 5 to 10 relative to SiO_2.

Spectroscopic studies of $GdScO_3$ provide an additional dimension to this scaling. Based on XAS and VUV SE measurements, and combined with an extension of *ab initio* calculations to complex oxides with Re-O-Tm bonding arrangements, it is shown that coupling of Re and Tm atomic d-states in these arrangements increases minimum band gaps and conduction band offset energies with respect to crystalline Si, thereby identifying novel and technologically important opportunities for band gap 'engineering' at the atomic scale.

2. Spectroscopic studies of group IVB Tm oxides and $GdScO_3$

The lowest conduction band states of ZrO_2 as determined from Zr $M_{2,3}$ and O K_1 XAS [1], and band edge optical absorption constants from VUV SE measurements [2] are associated with symmetry-split Zr 4d*-states, and a broader band derived form Zr5s*-states. Table I summarizes the relative energies of these spectral features for ZrO_2, as well as HfO_2 and TiO_2. Relative energies of these features in the $X_{2,3}$ spectra (X = L, M and N) normalized to the lowest d*-state energy, are essentially the same for ZrO_2 and HfO_2, except for a small difference in the d*-s* state splitting. In contrast, the d* state splitting in the TiO_2 $L_{2,3}$ spectra is smaller, and the d*-s* splitting is larger. Due to final state effects the d* state splitting show differences in the respective Tm $X_{2,3}$, O K_1 and absorption edge spectra. Figure 1 displays corresponding spectra for $GdScO_3$: the $L_{2,3}$ spectrum for Sc in Fig. 1(a), the O K_1 edge spectrum in Fig. 1(b), the optical absorption constant in Fig. 1(c), and additional absorption edge transmission for intra 4f-level transitions in Fig. 1(d) [3].

Table I. *Measured d*-d* and d*-s* splittings.*

oxide	$X_{2,3}$ d*-d* (d*-s*) ±0.2 eV	K_1 edge d*-d* (d-s) ±0.2 eV	band edge d*-d* (d*-s*) ±0.2 eV
TiO_2	2.0 (13)	1.8 (6)	1.4 (5)
ZrO_2	2.4 (12)	1.3 (4.5)	∼1.4 (<1)
HfO_2	∼2 (10)	1.5 (4.5)	∼1.4 (<1)

The features in the $L_{2,3}$ spectrum in Fig. 1(a) are associated with localized transitions between spin-orbit split Sc $2p_{1/2}$ and $2p_{3/2}$ states and symmetry split Sc 3d* states. Matrix element effects account for the lack of observable absorption from the Sc states to anti-bonding Sc 4s* states [4]. The spin-orbit splitting is ∼4 eV, the symmetry splitting of the 3d*-states is ∼2 eV, and the spectral width is <0.5 eV (the spectral resolution is ∼0.2 eV).

The two features at ∼532.5 and 536 eV in the O K_1 edge in Fig. 1(b) are associated with transitions to d*-states. Based on relative widths, the lower energy feature is Sc 3d*-like, and the higher is Gd 5d*-like. The splitting between these states, ∼3.5 eV is smaller than the splitting of ∼4.2 eV in ZrO_2 (4d*) and HfO_2(5d*), but larger than the 2.5 eV splitting in TiO_2 (3d*).

Figure 1(c) displays the optical absorption constant, α, at the band edge as a function of photon energy obtained from the analysis of VUV SE data. The transmission measurement in Fig. 1(d) establishes that the features between about 4.8 and 5.8 eV are due to intra 4f-level transitions characteristic of the partially occupied 4f-shell in Gd [5]. The rapid rise of absorption at approximately 5.8 eV in Fig. 1(c) marks the onset of transitions from the top of valence band, O 2p π non-bonding states, to the lower of the two d*-states. Since there is no distinct

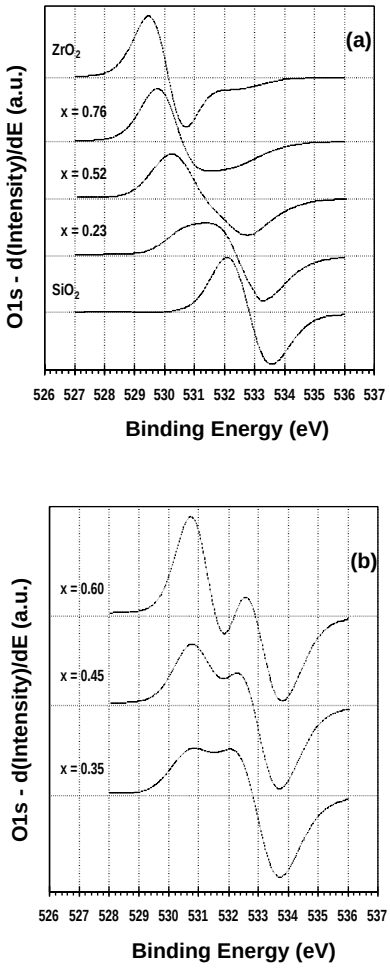

Fig. 2. Calculated band edge electronic structure of ZrO_2 and TiO_2. Energies are referenced to the top of the valence band.

spectral evident for the second d*-state, absorption above 6 eV is dominated by transitions to s*-states.

3. *Ab initio* calculations

The spectra for the group IVB oxides have been interpreted through *ab initio* calculations, the details of which will be published elsewhere [6]. The electronic structure calculations employ variational methods in which an exact Hamiltonian is used so that the variation principle applies. The calculations are done initially through a self-consistent field (SCF) Hartree-Fock calculation with a single determinant wave function, which does not include electron correlation. Following this, there is a configuration interaction (CI) refinement of the bonding orbitals based on a multi-determinant expansion wave function, and including electron correlation effects.

This method has been applied to small clusters that include the bonding of the transition metal atom to O neighbors terminated by H atoms. Calculations have been made for the ground state energy, and the Zr K_1, the Zr $M_{2,3}$, the O K_1, and the absorption edge transitions and the corresponding electronic structures for TiO_2, and HfO_2. Table I summarizes the relative energies of these spectral features for ZrO_2, as well as HfO_2 and TiO_2. Relative energies of these features in the $X_{2,3}$ spectra (X = L, M and N) normalized to the lowest d* state energy, are essentially the same for ZrO_2, HfO_2, and TiO_2 except for small differences in the d*-s* state splitting. The d*-d*, and d*-s* splittings are smaller in the K_1 edge and band edge spectra as well. The d*-s* splitting are greater for TiO_2, with no d*-s* overlap in the band edge spectra, as contrasted with marked overlap for both ZrO_2 and HfO_2. This trends have been are in agreement with theory.

Figure 2 compares the calculated band edge structures of ZrO_2 and TiO_2. All energies are referenced to the top of the valence band, which is comprised of oxygen atom 2p π non-bonding states. Consider first the valence band states. In order of increasing binding energy these are non-bonding O 2p π, and 3d Ti or 4d Zr π-bonded states, and 3d Ti or 4d Zr σ-bonded states with the corresponding O 2p π or σ orbitals. The overlap is larger for the Ti 3d-O 2p π-bonding than for Zr 4d-O 2p π-bonding, hence the difference of $\sim$2 eV. The differences in relative energy between the Ti 3d-O 2p and Zr 4d-O 2p σ-bonding states are similar as indicated by the dashed arrows. The separation of the conduction band d-states comes from the calculations, and the relative energy of the lowest conduction band state is from experiment. The energies of the lowest Tm conduction band states have a reversed π^*/σ^* ordering, and the energies relative the atomic Ti 3d and Zr 4d states and are respectively smaller consistent with the *bonding stabilization energy* being greater than the *anti-bonding destabilization energy*.

One of the more important features of Fig. 2 is the energy difference between the respective atomic d-states, 11.1 eV for the Ti 3d state, and 8.13 for the Zr 4d state, and the respective lowest anti-bonding states. This is approximately 2 eV, and is the basis for the scaling of elemental oxide band gaps with the energies of the respective atomic d-states that is displayed in Fig. 3. This explains the approximately linear dependence in the energy range between

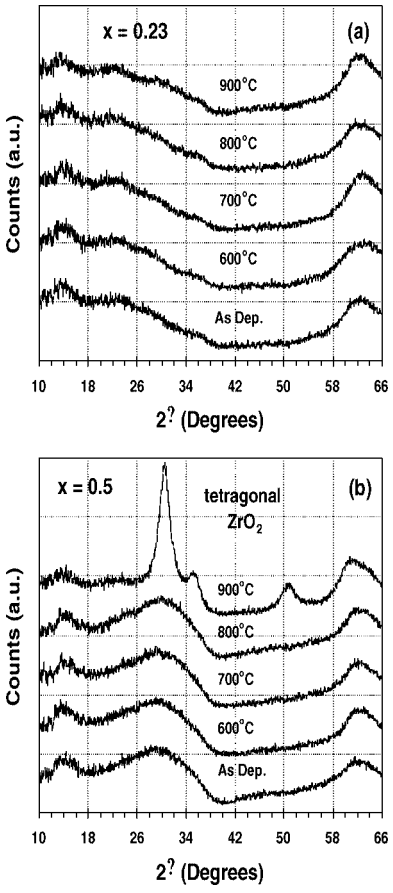

Fig. 3. (a) Empirical scaling of band gaps versus atomic d-state energy. Solid line – trend for transition metal oxides, dashed line – predicted scaling for complex oxides with d-state coupling. 3(b) Empirical scaling of conduction band offset energies with respect to Si versus atomic d-state energy. Solid line – trend for transition metal oxides, dashed line – predicted scaling for complex oxides with d-state coupling.

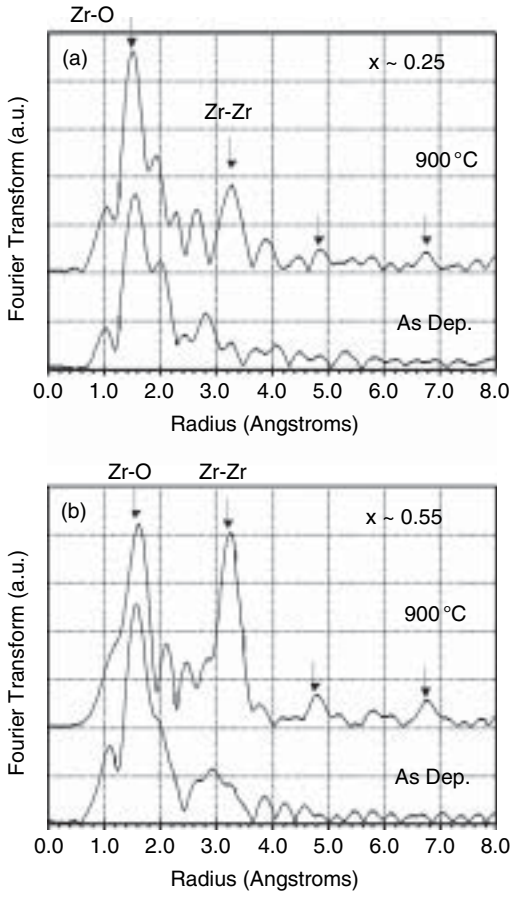

Fig. 4. Schematic representation of molecular orbitals for band edge electronic structure. Top: for elemental transition metal and rare earth oxides; bottom; for complex oxides with d-state coupling through O-atoms.

-11 and -8 eV, which includes in order of increasing (more positive) d-state energy, Ti, Nb, Ta, Sc, Zr and Hf. The bending over at higher energies, e.g., for Y or La, is a manifestation of interactions between higher lying $(n + 1)$ s*-states, and the n d*-σ–state band. The flattening out at lower energy occurs for oxides of Mo and W (not high-K candidates) where d-state occupancy is increased.

Based on this scaling, and results presented in Ref. [7], the minimum band gap in $GdScO_3$ is expected to be determined by transitions which terminate in d*-states with Sc 3d*-character. Since the top of the valence is O 2p p non-bonding, the valence band relative to vacuum are expected to be essentially the same in Sc_2O_3 and $GdScO_3$. The band gap for Sc_2O_3 as determined from transitions terminating in the lowest lying 3d*-state is a approximately 4.3 ± 0.1 eV [7], scaling arguments would place the lowest band gap in $GdScO_3$ at approximately the same energy, and less than 4.5 eV. This expectation is based on comparisons between the band gaps of TiO_2 and $SrTiO_3$, and Nb_2O_5 and $KNbO_3$ [8], where the respective band gaps differ by no more than 0.2 eV.

4. Interpretation of the spectra for $GdScO_3$

Since the lowest band gap in $GdScO_3$ is at ~4.9 eV, this represents a marked departure from the scaling discussed above. This is accounted for by considering differences between the bonding in $GdScO_3$ and the elemental oxides and oxides in Fig. 4. The local bonding in $GdScO_3$ includes arrangements in which both Gd and Sc atoms are bonded to the same O atom. This promotes a mixing of Sc 3d-states and Gd 5d-states, which contributes to both the valence band and conduction band electronic structure. Figure 4 presents an energy band scheme that applies. The upper part of the figure illustrates bonding in elemental Tm or Re oxides, e.g., Sc_2O_3 or Gd_2O_3, in which Tm or Re atoms, respectively, are second neighbors and bonded to a common O atom. The lower portion indicates changes that occur in complex oxides in which Tm and Re atoms are second neighbors through bonding to the same O atom. For $GdScO_3$, the overlap of the Sc 3d states both for π- and σ-bonding is greater than for the Gd 5d states, and this results in valence band, and anti-bonding states that are shifted in energy from their respective end member oxides, Sc_2O_3 and Gd_2O_3. Based on overlap integral differences, valence band π- and σ-states are at intermediate energies with respect to the corresponding elemental oxides states. This increases the energy of the lowest conduction band state with respect to Sc_2O_3, and also makes the separation between the two d*-states intermediate between those of a 3d-oxide and 5d-oxide. This is important for band gap/band offset energy scaling, and is included in Fig. 3.

The basis for the scaling comes from comparisons between $GdScO_3$ and ZrO_2, where the onsets of strong absorption occur respectively at 5.8 and 5.7 eV; this means that $GdScO_3$ has a band gap characteristic of a 4d Tm oxide. It is interesting to note that the average atomic d-state energy in $GdScO_3$, equal 0.5 $(-6.6\,\text{eV} + -9.4\,\text{eV}) = -8\,\text{eV}$ which approximately equal the atomic d-state energy of ZrO_2, -8.13 eV. In a parallel manner, the band gaps of ScO_3, ~4.5 eV and Gd_2O_3, ~6.3 eV average out

to a band gap of approximately 5.5 eV. This suggests that a virtual crystal model can be applied to complex Tm/Re oxides in which d-states of the constituent atoms are coupled through bonding to common O atoms. Bonding in Tm/Re silicates and aluminates is qualitatively different and has been addressed in Ref. [1] and [9]. The energies of Zr core states, and Si core states track across Zr silicate alloys with a constant separation [9]. This equivalent to the difference between the band edge transitions between O 2p π non-bonding states and Zr 4d* and Si 3s* states maintaining a constant energy separation that is shown in Ref. [1]. Tm (Re) silicate and aluminate alloys are the *two band* systems, where energies are maintained at relative end-member oxide levels, but relative absorptions change with relative concentration, whilst the complex $ReTmO_3$ display a qualitatively different *single band* behavior. Oxides with Gd_2O_3 and Sc_2O_3, with other than the 1 : 1 ratio are expected to display spectra characteristic of more than one environment; e.e., Sc_2O_3 rich alloys, should display multiple d*-state features at energies characteristic of both Sc-O-Sc, and Sc-O-Gd bonding arrangements.

5. Discussion

Figure 4 includes the application of the virtual crystal model to complex oxides. The square point is the experimental value for $GdScO_3$ and is plotted at the Sc atomic d-state energy of 9.35 eV. The diamond shape point is for a HfO_2 (5d) – Tio_2 (3d), 1 : 1 alloy, $TiHfO_4$, where the band gap is the average of HfO_2 (5.8 eV) and TiO_2 (3.1 eV) or 4.4 eV. The conduction band offset energies are estimated on the basis of the virtual crystal model. $GdScO_3$ is 'equivalent' to ZrO_2 with an offset of 1.5 eV, and $Hf(Zr)TiO_2$ is expected to have an offset energy of approximately 1 eV, whereas a Ta_2O_5-$2HfO_2$ alloy may have an offset as high as 1.4 eV. Thin film alloys are being prepared to test these predictions of the virtual crystal model. If they prove to be correct, then a virtual crystal behavior should occur in the dielectric constants as well, and therefore provide separate and independent control of offset energies and K. This would be particularly interesting for the TiO_2 and Ta_2O_5 complex oxides where the dielectric constants of the elemental Tm oxides, $\sim$50, and 30, respectively.

Abstract

In situ EXAFS spectra of liquid, vitreous and crystalline zinc chloride under pressure and temperature, have been obtained and analysed using advanced techniques for data analysis (GNXAS). A detailed experimental investigation of the short-range structural properties of zinc chloride is presented. X-ray absorption measurements of solid and liquid $ZnCl_2$ have been collected in the P = 0-12GPa and T = 296-800 K ranges of pressure and temperature, using synchrotron radiation. The analysis of the signal in vitreous and liquid $ZnCl_2$ has been performed using a technique that allows to extract information on the radial distribution function $g(r)$ obtained from molecular dynamics simulations or previous diffraction determination.

1. Introduction

The pressure and temperature dependence of the structural properties of liquids and glasses of tetrahedral oxides are of fundamental and technical interest. However, observing possible pressure-induced coordination changes in the liquid phase of MO_2-type oxide with tetrahedral network requires temperatures much too high for the diamond anvil cell experiments. Therefore, we have substituted the oxide by zinc chloride, a glass forming material which has relatively low melting and glass transition temperatures ($Tm = 593$ K, $Tg = 375$ K), at ambient pressure.

Zinc chloride is unusual among the halides for its high viscosity at the melting point and consequently its ability to supercool into a glass at a relatively low temperature. The generally accepted representation of the structure of non-crystalline $ZnCl_2$ is based upon a well-defined tetrahedral local structure in which chlorine anions surround the zinc cation [1, 2, 3, 4].

Crystallographic studies have clearly established the tetrahedral coordination of Cl^- ions about the Zn^{2+} ions in crystalline $ZnCl_2$. In 1963, Wyckoff [5] lists three polymorphs, α-$ZnCl_2$ ($I\bar{4}2d$), β-$ZnCl_2$($P2_1/n$) and γ-$ZnCl_2$ ($P4/nmc$). It was shown, however, by Brynestad and Yakel [6, 7] in 1978, that careful preparation of anhydrous $ZnCl_2$ leads to the formation of only one crystal structure, δ-$ZnCl_2$ which has the orghorhombic symmetry and space group $Pna2_1$. Recent work [8] confirm their conclusion tha the previously reported allotropic forms are the result of water contamination of δ-$ZnCl_2$. Raman and X-ray experiments have shown the existence of a second $ZnCl_2$ phase which has the $CdCl_2$-type layer structure with the zinc cations in a six-fold coordination [9, 10].

This paper presents a structural study based on X-ray absorption measurements of glassy, crystalline and liquid $ZnCl_2$ in the $P = 0$–12 GPa pressure range and $T = 296$–800 K temperature range, collected using synchrotron radiation. Determination of the local structure is performed using EXAFS refinement in the framework of the GNXAS method for data analysis [11, 12, 13].

2. Experimental techniques

2.1. *Sample preparation*

The $ZnCl_2$ glass samples were high-purity beads (99.99%, Aldrich chemicals). Due to the extreme hygroscopicity of the glass and subsequent devitrification to the cristobalite-type α-$ZnCl_2$ in the presence of minute amounts of water (as seen by Raman spectroscopy), all manipulation of the material took place in a helium-filled glovebox. The beads were finely ground in a mortar and then the powder was loaded without pressure medium in a 200μ-diameter sample chamber of a preindented rhenium gasket. The sample, fine ruby spheres and strontium borate doped with samarium were pressurized in a membrane driven diamond anvil cell.

The high temperature experiments have been performed with an external heater, which allows us to increase the temperature up to 800 K.

2.2. *Dispersive Extended X-ray Absorption Fine Structure*

X-ray absorption measurements were performed at the Zn K-edge, in LURE (Laboratoire pour l'Utilisation du Rayonnement Electromagnitique, Orsay, France) on the D11 beam line (Dispersive EXAFS, DCI storage ring). Figure 1 shows typical XAS spectra collected at different pressures and temperatures.

Measurements on crystalline $ZnCl_2$ have been recorded at ambient temperature, from 0.2 up to 11.8 GPa, with a pressure accuracy of about 0.1 GPa. As previously reported [9, 10], we observed a pressure-induced phase transition between $\gamma - ZnCl_2$

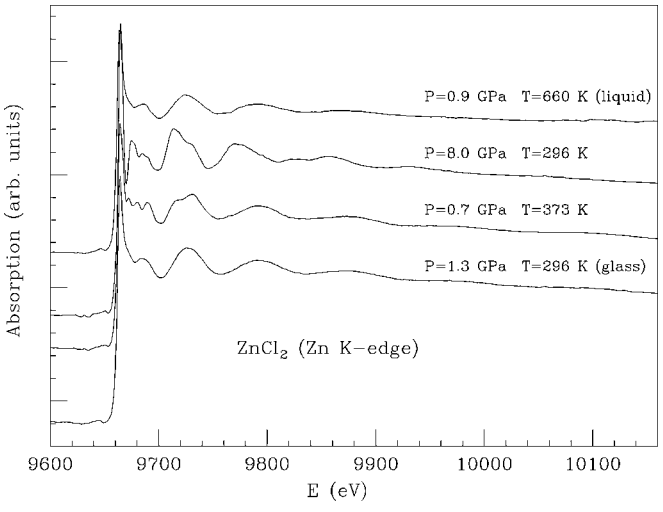

Fig. 1. X-ray absorption spectra of $ZnCl_2$ near the Zn K-edge, for four different pressures and temperatures in the glassy, liquid and two crystalline phases.

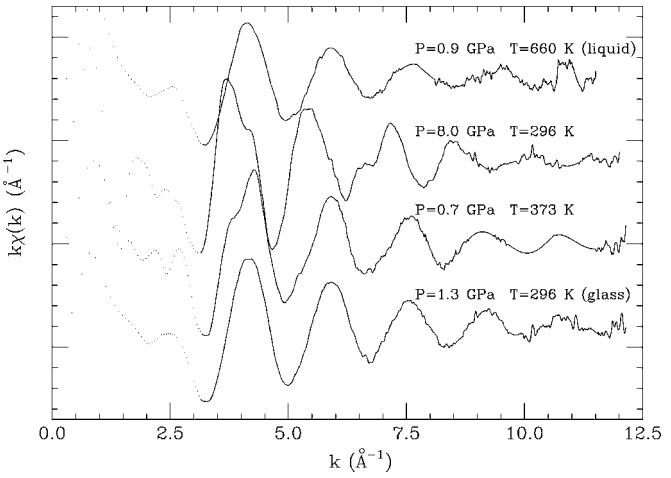

Fig. 2. Experimental XAFS data for four different phases of $ZnCl_2$.

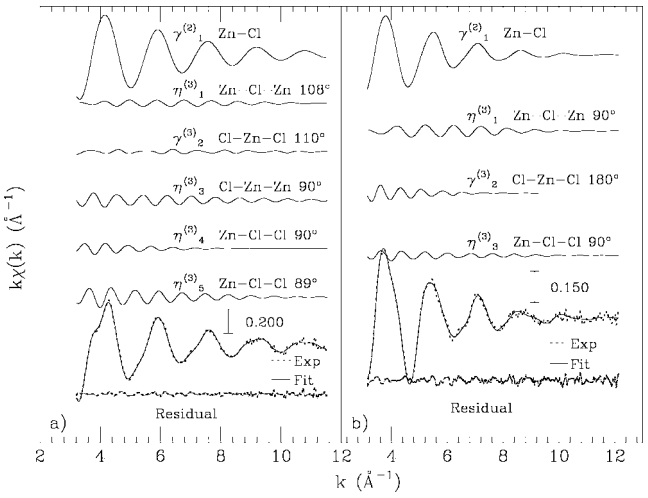

Fig. 3. Decomposition of the best-fit calculated multiple-scattering into individual two body ($\gamma^{(2)}$) and thr5ee-body ($\gamma^{(3)}$and$\eta^{(3)}$ including the two-body signal of the longest distance of the triplet) terms. a) Low-pressure crystalline phase $P =$ 0.3 GPa,$T = 396$ K. b) high-pressure crystalline phase $P = 2.6$ GPa,$T = 513$ K.

and a $CdCl_2-$type phase (see spectra at $P = 0.7$ and $P = 8.0$ GPa in Figure 1). Vitreous $ZnCl_2$ was measured only at ambient temperature and $P = 1.3$ GPa. By heating the sample above the glass transition temperature (3.73 K) we observed a crystallization of vitreous $ZnCl_2$, and then liquid was obtained at $P = 0.9$ GPa and $T = 660 \pm 10$ K.

The raw $k\chi(k)$ data for the four different phases are presented in Figure 2. The frequency difference between the two crystalline spectra is a direct manifestation of the increase of the first-shell average distance during the transition from the low-pressure crystalline phase (four-fold coordinated) to the high-pressure $CdCl_2-$type crystalline phase (six-fold coordinated). On the other hand, the vitreous, liquid and low-pressure crystalline phases have quite similar first-shell average distances, which is consistent with literature [4, 15]. We can see a softening of the oscillations for vitreous and liquid spectra which is a consequence of a lack of long-range order. The amplitude decrease for the liquid $ZnCl_2$ is due to an increase of thermal vibrations.

3. Results and discussion

3.1. *Methodology*

EXAFS data have been analyzed using the GNXAS package [13]. The experimental EXAFS signals of the four phases observed during the experiments are shown in Figure 3 and 4. They are compared with the corresponding best-fit model signals. Figure 3: low-pressure crystalline phase (a) and high-pressure crystalline phase (b). Figure 4: glassy phase (a) and liquid phase (b).

For the two crystalline phases the model signals include the first three coordination shells, modeled using asymmetric Γ-like distributions [12, 13]. The two-body and three-body signals of the model are calculated from the known structure at ambient conditions. Then only the more intense are kept for fitting experimental signals. In a first approach, average angle values have been kept fixed in order to minimize the number of free parameters.

For the disordered phases, we have used a method combining long-range information (tail) from MD and neutron diffraction data [14, 15], with the short-range sensitivity of the EXAFS ($\gamma^{(2)}$) [16].

In this paper, we present only the first-neighbour structural parameters R (interatomic distance) and σ^2 (Debye-Waller factor).

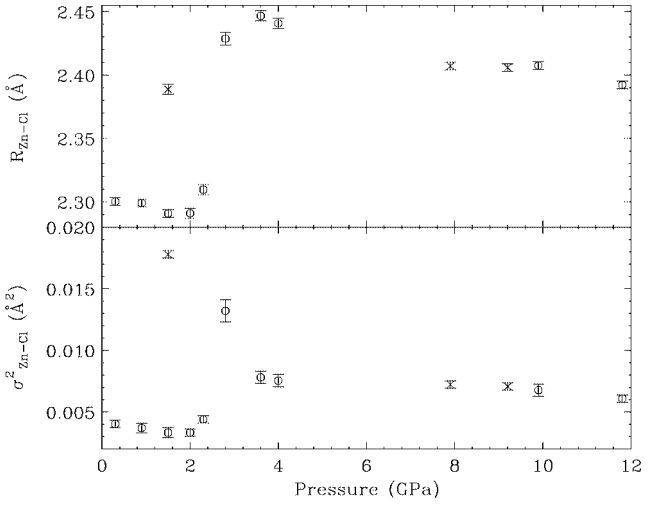

Fig. 4. Analysis of glassy and liquid $ZnCl_2$ spectra using a model $g(r)$ composed of two Γ -distribution peaks plus a tail contribution. a) Glassy phase $P = 1.3$ GPa, $T = 296$ K. b) Liquid phase $P = 0.9$ GPa, $T = 660$ K.

3.2. *Results*

The amount of water in the crystalline sample after loading was tested by Raman spectroscopy, that revealed a sharp peak at about 250cm^{-1}, characteristic of hydrated $\gamma - ZnCl_2$ according to other works [8, 9, 10]. Thus, low-pressure crystalline phase EXAFS analyses were done using $\gamma - ZnCl_2$ as a model for refinement.

The results of the ambient temperature structural refinement are reported in Figure 5. The error bars refer to a 95% confidence level and have been calculated using rigorous statistical methods accounting for correlations among parameters [13].

The pressure-induced phase transition from tetrahedral to octahedral $ZnCl_2$ occurs between 2 and 3.6 GPa. The first-neighbour distance starts from $R = 2.300 \pm 0.003$ Å at ambient conditions, then decreases on compression and shifts to $R = 2.446 \pm 0.004$ Å after the transition. Transition on decompression was not observed during these experiments because the lowest pressure reached was 1.5 GPa. However, the reverse transition began at this pressure, as seen from the high value of σ^2 and the decrease of R from 7.9 to 1.5 GPa.

The Debye-Waller factor, σ^2, is a parameter of disorder representing the sum of the static (configurational) and the

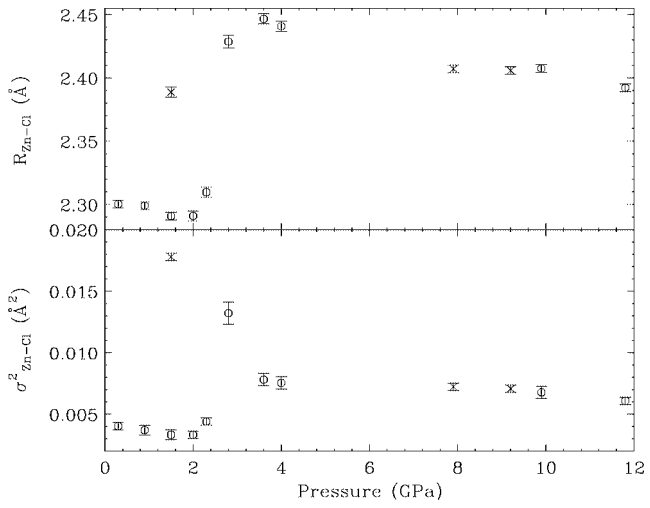

Fig. 5. First-shell parameters for solid $ZnCl_2$ determined by XAFS data-analysis as a function of pressure, at room temperature (o: compression, (×: decompression).

dynamic (thermal) disorder. During the isotropic compression of the low-pressure phase (up to 2 GPa) σ^2 decreases because of the decrease of the dynamic disorder. Actually, a decrease of σ^2. At the beginning of the transition, the increase of σ^2 is due to the increase of static disorder. A lot of atom positions are changing so the local structure is a mix of several configurations. In the high-pressure phase the static disorder is stabilized, and σ^2 decreases with the dynamic disorder, like in the low-pressure phase. However, the value of σ^2 is higher in the second phase because of longer interatomic distances.

Glassy $ZnCl_2$ was measured only at room temperature and P = 1.3 GPa. Structural refinement gives the value of R = 2.299 $\pm$ 0.004 Å and $\sigma^2 = 0.0036 \pm 0.004$Å^2. By annealing the sample above the glass transition temperature (373 K) we observed a crystallization.

Liquid $ZnCl_2$ was obtained at $P = 0.9$ GPa and $T = 660$ K from crystalline $ZnCl_2$. We obtained $R = 2.298 \pm 0.004$Å and $\sigma^2 = 0.0137 \pm 0.005$Å^2 as structural parameters. There is no significant difference between the first shell interatomic distance of crystalline, vitreous and liquid $ZnCl_2$ phases, at the same pressure, which shows the great stability of the tetrahedral configuration in this compound. We did not observe any thermal expansion by heating the low-pressure crystalline phase and the high-pressure one.

The values for R_{Zn-Cl} of the disordered phases obtained by Wong and Lytle [4] are quite different from those obtained in this work. The discrepancy is due to the need to involve a reference compound, in the EXAFS data-analysis method used in Ref. [4], in order to fix the phase factor of the EXAFS absorption coefficient. By contrast, the GNXAS data- analysis yields R_{Zn-Cl} directly like neutron or X-ray diffraction, which give R_{Zn-Cl} values closer to ours [1, 9, 15]. As a conclusion, we want to underline that EXAFS experiments combined with the GNXAS data analysis method is a really powerful tool to explore at the same time crystalline, vitreous and liquid $ZnCl_2$, at high pressure and high temperature.

Abstract

The solubility of actinides and actinide surrogates in a nuclear borosilicate glass was studied with cerium, hafnium, neodymium, thorium and plutonium. Cerium is a possible surrogate for tetravalent and trivalent actinides such as plutonium, hafnium for tetravalent actinide such as thorium, and neodymium for trivalent actinides such as curium or americium. X-ray absorption spectroscopy was used to obtain data on the local environment of the dissolved elements in the glass network. For glasses melted at 1200°C, the solubility limits of the elements studied were as follows: Nd > Ce > Th > Pu > Hf. A correlation has been established between the cation bonding covalence, the oxygen polyhedron and the solubility limit of the elements: the greater the solubility, the larger the oxygen bonds.

1. Introduction

High-level radioactive waste in France containing actinides, fission products and activation products produced by spent fuel reprocessing is incorporated into "R7T7" borosilicate glass. The material must be as homogeneous as possible from both a chemical and a microstructural standpoint to ensure optimum radionuclide containment. Any possible heterogeneities observed arise from various processes including the excess loading of an element at a concentration that exceeds the solubility limit. It is thus essential to know the solubility limit of the elements.

Emerging industrial requirements have led the plant operators to increase the minor actinide and plutonium loading factors in these materials, in particular the reprocessing of high burn-up fuel. In this context a study [1] was undertaken to determine the solubility limit and understand the solubilization mechanisms of these elements in borosilicate glass.

2. Experimental Protocol

2.1. *Surrogate Element Selection Criteria*

Glass specimens in which the actinides were replaced by lanthanides or hafnium, are used to prepare and optimize the making of radioactive samples. This facilitated analysis of the inactive materials by the techniques used in this study (SEM, XAS).

The surrogates were selected on the basis of criteria such as the oxidation state, ionic radius, or coordination number. Cerium was selected as a plutonium surrogate since both elements can be stabilized in the glass at oxidation states +III and +IV. Two other elements, neodymium and hafnium, were also investigated as surrogates for actinides with only one stable oxidation state in the glass (oxidation states +III and +IV, respectively). The solubility variation of these two elements depending on the glass fabrication parameters can thus be estimated irrespective of any change in the oxidation state. Actinides with only a single oxidation state in the glass include curium (Assefa [2]) and americium (Karraker [3]) for oxidation state +III, and thorium (Petit-Maire [4]) for oxidation state +IV.

2.2. *Sample Preparation*

Samples were prepared from oxide, nitrate, and carbonate precursors or from previously fabricated glass frit containing the following elements (wt%): SiO_2 58.84; B_2O_3 18.15; Na_2O 7.00; Al_2O_3 4.28; CaO 5.23; Li_2O 2.56; ZnO 3.24; ZrO_2 0.7. The glass compositions were simplified to facilitate analysis and understanding of the phenomena involved, except for the samples containing plutonium and curium, which were more complex (22 oxides) and representative industrial glass. Zirconium was removed from the glass composition containing Pu, however, to avoid interfering with the EXAFS signal, as these two elements have absorption edges at comparable energies ($E_{Pu} = 18.066$ keV, $E_{Zr} = 17.955$ keV). The surrogates or actinides were incorporated in the glass in the form of oxides or nitric acid solutions obtained by dissolving the relevant element nitrate in water or in 1 N nitric acid. The glass was melted under neutral atmosphere (argon) for curium, plutonium and a few cerium glasses, or oxidizing atmosphere (air) for the others, at temperatures between 1100 and 1400°C in zirconia or platinum crucibles to limit glass-crucible interactions. The glass samples containing surrogates were then quenched in air at a rate of about 100°C/min to prevent the formation of crystalline phases. The glass samples containing plutonium or curium fabricated in a radioactive environment were cooled down to T_g by shutting off the heat source in the melter (≈5°C/min). Tests were carried out to check that heterogeneous phases did not precipitate during cooling. About 5 grams of glass containing plutonium and a few tens of grams of glasses containing the other elements were fabricated under these conditions.

A few glass samples containing cerium were fabricated under reducing conditions, i.e. aluminum nitride was added to reduce the cerium according to the following reaction, considered the most likely based on thermodynamic calculations by Diaz [5]:

$$3Ce^{4+} + N^{3-} \rightarrow 3Ce^{3+} + 1/2N_2.$$

Bubbles formed by this reduction were observed during sample preparation.

2.3. *Solubility Measurement : Notion of Conditional Solubility*

The solubility of an element is defined as the maximum concentration of this element that can be loaded in the glass while maintaining its homogeneity. The solubility limit is determined by gradually increasing the concentration in the glass of the element in question until a heterogeneous phase appears in the system (crystallization or demixing). The secondary phase is then characterized by optical microscopy, SEM and EDS.

The solubility limit value measured by microscopy varies, however, depending on the form (liquid or solid) or particle size of the precursor containing the surrogate when it was added to the glass. Similarly, when excess surrogate was added to obtain the formation of crystals in the glass, a surrogate concentration exceeding the limit determined by microscopy was measured in homogeneous vitreous zones of the sample. This suggests that thermodynamic equilibrium was not reached and that solubilization of the surrogate could be limited by the precursor dissolution step. For this reason the term "conditional solubility", by analogy with conditional thermodynamic constants, is more appropriate when referring to the quantity measured by microscopy. In the remainder of this article, conditional solubility is implied whenever the term "solubility" is used.

2.4. *X-ray Absorption Spectroscopy*

XANES spectroscopy was used to determine the oxidation state of cerium and plutonium since both elements are found at oxidation states +III and +IV in the glass.

EXAFS spectroscopy was used to determine the local environment (number of oxygen atoms, N, and cation-oxygen distance, d) around the elements studied in the glass. EXAFS spectra of glasses containing thorium(IV), plutonium(IV) and curium(III) were obtained at the Stanford Synchrotron Radiation Laboratory (SSRL), and those for glass containing cerium(III), neodymium(III) and hafnium(IV) were obtained at the Orsay Electromagnetic Radiation Application Laboratory (LURE). The analyses were performed at room temperature by L_{III}-edge fluorescence detection for these elements. Petit-Maire [4] showed that the local environment of thorium in borosilicate glass is not temperature-dependent. Based on these results, it may be assumed that quenching does not affect the local environment of the element analyzed.

The data were processed to determine the structural parameters of the first-neighbor shell using programs developed by Michalowicz [6].

3. Experimental Results – Discussion

3.1. *Element Solubility*

The measured solubility variation (in mol%) is indicated in Figure 1 versus the glass fabrication temperature for each of the elements studied. The upper value shown on the error bars of the experimental results corresponds to the first glass in which heterogeneity was observed, and the lower value to the final homogeneous glass. The solubility can be observed to increase with the processing temperature. The magnitude of this increase is greater for the elements at oxidation state +III (e.g. neodymium) than for the elements at oxidation state +IV (e.g. hafnium or thorium). The heterogeneities observed when the solubility limit is reached are silicates or oxides. Phase separation was observed for cerium and neodymium when their concentrations reached about 2.7 mol% at processing temperatures of 1200°C or higher.

The cerium oxidation state was characterized by chemical titration in borosilicate glasses fabricated at various temperatures. The analyses showed that glasses contain a mixture of cerium(+III) and cerium(+IV) and that the percentage of Ce(+III) drops from 53.8% to 88.1% of the total Ce when the glass fabrication temperature increases from 1100°C to 1400°C. These results were confirmed by XANES analysis. Cerium reduction at higher temperatures affects its solubility, as observed by Li [7]. Fabricating the glass under reducing conditions at 1200°C by adding aluminum nitride as a reducing agent increases the solubility limit from 0.45 mol% to 1.75 mol%. Under these conditions the cerium is completely reduced as shown by XANES analysis of the glass. Work is now in progress in an attempt to obtain similar results with plutonium. The only parameter that has been studied to date for this type of glass is the processing temperature. A homogeneous glass containing 0.076 mol% (i.e. 0.85 wt% plutonium oxide) was fabricated at 1200°C; XANES examination of the glass showed that under these conditions over 90% of the plutonium is at oxidation state +IV (Figure 2). Although the solubility results obtained for plutonium are still incomplete, there is no evidence to date of any variation in the Pu solubility with the glass processing temperature.

The results obtained for curium are not shown in Figure1. A glass sample containing 1.9 wt% CmO_2 (0.14 mol% Cm) fabricated at 1200°C was found to be homogeneous. This is consistent with the results of a study by Inagaki [8] in which

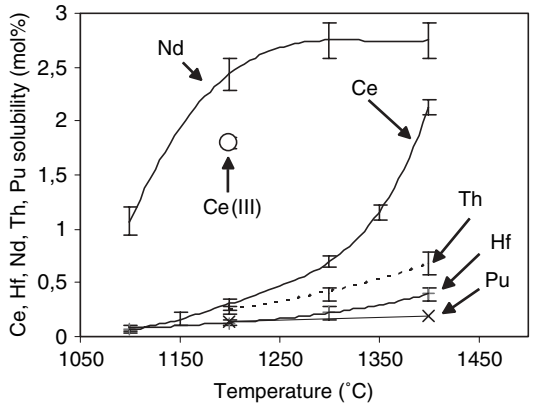

Fig. 1. Ce, Hf, Nd, Th, Pu solubility limits (mol%) determined experimentally in a borosilicate glass. At 1400°C the Pu solubility is lower than 0.192 mol%, works are in progress to have a better determination for the solubility of this element.

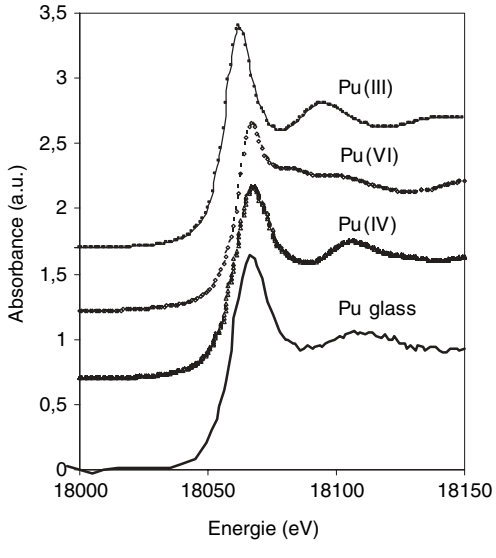

Fig. 2. XANES spectra of borosilicate containing 0.85 wt% of PuO_2 melted at 1200°C compared with the spectra of the reference compounds: Pu(III) in solution, Pu(IV) in PuO_2^{2+} in solution. To have a better understanding on the figure, the spectra are arbitrarily shifted along the vertical axis.

3.04 wt% curium oxide were homogeneously incorporated in a borosilicate glass.

3.2. *EXAFS Analysis of the Glass*

The purpose of these analyses was to propose hypotheses based on structural considerations to account for the observed differences in solubility of the elements studied. The result of EXAFS spectral analysis for each element are shown in Table I. The reference oxide compounds were analyzed by transmission; the silicates were simulated using the FEFF code [9] since we were unable to obtain these compounds.

The best simulations of the phase and the amplitude of Ce and Nd in borosilicate glass were obtained with the silicates $Nd_2Si_2O_7$ and $Ce_2Si_2O_7$. In the case of Ce-loaded glass, only the reduced glass samples containing exclusively Ce(+III) were analyzed. Its first neighbors are 8 oxygen atoms situated at a distance of 2.44 Å. It would be interesting to fabricate glass samples under more oxidizing conditions than in air to obtain Ce(+IV) in order to determine its environment. EXAFS analysis of glasses containing variable Nd concentrations showed that the local environment of this element was identical in each of the glasses containing 2.6, 0.52 or 0.26 mol%. The first-neighbor shell consists of 8 oxygen atoms at a distance of 2.49 Å.

The best fit of the experimental spectra for Pu(+IV) (Figure 3) and thorium were obtained using the PuO_2 and ThO_2 reference compounds. These results are consistent with published data for plutonium (Hess [10]) and for thorium (Petit-Maire [4], Farges [11]) in borosilicate glass.

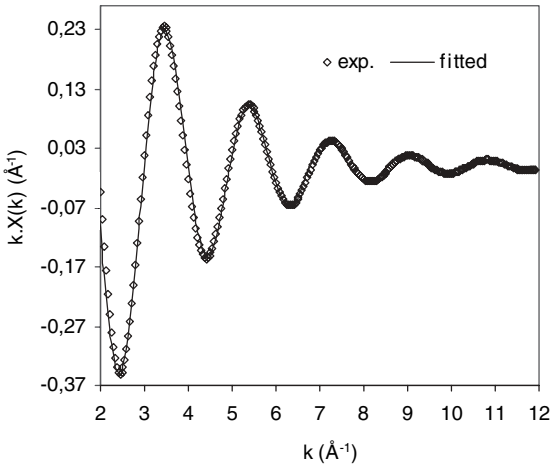

Fig. 3. Comparison between experimental EXAFS spectra and fitted spectra with PuO_2 reference compound for Pu in a borosilicate glass.

Table II. *Relation between field strength defined by Dietzel [12] and solubility of the considered element.*

Cation	Field strength (Dietzel)	Solubility at 1200°C (mol%)
Hf	0.92	0.1 ± 0.02
Pu	0.79	0.134 ± 0.06
Th	0.71	0.26 ± 0.04
Ce	0.5	1.6 ± 0.06
Nd	0.48	2.52 ± 0.06
Cm	0.5	

The length of the bonds established by actinides and surrogates with oxygen atoms in the glass network was determined by EXAFS analysis. Dietzel [12] defined the field strength parameter as the Z/d^2 ratio, where Z is the cation charge and d is the cation-oxygen distance. Network-forming cations such as B or Si exhibit a high field strength (between 1 and 2); conversely, network-modifying cations have a low field strength of between 0.1 and 0.4. Between these extremes are cations with intermediate field strength, including all the elements studied here (Table II). These intermediate cations occupy mixed positions in the glass network, i.e. they create bonds between chains of network-former tetrahedrons, or they may be either modifiers or formers depending on the particular glass composition. As shown in table II there is a correlation between the field strength as defined by Dietzel and the solubility limit of the element: the greater the field strength, the lower the solubility of the relevant element.

4. Conclusion

This investigation has shown that the solubility limits of the elements studied increase with the glass processing temperature. The elements at oxidation state +III exhibit higher solubility than the elements at oxidation state +IV. The greatest increase in solubility was observed for cerium: the higher solubility limit was attributable not only to the higher temperature but also to reduction of this element to Ce(+III).

The relatively similar behavior of the actinides at oxidation state +IV (Th, Pu) and hafnium, suggests that the surrogate elements are representative. Logically, therefore, by analogy with the results obtained with cerium, it should be possible to obtain a significant increase in plutonium solubility by reducing it to oxidation state +III.

Abstract

In order to understand precisely the changes induced by the reversible reaction of lithium with the electrode materials, XAS has been proved in many cases to be very efficient. The transformations generally concern the structure of the compound, at a short or a long range, and the oxidation state of the active element. We have studied, at the vanadium K edge, the behaviour of the compound $Li_{1.2}V_3O_8$, a promising electrode material for the lithium batteries. The XAS experiments have been performed, ex-situ or in-situ, in a classical way on systems close to equilibrium and, for the first time, during the battery cycling in using a dispersive XAS set-up. A plastic battery has been designed for this purpose and connected to an automated battery cycling system. The XANES part of the spectra has been decomposed into few simple mathematical functions and the results obtained at equilibrium and out of equilibrium are compared. The significant differences have been analysed in considering the voltage variations.

1. Introduction

Among the numerous materials which have been considered as positive electrodes in lithium batteries, the vanadium oxides occupy a primary role, especially when the negative electrode is made of lithium metal. This is due to their favorable voltage at about 3V versus the Li/Li^+ electrochemical couple. The reversible incorporation of lithium into all these materials induce, to various extent, structural modifications and redox processes due to the electron transfer from lithium to the host phase. X-ray absorption spectroscopy (XAS) is known to be a powerful tool to characterize the local structural environment of the atoms and to be highly sensitive to the oxidation states. In the last fifteen years, this technique has been largely used to characterize the lithium intercalated compounds [1–5], especially the vanadium oxides [6–8]. In the vanadium pentoxide V_2O_5, gradual changes in the vanadium coordination (V-O distances) and arrangement (V-V distances) have been put in evidence in considering the EXAFS part of the spectra and the changes of the pre edge peak intensities [8].

As for many battery materials, the experiments have been performed either ex-situ on samples prepared chemically or electrochemically, or in-situ on specially designed cells. The results obtained in these two different approaches are very similar, because in both cases the experiments are performed on materials very close to thermodynamic equilibrium. These conditions do not allow to characterize the phase during its functioning in the battery, i.e. when it is polarized during the discharge (lithium insertion) or the charge (lithium deinsertion) of the battery.

In this study we present XAS results obtained on $Li_{1.2}V_3O_8$, a vanadium oxide recently considered as a very good alternative to V_2O_5 as positive in metal lithium polymer batteries [9]. The experiments have been performed ex-situ or in-situ in static conditions, in the classical transmission mode, and, for the first time in dynamic conditions, during the battery functioning, in using a dispersive XAS experimental set-up.

2. Electrochemical results

Lithium trivanadate, $Li_{1.2}V_3O_8$, has been investigated as a positive electrode material for rechargeable lithium batteries during the past twenty years [10, 11]. Much research work has been focused on the structural characterization and cyclability of this compound. The crystal structure of $Li_{1.2}V_3O_8$ was first reported by Wadsley [12]. It has a monoclinic structure (space group $P2_1/m$) and is composed of two basic structural units, distorted VO_6 octahedra and VO_5 square pyramids. These two structural units share edges and corners to form layers [13]. Upon insertion, lithium atoms may occupy two different sites between the layers, octahedra and tetrahedra. The lithium insertion mechanism has been studied by X-ray diffraction (XRD) [13, 14]. When it is used as a positive in a lithium battery, the $Li_{1.2}V_3O_8$ compound can accommodate up to 3.8 lithium ions in the host structure with an operating voltage between 3.7V and 2V (figure 1). The lithium amount is determined by coulometric titration from the

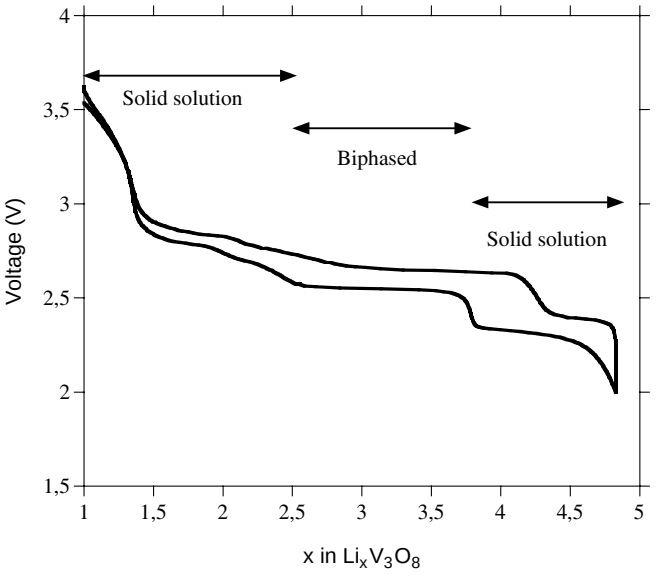

Fig. 1. Voltage versus composition curve in $Li_xV_3O_8$ system.

*e-mail: ouvrard@cnrs-imn.fr

current intensity passing through the battery in a given charge or discharge time. In considering the system $Li_xV_3O_8$, a combination of electrochemical and XRD results allow to conclude that

(*i*) for $1.2 \leq x \leq 2.6$, lithium is inserted in a single-phase reaction process. It corresponds to the gradual filling of empty sites changing mainly the stoichiometry without significant structural modifications.

(*ii*) the voltage plateau observed for $2.6 \leq x \leq 3.8$ is attributed to the coexistence of two phases whose compositions are close to $Li_3V_3O_8$ and $Li_4V_3O_8$. This last phase would have a defect rock salt structure, which is not significantly modified up to the composition $Li_5V_3O_8$.

3. Static experiments

Experiments have been performed at the vanadium K edge, in the transmission mode, on the DCI storage ring at LURE. Si_{111} and Si_{311} monochromators have been used to collect the data in the EXAFS and XANES parts of the spectra, respectively. EXAFS data treatment has followed a very classical procedure in using the WinXAS software [15] and the Feff phases and amplitudes [16].

Data have been collected for more than 20 different lithium contents and only few of them are displayed for the sake of clarity. The spectra have been normalized at the mid point of the first EXAFS oscillation. Figure 2 shows the changes of the edges with the lithium content upon lithium insertion and deinsertion. First we may notice that the process appears very well reversible. This is clearly evidenced by a comparison of the spectra for the pristine phase and the deintercalated one which are almost superimposed. There are two main tendencies in this spectra collection. The first one is a regular decrease of the pre-edge peak intensity upon lithium insertion. At the same time this peak is shifted towards the low energy part. This evolution is a clear signature of a reduction of vanadium and the evolution of its close oxygen environment towards a more centrosymmetrical one [7, 8]. The second clear change is a shift of the main edge towards the lower energy upon lithiation, in good agreement with a vanadium reduction. A lot of studies tried to correlate the shifts of the different singularities of the XANES spectra to the oxidation state of the element under study. In such an approach, there are two main difficulties. One of them is to take into account the fact that, for different compounds in which a given element has the same oxidation state, the edge shape and position are usually different [7]. The second one is to estimate the true position for the main edge whose the shape can be significantly modified by the oxidation state, as seen in figure 2. This is not surprising if we recall that the edge shape of a solid essentially reflects the electron density projected on the p orbitals of the considered element, and, therefore, is largely influenced by the atomic structure.

Most of the previous studies aiming to correlate the XANES spectra to the oxidation state define the singularities positions either in using first or second derivatives [8], or in considering the energy of the half height of the main edge as its position [7, 8]. In this study we have performed a complete and precise mathematical analysis of the first 30 eV of the normalized XANES spectra. We have chosen to model the continuum of empty electronic levels by an arc-tangent curve. Moreover, it is theoretically reasonable to simulate the shape of density of states by a gaussian curve. It is clear on the figure that a least three gaussian and one arc-tangent curve are necessary to simulate the first 30 eV of all the spectra. In order to minimize the freedom degree of the mathematical analysis we have limited the data treatment to this restricted hypothesis. The results are successful in the quality of the simulation (figure 3) and the gradual changes versus the lithium content of the positions of all the curves and the intensity of the pre-edge peak. From this analysis we have extracted precise positions and intensities, the last ones being given by the peak surface in the normalized spectra. As an example, figure 4 shows the variation of the pre-edge intensity versus the lithium content. It clearly demonstrates that the symmetry of the vanadium environment and the filling of the empty electronic states (redox process) vary linearly and reversibly with the lithium content.

This evolution is confirmed by the analysis of the EXAFS part of the spectra. Upon lithiation, we observe that the initial vanadium coordination of 5 (2+3) gradually tends toward a coordination of 6 with a unique V-O distance. The distance variations are very regular. The average distance increases with increasing vanadium size due to reduction.

This study in static conditions, identical to the one used in the XRD experiments, demonstrates that the oxidation state and

the structural environment of the vanadium atoms are modified very regularly and reversibly upon lithiation. This appears to be in contradiction with the XRD results which evidence the occurrence of defined phases with different structural arrangements. The only way to combine the results of these two techniques consists in considering a regular change of the V-O_n polyhedra and, at some peculiar degree of this transformation, the necessity to rearrange each other forming a different structure at long range order.

4. Dynamic experiments

Dynamic experiments have been performed on specially designed cells, in which a composite electrode containing the vanadium oxide is separated from a lithium sheet by a liquid electrolyte soaked in a separator, all the battery being inserted between sealed polymer films to protect the materials from moisture and oxygen. This battery is continuously cycled during the XAS data collection by an automated battery cycling test apparatus (Mac Pile). The lithium amount is continuously determined by coulometric titration. Due to polarization effect during the functioning and because we have chosen the same low voltage limit (2 volts), the maximum lithium content is lower in this case ($Li_{3.6}V_3O_8$) than in the equilibrium experiments ($Li_{4.2}V_3O_8$). The battery has been installed on the focussing point of the D11 beam line at DCI (LURE). Data have been collected, on an energy range of 500 eV, every 6 seconds with a bended Si_{111} monochromator.

At a first glance, the general evolution of the spectra, in both XANES and EXAFS, appears to go the same way as in the static experiments. The previously detailed treatment has been applied to the data. The evolution of the intensity of the pre-edge peak versus the lithium content is displayed on figure 5. It is remarkable that the changes on the discharge are almost perfectly linear, as observed in the static experiments, but that the process is, this time, largely irreversible. The variation on charge can be seen as an almost constant intensity followed by an abrupt modification at the composition $Li_2V_3O_8$. It is important to notice that this variation is, this time, similar to the voltage vs. Li content curve (see the charge curve on figure 1). We have no simple explanation to this surprising result, beyond the fact that, upon the functioning of the battery, there is certainly a large inhomogeneity of the lithium content inside each particle due to lithium diffusion. The lithium concentration is higher at the surface of the grain than in the heart during insertion (discharge) and the reverse can appear in some way upon deinsertion (charge). Presently, it is not possible to estimate the importance of this phenomenon but it appears that the vanadium is not able to react immediately and continuously, from a structural point of view, to the added lithium with its electron, giving rise to the observed hysteresis phenomenon.

This original study put clearly in evidence the importance of the kinetic for the local changes of the material when it is under the constraint of an electrochemical potential. Dispersive XAS appears as a unique tool to characterize the battery materials under their actual utilization, from a structural and redox point of view. Further experiments, including investigations on more cycles, will improve our understanding of the phenomenon, will allow to characterize the behavior upon polarization and relaxation, and will contribute to the improvement of the electrochemical performances.

Abstract

The mesoporous titania prepared by templating with hexadecylamine has an amorphous nature with a narrow pore size distribution centered at 2.8 nm and a Brunauer-Emmett-Teller (BET) surface area of $1230\,m^2\,g^{-1}$. The extremely large surface area implies that most of the atoms are exposed at the surface. XAFS spectroscopy was applied to investigate the microstructure of mesoporous titania. The EXAFS function, $k^3\chi(k)$, was considerably different from that of anatase. The amplitude decreased significantly in the large k region, suggesting large static and thermal disorders of the Ti-Ti bond. The third peak in the radial distribution function, which appeared at 3.4 Å in anatase and was attributed to the Ti atoms at the next nearest neighbouring site, was hardly observed in the Fourier transform of mesoporous titania. A comparison of the spectra at different temperatures revealed that the temperature dependence of the Debye-Waller factor for the Ti-Ti bond was significant. σ^2 was plotted against temperature and the effective surface Debye temperature of mesoporous titania was calculated to be 365 K. This is significantly lower than for the bulk titania crystals, 520 and 530 K for anatase and rutile, respectively.

1. Introduction

The templating using micelles of primary amine permits preparation of mesoporous inorganic oxides with a narrow pore size distribution and an extremely high surface area. Niobium [1], tantalum [2] and titanium [3, 4] oxides have been successfully synthesized by this method. Among those oxides titania attracts a great deal of attention due to its excellent performance in photocatalyst, photoelectronics, semiconductor etc. The BET specific surface area measured for mesoporous titania suggests that the majority of atoms are exposed at the surface [4]. The chemical bond and coordination structure of Ti in the bulk mesoporous titania can be influenced by the nature of the titania surface. The prominent peak in the preedge region of the Ti K edge XANES spectra has been attributed to 5-fold coordinated titanium [5]. The lack of peaks at $2\theta > 10^\circ$ in the Cu-K_α X-ray diffraction chart implies that the bulk phase is amorphous and, therefore, this physicochemical technique is not sufficient for analysing the nature of chemical bonds in this novel material. Since EXAFS spectroscopy requires structural order up to only a few Ångstrom around the target element, it can be a strong technique for structural studies, especially in a solid without periodic structure on the atomic scale. In this study we examine Ti K edge EXAFS spectra of mesoporous titania to clarify the local structure of Ti atom with emphasis on the static and thermal disorders of Ti-Ti bond.

2. Experimental

Mesoporous titania was prepared according to the literature [4] using hexadecylamine as a structural directing agent. The BET specific surface area was $1230\,m^2\,g^{-1}$ and a narrow mesopore size distribution peaking at 2.8 nm was obtained. X-ray absorption spectra of the Ti K edge were recorded on a BL-9A of the Photon Factory, High Energy Accelerator Research Organization, Tsukuba, Japan (Proposal #2002G269), with a ring energy of 2.5 GeV and a stored current of around 300–400 mA. A Si(111) double-crystal monochromator was used. The higher harmonics were removed by the total reflection on a Rh-Ni composite mirror and detuning the monochromator to 50%. The powder was diluted in boron nitride. A conventional transmission mode with detection using gas ion chambers was employed. The measurement of each spectrum was completed within 30 min. The drift of the monochromator between the measurements was 0.1 eV, which was estimated by the reproducibility of the edge position of Ti foil. This is comparable to the precision in the experiment [6] where a Si(111) double-crystal monochromator was also used and therefore the degree of drift does not cause any substantial errors in the following discussions.

EXAFS spectra were acquired five times under the same measuring conditions and from the extracted spectra, the average $\chi(k)$ was calculated. The EXAFS data were processed by a REX 2000 (Rigaku Co.) program assembly. The EXAFS oscillation is extracted by fitting a cubic spline function through the post edge region. After normalization using McMaster tables, the k^3-weighted EXAFS oscillation, $k^3\chi(k)$, in the 30–125 nm^{-1} region was Fourier transformed into a radial distribution function. The amplitudes and phase-shift functions for Ti-O and Ti-Ti bonds were calculated by FEFF 7.02 code. The amplitude reduction factor ($S_0{}^2$) was chosen to be 1 with a lifetime broadening (V_i) equal to 0.

3. Results and Discussion

The EXAFS spectra of the Ti K edge measured at 100 and 300 K are shown in Figure 1. Smaller amplitude and fewer oscillations are found in EXAFS of mesoporous titania than of anatase. As the measuring temperature of mesoporous titania rises, the oscillation in the high k region ($>9\,Å^{-1}$) smeared out and the amplitude in the low k region ($<4\,Å^{-1}$) decreased. These temperature dependent changes suggest large thermal vibration of the chemical bonds in the solid. Figure 2 shows Fourier transforms of EXAFS functions over 3–12.5 $Å^{-1}$. The peaks at 1.6, 2.7 and 3.4 Å in the FT of anatase are attributed to Ti-O, Ti-Ti and Ti-Ti bonds, respectively. The intensities of these peaks are reduced in

mesoporous titania. A small peak due to Ti-Ti bond appears in the spectrum measured at 100 K while it is hardly observed when the temperature is 300 K. The third peak around 3.4 Å almost disappeared at all temperatures. We filtered the peaks in radial distribution functions by the window between 0.7 and 3.1 Å and, after inverse Fourier transformation, the data were fitted with theoretical functions over 4–12 Å^{-1} in k-space. The best fitting results are summarized in Table I and Figure 3. The distances of Ti-O and Ti-Ti in mesoporous titania are shorter than those of anatase. This is apparently contradictory to the large thermal disorder observed in Figures 1 and 2. This can be reasonably explained by the anharmonicity of the pair distribution function that is not negligible in determining the structural parameters as have been reported in an oxide [7]. When the cumulant expansion technique was applied to these spectra, the bond lengths became larger than those in anatase: r(Ti-O) = 1.99–2.00 and r(Ti-Ti) = 3.04–3.09 Å.

Since σ for Ti-Ti bond is represented by $\sigma^2 = {\sigma_0}^2 + \sigma(T)^2$, where σ_0 is a disorder term due to static disorder independent of the temperature and $\sigma(T)$ is the temperature dependent term, and the latter term is correlated with the Debye temperature, σ^2 for Ti-Ti bond was plotted as a function of temperature in Figure 4. Since mesoporous titania is mostly composed of surface atoms, the Debye temperature can be more simply determined than in the formulations depending on the lattice. It has been claimed that the effective Debye temperature of a surface layer can be evaluated by emitting electron probes, e.g. low energy electron diffraction, X-ray photoelectron spectroscopy, valence band photoemission, and inverse photoemission [8, 9]. The intensity of the emerging photoelectron beam depends

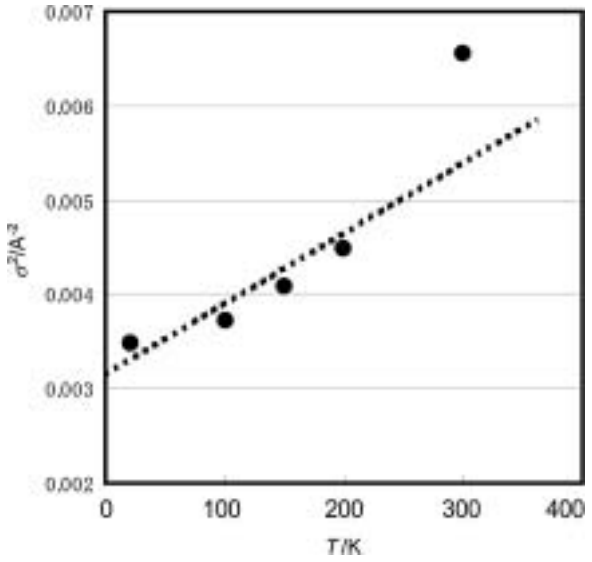

Fig. 4. Temperature dependence of Debye-Waller factors for Ti-Ti bond in mesoporous titania.

exponentially on the substrate temperature. The disorder factor in the index is inversely proportional to the Debye temperature squared. The large surface area allows us to apply this formulation to σ^2 for mesoporous titania. The Debye temperature thus deduced is 365 K, for mesoporous titania. This is significantly lower than the bulk titania crystals, 520 [10] and 530 K [11] for anatase and rutile, respectively. To the best of our knowledge, the Debye temperature of TiO_2 single crystal surface has not been reported. $\Theta_D(\text{surface})/\Theta_D(\text{bulk}) = 0.70$ will be smaller than the ratio in single crystal surface such as rutile(110), because both sides of the mesoporous wall are exposed while one side of the surface atomic layer in a single crystal is bound to the bulk lattice.

Abstract

Determination of structures using X-ray powder diffraction is complicated if the reflection intensities are mainly influenced by the scattering from heavy atoms and the atomic coordinates of light atoms remain uncertain. A method like EXAFS, which is sensitive to short range order, gives reliable atomic distances in the surroundings of heavy atoms with a precision of ±0.02 Å. The probability for obtaining the complete structure from X-ray powder diffraction increases if one includes parameters derived from EXAFS measurements as restraints during the procedure of structure solving. We demonstrate the potential of combining EXAFS and X-ray powder diffraction by solving the structure $UO_2[H_2AsO_4]_2{\cdot}H_2O$. The procedure starts with the determination of space group and cell parameters from XRD powder data. In a second step the absolute values of the structure factor |F| are separated by iterating a decomposition formula. The heavy atom positions are determined by direct methods. In the third step atomic distances of coordination polyhedra are estimated using EXAFS. Subsequently, the complete coordination geometries around the heavy atoms including reliable distances are used as restraints in the structure solving and refinement procedure.

1. Introduction

In crystal structures containing heavy atoms, the X-ray scattering process is only weakly influenced by light atoms, whereas the contribution of heavy atoms dominates. A determination of heavy-atom coordinates in the unit cell using X-ray powder diffraction is possible but sometimes it is difficult to locate the light atoms. This can happen under certain circumstances also for single crystal structures. On the other hand, a short-range order method like EXAFS gives reliable atomic distances in the surroundings of heavy atoms also in solid state and allows the characterisation of the coordination polyhedra more accurately. The advantage of EXAFS for determining heavy-atom structures was demonstrated in a recent study of $Cu[UO_2AsO_4]_2{\cdot}12H_2O$ and $Cu[UO_2AsO_4]_2{\cdot}8H_2O$ [1]. Furthermore, studies of local structural ordering effects are possible by including EXAFS measurements. This was demonstrated by the simultaneous refinement of EXAFS and XRD data [2] that were used to determine the structure of $Gd_2Ba_2CaCu_2Ti_3O_{14}$ [3], where neither of the heavy-element sites was accurately described by the long-range structural model.

However, the structure of coordination polyhedra is not completely independent and can be understood as a rigid unit. The introduction of molecule sequences or coordination polyhedra as rigid bodies in the powder diffraction refinement improves the probability to solve the structure [4] because the number of refinable parameters can be drastically reduced. In the case of X-ray powder pattern this is particularly useful since the ratio of reflection intensities to refinable parameters is typically low. In this paper a new procedure will be used to generate coordination polyhedra by obtaining experimental values from EXAFS. Including the information from EXAFS as restraints in the structure solving procedure and refinement, the probability increases to obtain the complete structure from powder diffraction data. The procedure is demonstrated using $UO_2[H_2AsO_4]_2{\cdot}H_2O$, which has a known crystal structure [5], as an example. For this example uranium and arsenic serve as heavy-atom framework whose coordinates will be analyzed by X-ray powder diffraction and serve as absorbing elements for U L_{III} and As K edge EXAFS measurements.

2. Experimental

EXAFS measurements were carried out on the Rossendorf Beamline (ROBL) [6] at the European Synchrotron Radiation Facility (ESRF) under dedicated ring conditions (6.0 GeV, 100–200 mA). X-ray powder diffraction measurements were performed twice, at a conventional X-ray source, and at ROBL. The monochromator of ROBL, which is equipped with a water-cooled Si(111) double-crystal system, was used in channel-cut measuring mode. Higher harmonics were rejected by two Pt coated mirrors. Energy steps in the EXAFS spectra were calculated giving corresponding k-space steps of 0.05 $Å^{-1}$. For EXAFS measurements the powder was mixed with boron nitride and pressed as pellet with a diameter of 13 mm. The amount of uranium used was calculated to give a jump of one in the ln(I0/I1) function across the uranium L_{III}-edge. The same sample was used for the measurements at the As K-edge. Uranium L_{III}-edge and arsenic K-edge EXAFS data were collected in transmission geometry using argon-filled ionization chambers. A closed-cycle He cryostat was used to analyze larger atomic distances by reducing thermal oscillations. First inflection points at the Y K-edge at 17038 eV and at the Au L_{III}-edge at 11919.7 eV were used for energy calibration of EXAFS spectra. The energy in the X-ray diffraction measurements were calibrated using silicon powder. EXAFS data were extracted from the raw absorption spectra by standard methods using the computer program EXAFSPAK [7]. Scattering phase and amplitude functions were calculated using FEFF 8 [8]. The X-ray diffraction data were analyzed using the programs PowderCell [9], CRYSFIRE [10] and SHELX-97 [11].

3. Results and discussion

The X-ray diffraction measurements with conventional Cu Kα radiation were performed in Bragg-Brentano geometry in order to obtain a high scattering intensity. The sample for diffraction measurements at the synchrotron was prepared in a quartz glass capillary with a diameter of 0.3 mm and measured by

*email hennig@esrf.fr

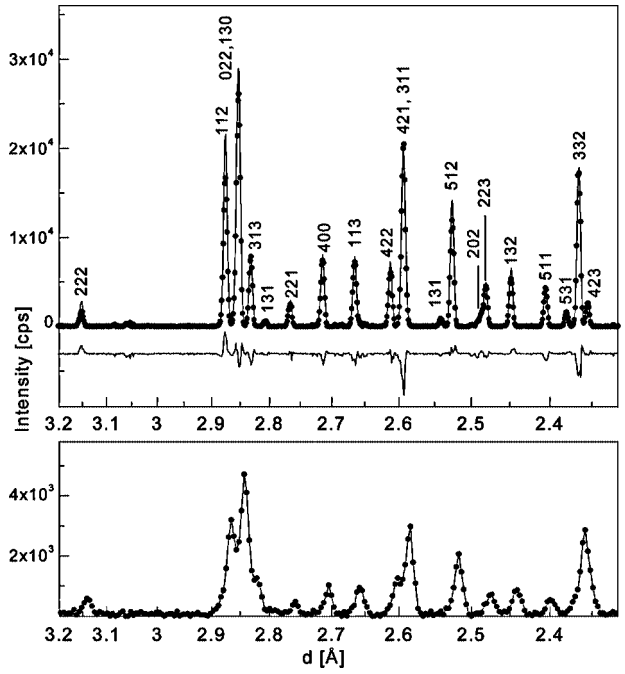

Fig. 1. Detail of X-ray powder diffraction pattern on $UO_2[H_2AsO_4]_2{\cdot}H_2O$, data obtained with Cu Kα radiation (bottom) and synchrotron radiation (top).

sample rotation in Debye-Scherrer geometry. The preparation in a capillary and the rotation reduce crystallite orientation effects. In Fig. 1 the diffraction patterns are given. For comparison the data are shown in *d*-space. A high angle resolution was achieved with the X-ray powder diffraction measurement at ROBL. The synchrotron based data show a Gaussian profile shape whereas the peak shape of the sample measured with the Cu Kα radiation was approximated with a Pseudo-Voigt profile.

The proposed procedure starts with the determination of space group and cell parameters from peak positions. The peak positions, separated from powder diffraction data, were analyzed using the program CRYSFIRE. In a second step, the individual intensities are extracted from powder pattern using the program PowderCell. The profile fitting procedure in this program does not need any structural model. It refines the cell parameters to be consistent with the angular position of the reflections according the Le Bail algorithm [12]. During each iteration step the lattice constants were refined according the chosen intensity distribution. Details of data collection and fit parameters obtained after final profile refinement are given in Tab. I.

Preliminary heavy-atom positions were found by direct methods using the intensities obtained by the first decomposition step of the X-ray powder pattern. In the third step, the coordination polyhedra and their connections were determined using EXAFS.

Fig. 2 depicts the As K-edge k^3-weighted EXAFS spectra of $UO_2[H_2AsO_4]_2{\cdot}H_2O$. The corresponding fit results are presented in Tab. II. The measurement at room temperature (298 K) shows that As is surrounded by four oxygen atoms at an average distance of 1.68 Å indicating an $[AsO_4]$ tetrahedron. In order to reduce the thermal atomic movements, the same sample was measured at 15 K. This measurement shows that each $[AsO_4]$ tetrahedron is surrounded by two uranium atoms at a distance of 3.71 Å. The bond length points to a monodentate connection between the arsenate and the uranyl polyhedra. Corresponding to the $[H_2AsO_4]$ sequence of the chemical formula, two of the oxygen atoms are protonated.

EXAFS measurements of $UO_2[H_2AsO_4]_2{\cdot}H_2O$ at the U L_{III}-edge are shown in Fig. 3. The fit results are given in Tab. III. Two axial oxygen atoms (O_{ax}) are at a distance of 1.77 Å and five

[a]Errors in distances R are ±0.02 Å, [b]errors in coordination numbers N are ±25 % with standard deviations in parentheses, *this value is influenced by the U-As shell at 5.45 Å.

equatorial oxygen atoms (O_{eq}) are detected at an average distance of 2.38 Å. The high Debye-Waller factor of 0.0068 Å^2 indicates that the equatorial oxygen atoms are not symmetry-equivalent. Taking into consideration that the errors in coordination numbers of distant shells are reduced at low temperatures, the uranium atom is coordinated by four As atoms via oxygen atoms. The EXAFS data show clearly that uranium is coordinated by 5 oxygen atoms in the equatorial shell. The fifth equatorial oxygen atom belongs to a H_2O molecule given in the chemical formula.

The position of light atoms in the unit cell are determined by including the EXAFS results as help for the interpretation of the first difference Fourier synthesis. Subsequently, average bond lengths of coordination polyhedra [$UO_{ax2}O_{eq5}$] and [AsO_4] obtained by EXAFS were used as restraints in the first cycles of structure solving. The polyhedron geometry was assumed as regular [AsO_4] tetrahedron and equal angle distribution in the equatorial shell of [$UO_{ax2}O_{eq5}$]. The structure was refined by cycles of powder pattern decompositions using the actual structural parameters and SHELXL-97 calculations (Tab. IV, Fig. 4). The structure refinement in the final step needed also the restraints from EXAFS, strong restraints for conventional powder diffraction data, and a reduced number of restraints for synchrotron data. Without any restraints the refinement procedure was unstable. The refinement converged with R1(on F) of 0.082 and 0.071 for 124 peaks of the conventional X-ray source and 401 reflections of the synchrotron, respectively.

Abstract

Dilute nitrides, in particular $In_xGa_{1-x}As_{1-y}N_y$ are very interesting alloys because of their actual and potential applications in the field of telecommunications and photovoltaics. A full knowledge of the local structure around each kind of atom, in particular the local ordering, is of fundamental importance because it is predicted to affect the electronics properties of these alloys. In this work we investigated the local environment of N and In by X-Ray absorption Fine Structure (XAFS). By exploiting the polarization dependency of XAFS we were able to demonstrate that N is fully substitutional to As. The lineshapes of the N K-edge XANES spectra are in fact identical, setting different grazing angles, which is a fingerprint of the cubic geometry of the N site. This information has been exploited to generate atomic clusters that very well simulate the experimental N K-edge XANES in the Full Multiple Scattering approach and to elaborate a multi-shell fit for XAFS data at the In K-edge. We concluded that N preferentially links In atoms, even if this short range ordering is by far weaker than the predicted one.

1. Introduction

In 1996 it was discovered that the substitution of a small fraction of As with N in $In_xGa_{1-x}As$ epitaxially grown on GaAs causes a giant reduction in the band gap of the alloy [1]. This effect, previously observed in GaAs:N since 1992 [2], became rapidly an object of theoretical studies addressed to understand its physics. The possibility to red-shift the band gap of $In_xGa_{1-x}As$ down to less than 1.0 eV is extremely important because these very long wavelengths are optimal for realizing modern Vertical Cavity Surface Emitting Lasers (VCSELs) employed in fibre optic communication; moreover the growth of InGaAsN on GaAs is quite simple and cheap. The light N atoms act as strain moderators, and permit to reach the required wavelengths limiting at the same time the indium content in the epilayers, which would otherwise relax because of the great difference in the lattice parameter between high In-content $In_xGa_{1-x}As$ and the GaAs substrate. Relaxation limits the performances of $In_xGa_{1-x}As_{1-y}N_y$-based optoelectronic and photovoltaic devices. Recently, a preferential In-N bonding has been predicted [3] for these alloys and some experimental reports have quantitatively confirmed this general trend measuring in hydrogenated [4] and annealed [5] $In_xGa_{1-x}As_{1-y}N_y$ a relative number of In-N bonds vs. In-As bonds greater than in a random alloy. Another recent experimental work qualitatively supports the hypothesis of the ordering induced by annealing [6]. Such an ordering has been predicted to inhibit the red shift of the band gap, resulting in severe material properties limitation. Blue shift has already been observed in annealed (nearer to equilibrium condition) samples [7], even if a conclusive demonstration of the parallelism between optical effects and structural ordering does not exist at present in literature. X-Ray Absorption Fine Structure is the ideal tool to address the issue of short range ordering (SRO). In order to build a simple structural model to fit EXAFS data, some preliminary information is of significant importance; first of all we have to know if N substitutes As atoms or if it precipitates forming other compounds, in the latter case we have to determine the substitutional fraction and the geometry of the N site in the precipitates. Finally we have to take into account the possibility for N atoms to occupy an interstitial site, forming As-N and N-N split interstitials as proposed by Li *et al*. [8].

Information on the geometry of the N sites can be obtained by exploiting the polarization dependence of the XAFS signal [9]:

$$\chi(k) = -3\frac{(\hat{\epsilon}\cdot\widehat{r_1})^2}{kr_1^2}\mathrm{Im}[e^{2ikr_1+2i\delta_1^1}f(k,\pi)]. \quad (1)$$

In this equation we underline the contribution to the EXAFS signal of a single neighbor located at distance r_1 relative to the absorber. $\hat{\epsilon}$ is the polarization direction of the X-rays, $\widehat{r_1}$ = unity vector in the absorber-scattered direction, k = photoelectron wave vector, $f(k,\pi)$ = backscattering amplitude, δ_1^1 = central atom phase shift. Turning the sample it is possible to set different angles between a definite crystallographic direction and the electric field of linearly polarized synchrotron radiation. Since cubic symmetry is isotropic from the standpoint of electron charge density, polarization dependence of N K-edge XANES should be absent in case of pure substitutional N, otherwise it should be significant in case of formation of hexagonal precipitates like GaN. In this paper we demonstrate that in our samples N is fully substitutional to As and how this information can be exploited to very well simulate N K-edge XANES in the full multiple scattering approach and to elaborate a robust multi-shell fit for XAFS data at the In K-edge.

2. Experimental

Two series of 140 nm thick $In_xGa_{1-x}As_{1-y}N_y$ epilayers were specifically grown by gas-source molecular beam epitaxy on (001) GaAs substrate in order to highlight the effects or SRO on the XAS data. The In and N concentration is in fact similar ($x \approx 0.04$, $y \approx 0.02$ in the first series and ≈ 0.03 in the second series), so the expected relative In-N coordination should be very high in the case of maximum In-N + Ga-As ordering (about 50% for series I and 90% for series II). Growth temperature was in the range 400–430 °C, thermal annealing was performed at 700 °C,

*ciatto@esrf.fr

for different times (90 and 300 s) [10]. Indium concentration was determined by Rutherford Backscattering Spectrometry, nitrogen concentration by combining (004) High Resolution X-Ray Diffraction (HRXRD) and Nuclear Reaction Analysis (NRA) measurements.

In K-edge measurements were performed at the European Synchrotron Radiation Facility in Grenoble (BM8, Gilda CRG beamline), exploiting a sagittally focusing monochromator equipped with Si [311] crystals, run in the dynamical mode [11]. The In K_α fluorescence signal was monitored using a thirteen-element hyper pure Ge detector. N K-edge measurements were performed at the BESSY II facility in Berlin (U49/2-PGM2, Cottbus beamline). Also in this case fluorescence detection was used in order to guarantee bulk sensitivity, using a window-less single element hyper pure germanium detector.

3. XAS Data Analysis

EXAFS oscillations at the In edge were extracted from the raw data with the AUTOBK code [12]: the pre-edge region was fitted with a linear function while the atomic background was interpolated by a cubic spline with 15 knots. Data analysis was performed by *ab-initio* modeling of the XAFS signal using the FEFF 8.00 code [13]. The theoretical signals were calculated using InGaAs and InN model clusters. Quantitative analysis was performed in the range $k = 3.0 \div 13.4\,\text{Å}^{-1}$ and $R = 1.6 \div 4.8\,\text{Å}$ (R values not corrected for the phase shift). The FEFFIT program [14] was used to extract the structural parameters: relative In-N coordination (and, as a consequence, In-As coordination), bond lengths and Debye-Waller factors.

N K-edge XANES spectra were simulated *ab-initio* in the real space full multiple scattering approach using self consistency for the potential; The FEFF 8.00 code, modified in order to treat large clusters, was exploited to perform the simulations. The cluster for simulating $GaAs_{1-y}N_y$ was generated by substituting an N impurity to the central As in a GaAs structure (GaAs:N) and relaxing the first and second shell distances through minimization of a valence force field potential [15] with appropriate force constants [16]. The same procedure was adopted for a N impurity in InAs. In order to simulate the quaternary alloys with different. In contents we exploited linear combinations of the simulated XANES spectra for GaAs:N and InAs:N.

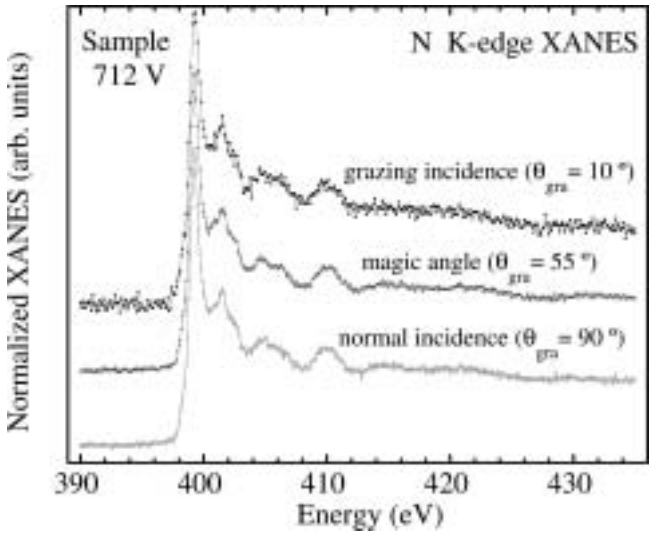

Fig. 1. N K-edge XANES taken on $In_{0.038}Ga_{0.962}As_{0.9665}N_{0.0335}$ for different grazing angles.

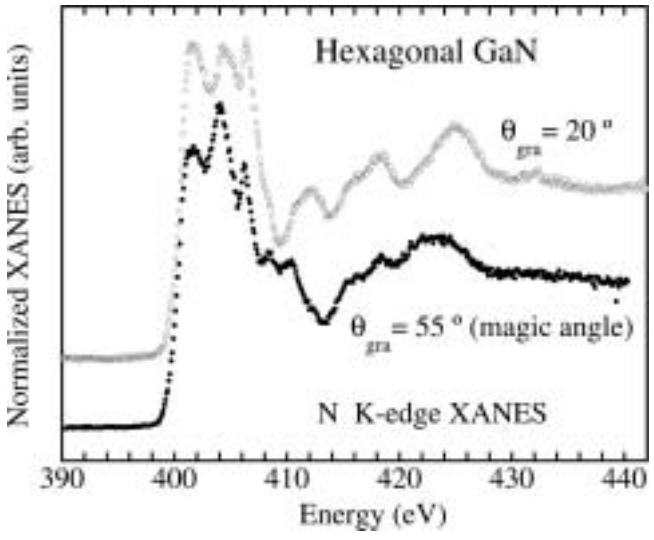

Fig. 2. N K-edge XANES of an hexagonal GaN standard for different grazing angles.

4. Substitutional Character of Nitrogen

In fig. 1 we report three N K-edge XANES spectra for sample 712 V ($In_{0.038}Ga_{0.962}As_{0.9665}N_{0.0335}$) taken with different incidence angles. The grazing angle (θ_{gra}) was respectively fixed to 10° (nearly grazing incidence), 55° and 90° (normal incidence). Straightforwardly θ_{gra} is also the angle between the electric field and the normal to the sample surface (in our case the [001] crystallographic direction referred to the substrate). In an hexagonal system $\theta_{gra} = 54.73°$ is the angle for which directional effects are like averaged, due to a cancellation in the expression of the squared cosine of the angle between the electric field vector and the direction of maximum electron charge density (δ), which enters the formulation for the absorption cross section [17], [18].

$$\cos^2\delta = \tfrac{1}{3} + \tfrac{1}{8}(1 + 3\cos 2\alpha)(\cos 2\theta_{gra} + \tfrac{1}{3}). \quad (2)$$

In this equation α is the angle between the direction of maximum electron density and the normal to the surface, for $\theta_{gra} = 54.73°$ the term in the last parenthesis becomes zero so that $\cos^2\delta$ and, as a consequence, the absorption cross section does not depend on α.

The three spectra in fig. 1 are virtually identical, evidencing there is no polarization dependence of N K-edge XANES: this is a fingerprint of the cubic symmetry of the structure. For a non-isotropic symmetry group (as the hexagonal) significant variations in the relative intensity of the XANES resonances would be otherwise observable; this is evident in fig. 2 where two N K-edge XANES spectra for an hexagonal GaN standard sample, respectively taken at $\theta_{gra} = 20°$ and $\theta_{gra} = 55°$, are reported. As concerns a possible different N location in the lattice, N complexes such as N-N and N-As split interstitials would give sharp resonances in the pre-edge region of the XANES, which are not observed in our case. The substitutional character of nitrogen is confirmed by comparing random and channelling NRA spectra, the latter obtaind aligning the deuterium beam used as probe along a definite crystallographic plane. The N substitutional fraction estimated by this technique is close to 100% for all samples, independent on the annealing [19].

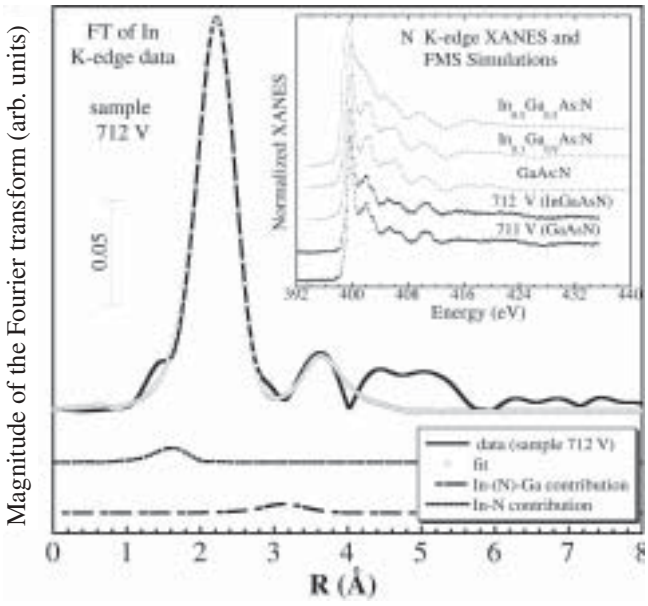

Fig. 3. Fit on the Fourier transform of the In K-edge EXAFS for sample 712 V with the relative N-related paths contributions (at the bottom); in the inset experimental XANES (the two bold lines at the bottom) and FMS simulations for x = 0%, 10%, 50%.

5. The Short Range Ordering

The knowledge of the kind of site occupied by N atoms in the alloy allows us to use the substitutional impurity model cited above for generating clusters employed in the FMS simulations of N K-edge XANES. The excellent results obtained, reported in the inset of fig. 3, proof the reliability of the model. At the bottom of the inset we reported the experimental XANES of the ternary sample 711 V ($GaAs_{0.9696}N_{0.0304}$) together with that of the quaternary 712 V. The two spectra are virtually identical and very well simulated starting by a simple GaAs:N "impurity" cluster (third line moving towards the top of the inset). This suggests that, if present, the N-In preferential bonding is quite weak. If it was stronger, according to the predictions based on Monte Carlo calculations [3], that would result in a very different lineshape, closer to the fifth line of the inset of fig. 3, which reports a simulation for an alloy where the indium content is 50%. On the other hand, 10% of indium in the alloy (fourth line) is not sufficient to sensibly modify the simulations i.e. we can neither exclude nor demonstrate the occurrence of weak ordering starting by the only N K-edge XANES. Fits of EXAFS spectra at the indium edge provide us with a quantification of the In-N preferential bonding. Having acquired knowledge of the substitutional character of nitrogen, we could use a single variable y_{In-N} in order to estimate the probability of an In nearest neighbor site to be occupied by a N atom ($1 - y_{In-N}$ for As). This variable allowed to easily model at the same time the second shell, where Ga atoms (the low In content made us unsensitive to the In-In coordination) were divided into those coordinated via a first shell As and the those coordinated via a first shell N. y_{In-N} weights the relative amplitude of the two subshells, situated at different distances from the absorber. In fig. 3 we report a fit on the Fourier Transform for sample 712 V, underling the contribution of first and second shell N-related paths (bottom). Details of this analysis and systematic discussion of the results achieved on all the samples at the indium edge have been object of a recent work [5]. We remind here of our conclusive finding: in annealed samples ordering has the same sign as predicted (In-N preferred to In-As) and the probability for an N atom to occupy an In-first neighbor site is up to three times the random one. Nevertheless our measured SRO parameters are about an order of magnitude smaller than those calculated via Monte Carlo simulations [3]. As grown samples, on the other hand, are virtually random alloys due to their far from equilibrium condition.

6. Conclusions

We addressed in this paper the issue of short range ordering (SRO) in $In_xGa_{1-x}As_{1-y}N_y$, a diluted nitride of great technological interest. We concentrated particularly on demonstrating how N is totally substitutional to As (i.e. cubic symmetry of the structure) by means of crossed N K-edge XANES, exploiting the linear polarization of synchrotron radiation, and NRA-channelling measurements. Holding this information we could elaborate simple model clusters to simulate N K-edge XANES and to fit In K-edge EXAFS data. The latter allowed us to give a quantitative estimation of SRO which, in annealed samples, holds the same sign as in predictions (preferential In-N vs. In-As bonding) but is about one order of magnitude weaker.

Abstract

The Ti K-edge EXAFS for $PbTiO_3$ measured in the temperature range including the critical temperature (763 K) due to the phase transition from tetragonal to cubic phase is discussed from the local point of view. Three kinds of atomic pairs, shorter Ti-O(1), medium Ti-O(2) and longer Ti-O(3) were analyzed independently. The interatomic distance of Ti-O(3) changes at T_c discontinuously and shows a "displacive" type transition. On the other hand, EXAFS shows that the lattice distortion remains even in cubic phase, which indicates "order-disorder" type transition. The peak intensity at the pre-edge region in XANES, which indicates the distortion of Ti atoms along the *c*-axis of the oxygen octahedron, corresponds to the distortion obtained from EXAFS analysis.

1. Introduction

X-ray absorption fine structure (XAFS) has become a technique to study local structures as a complementary technique to diffraction methods which are based on long-range order [1]. $PbTiO_3$ has long been considered as "displacive" type ferroelectrics: The perovskite $PbTiO_3$ shows tetragonal structure at $T < T_c$ (=763 K) (lattice parameters $a = b = 3.89$ Å and $c = 4.15$ Å at 300 K [2]) and cubic structure at $T > T_c$ ($a = b = c = 3.905$ Å at 773 K). On the other hand, if the local distortion does not change with temperature across T_c the transition is "order-disorder" type. In this case, only the orientations of the distortion within a small domain change with temperature; the orientation is arranged along the preferable direction below T_c, but it is disordered above T_c.

The local structural change of $PbTiO_3$ has been extensively studied by Sicron *et al*. using XAFS of both Pb L_{III} and Ti K-edges [3, 4]. These results show that an essential element of "order-disorder" is present even in this normally pure ferroelectric crystal, which displays a soft mode and a dielectric constant of typical "displacive" type ferroelectrics. Recently, a more detailed study by Pb L_{III} edge EXAFS for $PbTiO_3$ has been carried out [5] where three kinds of atomic pairs Pb-O(1,2,3) are analyzed independently. Shorter atomic pairs of Pb-O(1,2) show "order-disorder" type behavior, on the other hand, the longest Pb-O(3) shows "soft mode" behavior [5].

In this paper, we study the local structural change around Ti atoms in $PbTiO_3$ crystal through T_c in more detail. Actually, there exist three types of Ti-O pairs by tetragonal distortion; longer and shorter interatomic distances along the *c*-axis and a medium Ti-O pairs perpendicular to the *c*-axis. Our results show that the local distortion remains above T_c in which $PbTiO_3$ shows cubic phase.

2. Experimental and Data Analyses

The powder sample of $PbTiO_3$ (99.99%) was purchased from Soeakwa Co. Ltd. and was checked by X-ray powder diffraction to assure its crystal structure. The powder was mixed with BN and was dry pressed for producing a pellet that could be easily handled and placed within the furnace. X-ray absorption spectra of Ti K-edge (4.95 keV) were measured at BL9A of Photon Factory (KEK) in transmission mode. A Si(111) double crystal monochrometer was used. The temperature range for measurement was from 300 K to 923 K.

The EXAFS analysis was performed according to XANADU code [6] and it is given only briefly here. The normalized EXAFS interference function, $\chi(k)$, was multiplied by a Hamming window function to reduce the ripples in the Fourier-transformed spectra in *r*-space. The *k*-range for the Fourier transform was from 2.95 to 8.8 $Å^{-1}$.

3. Results and Discussion

We discuss here the result for Ti K-edge XAFS. Figure 1 shows the EXAFS oscillation functions, $k^2\chi(k)$, of Ti K EXAFS for $PbTiO_3$ crystal at various temperatures obtained by transmission measurement. Although the signal in the transmitted ionization chamber is not so large due to the absorption by Pb atoms, satisfactory data quality has been obtained up to 8.5 $Å^{-1}$ for EXAFS analyses even at high temperatures. As the temperature increases the amplitude of the EXAFS function decreases gradually. Figure 2 shows the Fourier transforms of Ti K EXAFS for $PbTiO_3$ crystals at various temperatures as shown in Fig. 1. The peak intensity decreases as temperature increases and change of the fine structure is observed. The atoms are distorted along the *c*-axis at tetragonal phase: There are three kinds of Ti-O atomic pairs; shorter Ti-O(1), medium Ti-O(2) and longer Ti-O(3) as shown in Fig. 3. The peaks from 1 to 2 Å include three Ti-O pairs. In the case of Ti K-edge we tried to perform 3 shell-fitting in order to obtain the structural parameters and reasonable results were obtained. Our unknown parameters for the fitting are *r* and σ^2 for each shell and the total number of them is 6.

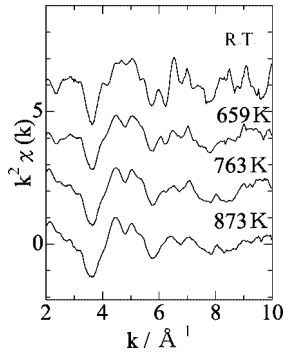

Fig. 1. EXAFS oscillation functions, $k^2\chi(k)$, of Ti K-edge EXAFS for $PbTiO_3$ crystal at various temperatures.

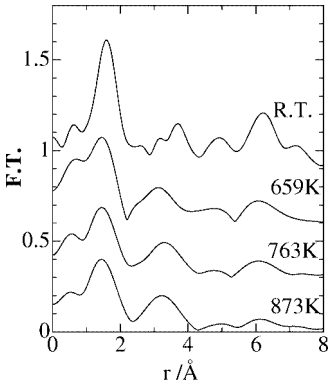

Fig. 2. Fourier transforms of Ti K-edge EXAFS for $PbTiO_3$ crystals at various temperatures as shown in Fig. 1.

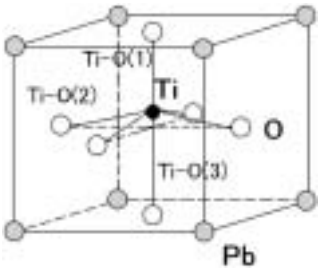

Fig. 3. Schematic structure of $PbTiO_3$ in the tetragonal phase. The central atom is Ti (Black circles), white circles represent O atoms and gray circles represent Pb atoms.

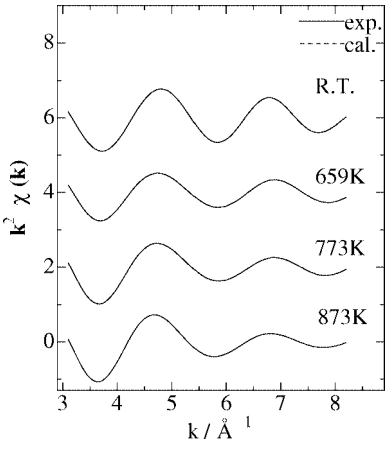

Fig. 4. Example of the quality for 3-shell fitting in the present study at various temperatures.

Figure 4 shows an example of the quality of 3-shell fitting in the present study at various temperatures. The fitting results reproduce the experimental spectra well. Figure 5 shows the contributions of each shell as a function of r which is obtained from the theoretical fitting for the Ti K-edge of $PbTiO_3$. Figure 6 shows the variations of three kinds of Ti-O interatomic distances with temperature. We also easily find the tetragonal distortion below T_c as shown in Pb L_{III}-edge EXAFS [5]. For example in the tetragonal phase at 300 K, the distance for Ti-O(1) is about 1.8 Å, that for Ti-O(2) is about 2.0 Å and that for Ti-O(3) is 2.4 Å. From these values we can estimate the distortion of Ti atoms with O atoms in the tetragonal phase. The distortion of Ti atoms from O atoms for c-axis is about 0.35 Å at 300 K for the tetragonal phase, which is the same value as that obtained by Sicron *et al.* [3, 4].

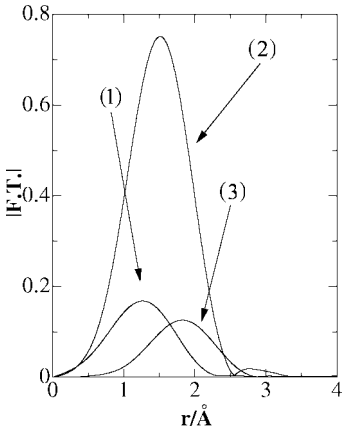

Fig. 5. The contributions of each shell in Ti K-edge fitting for $PbTiO_3$ as a function of r at 300 K.

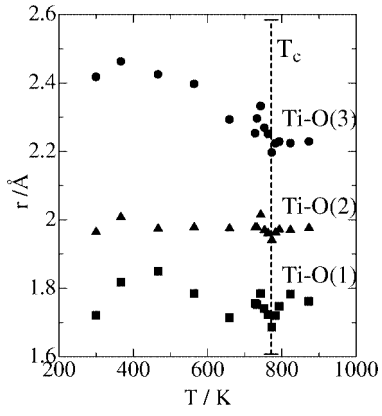

Fig. 6. Variations of three kinds of Ti-O interatomic distances with temperature.

The interatomic distance of Ti-O(2) is almost constant in the whole temperature range including T_c. That of Ti-O(3) decreases as temperature increases up to T_c and does not change with temperature at $T > T_c$. As for Ti-O(1), we find complex behavior between Ti-O(2) and Ti-O(3). That is: the longest Ti-O(3) shows typical "displacive" behavior and Ti distortion remains at temperatures above T_c. These phenomena are quite similar to the result of Pb-O obtained from Pb L_{III}-edge EXAFS study [5]. At $T > T_c$, the interatomic distance for Ti-O(1) is 1.75 Å, that for Ti-O(2) is 2.0 Å, and that for Ti-O(3) is 2.25 Å. This difference in Ti-O distance shows that atomic distortion remains at the cubic phase.

Figure 7 shows X-ray absorption near edge structure (XANES) of Ti K-edge for $PbTiO_3$ at various temperatures. We can find two clear peaks (A and B) before the edge. The origins of these two peaks are assigned to the transition from 1s to $3d_{xy}$ and $3d_z^2$ from the symmetry of the orbital, respectively. Although these transitions are forbidden generally in the dipole approximation, they are allowed by mixing with oxygen p-state orbitals due to the distortion of Ti atoms from the oxygen octahedron. That is the existence of these peaks indicates that Ti atoms are distorted.

Figure 8 shows the temperature variations of the intensity of peak A in Fig. 7 (solid circle). The peak intensity of A decreases gradually as the temperature increases up to T_c and decreases discontinuously at T_c and it is almost constant at $T > T_c$. The peak intensity of A ($= I_A$) is known to be approximately proportional to the amplitude to the Ti atom distortion as [7],

$$I_A = C\boldsymbol{e} \cdot d, \tag{1}$$

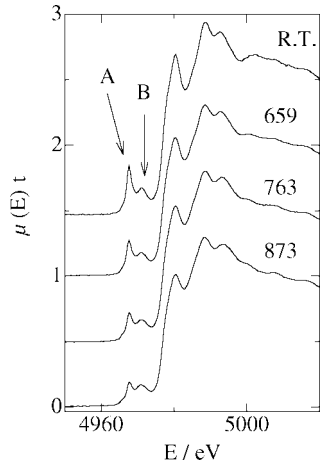

Fig. 7. X-ray absorption near edge (XANES) spectra of Ti K-edge for $PbTiO_3$ at various temperatures.

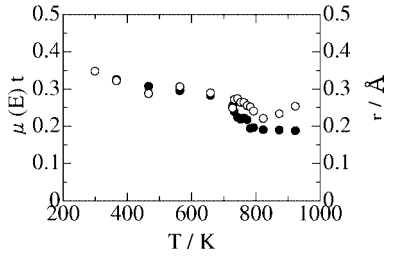

Fig. 8. Temperature variations of the intensity of peak A in XANES (Solid circle) and Ti atom distortion from the center of the oxygen octahedron (open circle).

where $\boldsymbol{e}$ and d are the unit vector in the direction of the electric field of incident X-rays and the distortion of a Ti atom from the center of an oxygen octahedron, respectively. C is a proportionality constant. The behavior in Fig. 8 indicates that the distortion of Ti atoms from O octahedron decreases as temperature increases and it remains finite at $T > T_c$. The values of the Ti atom distortion (d) along the c-axis with temperature evaluated from the present EXAFS by

$$d = (r_{\text{Ti-O(3)}} - r_{\text{Ti-O(1)}})/2 \quad (2)$$

are also presented (open circle) in Fig. 8. When we put the constant C to be 1.0, the curve of d vs T coincides approximately with that of I_A vs T at room temperature. d shows the same behavior as I_A and decreases as temperature increases up to T_c. As discussed previously 0.35 Å of d is the same as the value Sicron *et al*. reported [3, 4]. However they concluded that d is almost constant at the temperature range from low temperature to T_c and decreases slightly with 30% at $T > T_c$. On the other hand, our result shows clear decreasing of d in the ferroelectric phase ($T < T_c$).

4. Conclusion

We measured Ti K-edge EXAFS for $PbTiO_3$ in the temperature range including T_c. The structural changes were discussed from the viewpoint of short-range order. Three kinds of atomic pairs, shorter Ti-O(1), medium Ti-O(2) and longer Ti-O(3) were analyzed independently. The longest Ti-O(3) is discontinuously changed at the transition. The distortion of Ti atoms evaluated from EXAFS indicates that tetragonal distortion remains above T_c. The XANES study supports the temperature dependence the Ti distortion from EXAFS. The proposed solution may not be unique and further measurements, e.g. fluorescence mode for Ti K-edge XAFS, will hopefully confirm the obtained results.

Acknowledgements

The synchrotron radiation experiments were performed at Photon Factory in KEK under Proposal No. 2003G233.

Abstract

A series of mononuclear complexes with 1-phenyl-3-(2-phenylsulfanyl-phenyl-amino)-pent-2-en-1-one (**Ia**) and 1-phenyl-3-(2-phenylsulfanyl-phenylamino)-but-2-en-1-one (**Ib**) ligands, which mimics the active site of copper, cobalt and nickel proteins, have been synthesized and structurally characterized by EXAFS.

EXAFS analysis has shown that NiL_2 and CoL_2 complexes with $L =$ **Ia** are hexacoordinated by added Ni-S and Co-S bonds in contrast with square-planar NiL_2 (CoL_2) complexes with $L =$ **Ib**. The CuL_2 complexes with both $L =$ **Ia** and $L =$ **Ib** ligands have the CuN_2O_2 planar coordination.

1. Introduction

The diversity in the structures of active site of metalloproteins is reflected in many different functions that they perform. The functional properties of the metallic cores in a metalloproteins depend on the coordination geometry of metal, the number and the nature of coordination ligands. The structure of many metalloproteins has been elucidated from single crystal X-ray diffraction. Despite this fact, detailed understanding both the structural and functional properties of the metallic cores of many proteins is often limited. In recent years the synthesis of small-molecule complexes, structural and functional mimics of native metalloproteins has become an intensive area of research in chemistry. A numerous model compounds of mononuclear copper- and nickel-containing metalloenzymes, such as cytochrom oxidase, azurin, plastocyanin etc. have been synthesized and reported [1–3].

In this paper we report the synthesis and EXAFS study of novel copper, cobalt and nickel complexes as a models for the $MeN_2O_2(S_2)$ active site in metalloproteins.

2. Experiments and Data Analysis

2.1. *Preparation*

The ligands 1-phenyl-3-(2-phenylsulfanyl-phenylamino)-pent-2-en-1-one (**1a**, $R_1 = H$, $R_2 =$ Ph) $C_{21}H_{17}NOS$ and 1-phenyl-3-(2-phenylsulfanyl-phenylamino)-but-2-en-1-one (**1b**, $R_1 = CH_3$, $R_2 =$ Ph) $C_{22}H_{19}NOS$ were prepared according to the technique described in our previous works [4, 5]. The Cu, Ni and Co complexes **II** and **III** were synthesized as follows. The corresponding ligand and metal acetate were dissolved in methanol. The reaction mixture was stirred and boiled for 40 min. The solids formed were filtered and purified in methanol. The resulting product was recrystallized from toluene and dried.

2.2. *XAFS measurements*

The Cu, Co and Ni K-edge XAFS spectra were measured in transmission at the EXAFS-spectrometer of Synchrotron Radiation Siberian center with the storage ring, operating at an energy beam of GeV and a current of 80 mA. A Si (111) double-crystal monochromator determined X-ray energy. The intensities of both incident and transmitted X-ray beams were measured with ionization chambers filled with Ar gas. Samples were prepared as sandwich between two layers of Maylar film. The thickness of the samples was calculated in order to obtain an absorption jump at the edge $\Delta\mu x \cup 1.0$, where μ is "free" atom absorption, x is a thickness of a sample.

XAFS data analysis was carried out using a standard procedure. The EXAFS functions $\chi(k)$ were obtained from the X-ray absorption spectra by subtracting a Victoreen curve background removal, normalization on the height of the edge and reduction of the absorption data $\mu(E)$ to the EXAFS functions $\chi(k)$ where k is the photoelectron wavevector. The threshold energy E_0 was defined as the maximum of the first derivative of the absorption edge.

The Fourier transformations of EXAFS were performed in the k range 2.6–13.0 Å^{-1}. A Bessel window $w(k)$ with smoothness coefficient 2 and k^2 weighting were used. The structural models were built by a least-squares curve-fitting utilizing *ab initio* calculation for amplitude and phase of the scattering factors by means of FEFF7 [6]. The initial parameters for fit were obtained from crystallographic data of **II**(Ni) for Ni and Co complexes [5], and $Cu(OC(NH_2)(NHNH_2))_2Cl_2$ [7] for Cu-complexes. The fitting refined parameters were: E_0, R (the radii of coordination spheres (CS)), σ^2 (the Debay-Waller factor). Coordination numbers N were fixed. The quality of the fit was determined using a least-squares fitting parameter, Q, defined as:

$$Q(\%) = \frac{\sum[k\chi_{\exp}(k) - k\chi_{\text{th}}(k)]^2}{\sum[k\chi_{\exp}(k)]^2}.$$

3. Results and discussion

The Ni-complex **II** with **Ia** ligands differs from the Ni-complex with **Ib** ligands replacement of $R^1 =$ H by CH_3 (Figure 1). However such replacement leads to considerable difference of physic-chemical properties of these compounds. The Ni-complex **II** is brown and paramagnetic, while the Ni-complex **III** is green and diamagnetic. It indicates that the surroundings of Ni atoms in these complexes is essentially different.

The Fourier transforms (FT) of Ni K-edge EXAFS spectra of the Ni complexes are shown at Figure 2. For both complexes the first major peak at the FT corresponds to the Ni first CS from two nitrogen and two oxygen atoms. For the Ni-complex **II** the second prominent peak at $r = 2.05$ Å is attributed to two

coordinated sulfur atoms. The EXAFS function was calculated by FEFF7 using the atomic coordinates, which were taken from single crystal diffraction data for this compound [5]. A fit results are listed in Table I. The bond lengths obtained are in good agreement with the crystallographic data. The average value of the Ni-O/N bond lengths for this Ni complex **III** is lower than that for the complex **II** ($R = 1.88$ Å versus $R = 2.05$ Å). The absence of the sulfur atom coordination and such short Ni-O/N bond lengths point on a square-planar configuration of the **III**(Ni) complex. Figure 2 (Co K-edge) shows that FT of the Co complex is very similar to FT of **II**(Ni). Thus, local surroundings of these metal atoms are similar and Co complex has the square-planar structure **II** as well (results of the EXAFS analysis are shown in Table I).

In opposite to Ni and Co complexes, the FT of Cu-complexes with **Ia** and **Ib** ligands are close to each other (Figure 3). The FT of Cu complexes has a major peak, corresponding to four nitrogen and oxygen atoms of the first CS. The outer shells of the Cu complexes represented by the several small peaks can be simulated by four carbon atoms at 2.89–2.98 Å. The results of the

Abstract

The local environment and the charge state of Tm atoms in PbTe were studied by EXAFS and XANES techniques at the L_{III} absorption edge of Tm (8.648 keV). It was revealed that Tm atoms predominantly substitute for Pb atoms in PbTe and are surrounded by Te atoms at a distance of 2.99 ± 0.02 Å. Tm atoms were found to be in Tm^{3+} charge state independently of the section of the phase diagram used for Tm doping. These results are in agreement with the results of previous investigation of the Pb-Tm-Te phase diagram.

Electrical studies of PbTe(Tm) with large deviation from stoichiometry revealed that the electron concentration was about one order of magnitude lower than the total Tm concentration and remained nearly constant (about 10^{19} cm^{-3}) while varying the sample composition. Reduced electrical activity of the Tm impurity in PbTe was explained by effect of selfcompensation.

1. Introduction

Narrow-gap IV-VI semiconductors have attracted considerable attention due to their wide application in infrared (IR) optoelectronics. They are mainly used for production of photodiodes and photoresistors, as well as for lasers, working in middle and far IR regions. At the present time the development of new types of photodetectors is closely connected with utilizing of unusual impurity effects recently discovered in doped IV-VI semiconductors. The study of impurity states created by doping of these semiconductors with some of III-group elements [1], transition [2] and rare-earth metals [3], each of which can have several charge states, revealed unusual physical properties, such as the pinning of the Fermi level and giant IR photoconductivity. The appearance of these effects in PbTe(In) was attributed to the In^{+}-In^{3+} valence switching [4]. It should be noted, that if the doping impurities have magnetic moment, the doped semiconductor may exhibit interesting magnetic properties [2, 3].

It is well known that Tm atom in thulium chalcogenides can also exist in two charge states (Tm^{2+} and Tm^{3+}) or exhibit intermediate valence [5–9]. Thulium ion is divalent in bulk stoichiometric TmTe [9] and trivalent in bulk TmS [6], while in thin surface layer of TmS the Tm ion is divalent [6, 7]. The transition from Tm^{2+} to Tm^{3+} in bulk materials may be related to an increase of splitting of 5d states in a crystal field with the decrease of the lattice parameter, which results in disappearing of energy gap in the case of TmS. In Tm_2Te_3 [9] as well as in Tm_2O_3 [10] Tm atom is in trivalent state. It should be noted that the lattice parameter in TmTe is larger than in Tm_2Te_3, so the transition from Tm^{2+} state in TmTe to Tm^{3+} state in Tm_2Te_3 can be explained in a similar way. The pressure, temperature and component concentration are also the factors, which can affect the charge state of Tm in compounds and solid solutions [11]. The anion radius of Se^{2-} and the lattice parameter in TmSe have intermediate values between the corresponding data for TmS and TmTe and, therefore, the charge state of Tm in TmSe is difficult to predict from simple reasons. Based on experimental data, the authors of [8] came to a conclusion that Tm has a mixed valence in bulk TmSe.

As follows from all the above, thulium impurity in PbTe may have different valence, and so we decided to carry out direct measurements of the Tm charge state in Tm-doped PbTe and to compare the results with those obtained from electrical measurements on these solid solutions.

XAFS spectroscopy is known to be a powerful tool for studies of the charge state and local environment of rare-earth atoms with different valence in compounds and solid solutions. XAFS technique has two main advantages:

1) it can measure directly the ratio of number of ions in different charge states by analyzing the structure of the spectrum near the absorption edge;
2) it enables to obtain the instantaneous radial distribution function of the distances to neighbors of possibly unstable (in valence) ions from the analysis of EXAFS data.

Strong white lines at the absorption edge distinguish the L_{III} X-ray absorption spectra of the rare-earth metals. These lines arise from transitions from atomic $2p_{1/2}$ (L_{II}) and $2p_{3/2}$ (L_{III}) levels into partially filled large density d states. The shape and structure of these lines depend on the electron configuration and charge state of the atom. Therefore the study of these lines can give information on charge states, in particular, charge state of the Tm atom in PbTe. XANES and EXAFS techniques have been already used for investigation of the charge states and local environment of Tm atoms in all thulium monochalcogenides [12, 13] and some their solid solutions [10]. XAFS spectroscopy data confirmed that Tm is divalent in TmTe, Tm is trivalent in TmS, but in TmSe it exhibits an intermediate valence state in the bulk and the divalent state at surface [10, 12]. The value of bulk mean valence in TmSe was shown to be sensitive to the stoichiometry of samples.

To our knowledge, there are only few published XAFS data on the charge state of the Tm impurity in other crystals, besides monochalcogenides. Detailed results on ZnS(Tm) [14] and $CaSO_4$(Tm) [15] are only available. Although lead chalcogenides have received particular attention, the systematic study of the impurity charge states in them by X-ray absorption was not undertaken yet.

In this paper we present new results on EXAFS, XANES and electrical studies of Tm-doped PbTe.

2. Samples and experimental

All measurements were carried out on polycrystalline samples and single crystals of PbTe(Tm).

XANES measurements on PbTe(Tm) were performed on single crystals grown by Bridgman method along the PbTe-TmTe and PbTe-Tm_2Te_3 sections of the phase diagram and on polycrystalline samples of TmTe, Tm_2Te_3 and Tm_2O_3. The concentrations of thulium in PbTe(Tm) were 0.85 and 3.0 at.%, correspondingly. The samples were synthesized from binary compounds PbTe, TmTe or Tm_2Te_3 in evacuated quartz ampoules. Before XANES measurements the crystals were powdered in argon atmosphere and placed into a special argon-filled camera. Argon atmosphere prevented the oxidation of samples, the manifastation of which was detected in our previous EXAFS study of Tm-doped PbTe samples. All single crystals of PbTe(Tm) had the NaCl crystal structure, while Tm chalcogenides had either the NaCl structure (for TmTe) or the NaCl-based superstructure (defect NaCl structure with Tm vacancies of the Sc_2S_3 type for Tm_2Te_3) at 300 K. Oxide Tm_2O_3 had the Mn_2O_3 structure at 300 K.

EXAFS measurements on PbTe(Tm) were performed on the samples grown by Bridgman method along the PbTe-TmTe sections of the phase diagram. The Tm concentrations in Tm-doped PbTe were 3.0 and 5.0 at.%. It should be noted that no special efforts were undertaken to prevent the sample oxidation in this EXAFS experiment.

Electrical measurements were performed on a series of polycrystalline PbTe(Tm) samples with different deviation from stoichiometry. The samples were prepared by alloying the beforehand synthesized $(PbTe)_{0.985}(Tm_2Te_3)_{0.015}$ compound with extra lead or tellurium in evacuated quartz ampoules. Concentration of Tm in all these samples was 3.0 at.%. The samples were annealed at 800 °C for 60 hours.

EXAFS experiments were carried out on station 7.1 of the synchrotron radiation source of Daresbury Laboratory (UK) with an electron beam energy of 2 GeV and maximum storage ring current 250 mA. The synchrotron radiation was monochromatized by two flat Si (111) crystals. Spectra were measured at the L_{III} absorption edge of Tm (8.648 keV) in fluorescence mode at 300 K. Before EXAFS measurements the samples were powered, the powders were sifted through a sieve and then rubbed onto the surface of adhesive tape. The thick-sample limit for the fluorescence measurements was achieved by folding the tape (8…16 layers). More detailed description of the experiment and EXAFS spectra processing can be found elsewhere [16].

XANES data were collected on EXAFS station at VEPP-3 (Novosibirsk, Russia) with an electron beam energy of 2 GeV and maximum storage ring current 100 mA. Measurements were performed at 300 K at the L_{III} absorption edge of Tm in fluorescence mode in oxygen-free atmosphere. The standards for Tm^{2+} and Tm^{3+} valence states were TmTe, Tm_2Te_3 and Tm_2O_3.

The measurements of conductivity and Hall effect were done by standard technique on rectangular-shaped samples with typical dimensions of $4 \times 1 \times 5\,mm^3$ at room temperature. The current and potential contacts to the samples were soldered by indium.

3. Results and discussion

Figure 1 shows the EXAFS spectrum for $Pb_{0.95}Tm_{0.05}Te$ sample obtained at the Tm L_{III} edge. The analysis of the first shell revealed that Tm atoms substitute for the metal atoms in PbTe and are surrounded by tellurium atoms at a distance of 2.99 ± 0.02 Å. Moreover, in the first shell a contribution from the atoms, located at 2.26 ± 0.02 Å was found. The comparison of the obtained distances with known bond lengths in TmTe [12], Tm_2Te_3 [13] and Tm_2O_3 [17] compounds showed that, apparently, Tm atoms in PbTe are in the trivalent state, that is indicated by negligible difference in distances of Tm-Te in PbTe(Tm) (2.99 Å) and Tm-Te in Tm_2Te_3 (3.02 Å). Concerning the atoms located in the first shell at a distance of 2.26 Å, one can see that this distance is close to mean Tm-O distance in Tm_2O_3 (2.25 Å). Therefore we think that, except Te, the oxygen atoms are also present in first shell of Tm. The appearance of oxygen in our samples may be a result of oxidation of samples during their synthesis, preparation and measurement.

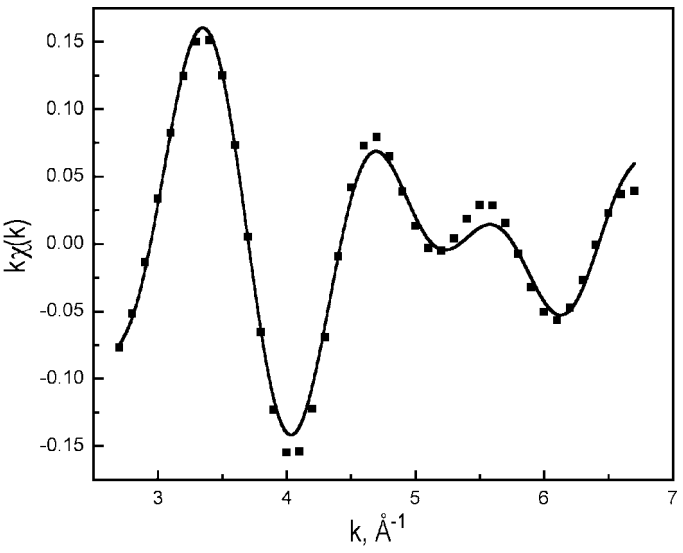

Fig. 1. EXAFS data corresponding to the first shell of $Pb_{0.95}Tm_{0.05}Te$ obtained at the Tm L_{III} edge at 300 K. Points are experimental data and the line is its best theoretical approximation.

In spite of the presence of oxygen in the samples, the conclusion that Tm impurity atoms in PbTe substitute predominantly for Pb atoms is still valid. However, uncontrolled oxidation may prevent the reliable determination of the charge state of Tm in PbTe. That is why we decided to carry out additional XANES measurements in oxygen-free atmosphere with a special care to prevent oxidation during the sample preparation.

Figure 2 presents the XANES spectra for two samples of PbTe(Tm) with different Tm concentration, as well as for TmTe and Tm_2Te_3 compounds. It is seen that the L_{III} absorption edge of Tm is denoted by a strong white line. This line is in fact a general feature of L_{III} edges for all rare-earth atoms in 2+ and 3+ valence states and is mainly due to transitions into empty 5d state. As follows from this figure, the spectra corresponding to the different electron configurations and charge states of Tm, differ considerably. The edge structure of Tm in Tm_2Te_3 (Tm^{3+} charge state) consists of one strong white line. The same structure was observed in Tm_2O_3. The XANES spectra of Tm in TmTe (Tm^{2+} charge state) have characteristic doublet structure, in which the long-wavelength white line has nearly the same shape as that of Tm^{3+} in Tm_2Te_3, but is shifted by nearly 8 eV towards lower energy.

Comparative analysis of spectra obtained for Tm-doped PbTe crystals and standard samples leads to a conclusion that Tm

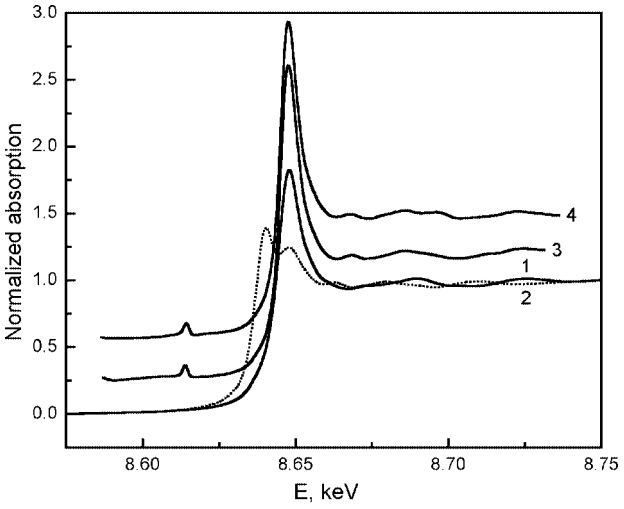

Fig. 2. Normalized XANES spectra obtained at the Tm L_{III} edge for Tm_2Te_3 (1), TmTe (2), PbTe-Tm_2Te_3 solid solution (3) and PbTe-TmTe (4) solid solution at 300 K.

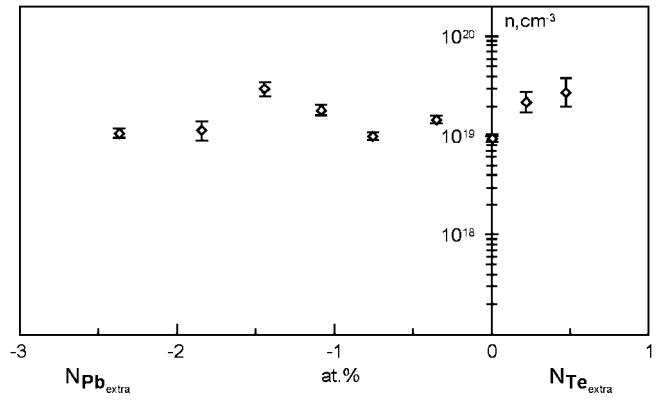

Fig. 3. Dependence of the electron concentration on the deviation from the stoichiometry for $Pb_{0.97}Tm_{0.03}Te$ samples at 300 K.

atoms in PbTe are in the Tm^{3+} charge state independently of the section of the phase diagram used for Tm doping. Indeed, in XANES spectra for PbTe(Tm) we failed to detect even the minor contribution of the second line observed for Tm^{2+} states. This result is in agreement with the data of our EXAFS measurements and the results of the Pb-Tm-Te phase diagram investigation [18], which established that the PbTe-TmTe section of the phase diagram is not quasibinary and at high Tm concentration in samples the Pb precipitations may even arise.

Data obtained from EXAFS and XANES spectra give evidence that Tm atoms in PbTe substitute for Pb atoms and are in the trivalent state and, therefore, must play a role of a single charged donor in these crystals. This conclusion was confirmed by our electrical measurements. Indeed, all investigated PbTe(Tm) samples had n-type conductivity; however, the expected direct relation between Tm and free carrier concentrations in the samples was not found. Measured electron concentration was about one order of magnitude lower than the value expected for single charged donors. To study the origin of this discrepancy, additional experiments on non-stoichiometric samples were performed.

Assuming the single charged donor behavior of the Tm atom, one could expect that addition of extra Pb within the homogeneity region of PbTe(Tm) would result in an increase of free electron concentration, while the addition of extra Te would decrease it. The dependence of the carrier concentration on the deviation from the stoichiometry is shown in figure 3. It is seen that the electron concentration remains nearly constant when varying the sample composition. There are two ways to explain these results.

The first explanation is the pinning of the Fermi level by Tm impurity, by analogy with the action of the In impurity. In the case of indium the In atoms are present simultaneously in both charge states (In^+ and In^{3+}) and the addition of extra Pb or Te changes only their relative concentrations. The pinning of the Fermi level in this case is provided by In^+ ions, which are negative-U centers (centers with negative correlation energy). However, the supposition that Tm has the same properties in PbTe disagrees with our XANES data, which indicates the existence of only one charge state of Tm.

The second explanation of the obtained dependence of the carrier concentration on the composition supposes that the donor action of Tm is compensated by the acceptor behavior of intrinsic defects in PbTe, such as Pb vacancies. It is known that the doping of lead chalcogenides with high concentration of I, Cl, In or Ga donor impurities results in an increase (by more than one order of magnitude) in solubility of extra stoichiometric Te, while doping them with Tl or Na acceptor impurities leads to an increase in solubility of excess Pb [19–21]. The nature of such a selfcompensation effect is that the doping of a sample with electrically active impurities makes it energetically favorable the formation of intrinsic point defects that have an opposite electrical sign. Due to selfcompensation, the change of the carrier concentration is always smaller than the concentration of the doping impurities. In our opinion this explanation seems to be more preferable.

4. Conclusions

In conclusion, the X-ray absorption and electrical studies of Tm-doped PbTe crystals revealed that Tm atoms predominantly substitute for Pb atoms and are in Tm^{3+} charge state independently of the section of the phase diagram used for Tm doping. This conclusion is in agreement with the results of investigation of the Pb-Tm-Te phase diagram. Reduced electrical activity of Tm impurity in PbTe is explained by the effect of selfcompensation.

Abstract

We have investigated the lattice relaxation around impurity atoms at the anion sublattice in CdTe, such as As acting as acceptor and Se which is isovalent to Te, with fluorescence detected EXAFS. We experimentally verify the lattice relaxation with a bond length being reduced by 8% around the As atom as inferred indirectly from *ab-initio* calculations of the electric field gradient in comparison with the measured value in a PAC experiment (S. Lany *et al*., Phys. Rev. B **62**, R2259 (2000)). In the case of the isovalent impurity atom Se, the bond length is similarly reduced as determined experimentally by EXAFS and by model calculations with the density functional theory implemented in the WIEN97 program. In contrast to this inward relaxation, preliminary calculations for Br in CdTe, the next element in the series As, Se, and Br, which acts as donor at the Te sublattice, indicate an increase in bond length, an interesting prediction waiting for experimental verification.

1. Introduction

The incorporation of impurity atoms is often accompanied with lattice distortions and the formation of defect complexes. Local strain fields introduced by the impurities can drastically influence electrical and optical properties. Knowledge about these local effects is mainly derived from measurements, which determine the local structure only indirectly (like e.g. Electron Spin Resonance, Perturbed Angular Correlation (PAC), Zeeman- and Piezoscopic FTIR studies). A rather direct experimental access to lattice distortions is provided by the X-ray absorption spectroscopy (EXAFS). In this contribution we report on measurements of the lattice relaxation around the acceptor dopant As, and the isovalent impurity Se at the Te sublattice in CdTe with EXAFS. The experimental challenge lies in the necessary compromise between a concentration high enough for an EXAFS detection, but low enough to avoid compensation and clustering of the dopants in the semiconductors. In the case of As in CdTe, the aim was to experimentally verify the lattice relaxation around the impurity atom as determined theoretically with the LAPW method used to calculate the electric field gradient in comparison with the measured value in a PAC experiment [1]. In order to understand the driving force for the lattice relaxation we also determined the relaxation around Se, the neighbouring element to As and isovalent to Te, for which no doping effects in CdTe are known. Finally we have extended our calculation to the next neighbouring element, Br, acting as donor when incorporated substitionally at the Te sublattice.

2. Experiment and theory

2.1. *Experimental details*

The incorporation of arsenic as the acceptor dopant in CdTe was done by ion implantation at the tandetron of FZ Rossendorf. A total dose of $7 \times 10^{15}\,\mathrm{cm}^{-2}$ As atoms was almost uniformly distributed up to a depth of 3 µm. The samples, originally from Crystec GmbH[2], were thermally treated before and after the implantation following the approaches [2] in which As was predominantly incorporated as acceptor at the Te site as checked by photoluminescence (PL) measurements. To reduce background in the fluorescence detected EXAFS from undoped sample material, the crystals were thinned from the back to a total thickness of about 30 µm. For the case of Se in CdTe we used mixed $CdTe_{1-x}Se_x$ crystals, provided by M. Fiederle[3], which were powdered, mixed with graphite or polyethylene, and pressed into pellets.

To determine the local structure around As and Se we have measured the K-edge absorption at the X1-beamline of HASYLAB at DESY. In the case of As we measured the absorption in the fluorescence mode with the 5-segment Ge-detector, the fluorescence being detected in line with the polarisation vector of the incoming synchrotron radiation. To reduce the influence from elastic and inelastic scattering of the incoming radiation, critical absorption was employed using a foil made out of Ge powder mixed with polyethylene. In the case of Se, the absorption could be measured in transmission on the powdered samples. The absorption on Cd and Te was measured in transmission, too. For the measurements, the samples were mounted on a He gas flow cryostat, keeping the temperature at approximately 18 or 300 K.

The analysis of the observed absorption spectra was done following the standard FEFF procedure [3, 4] including the background treatment with AUTOBK [5]. In the case of Se in the mixed crystal, a combined multiple data set fitting procedure of the data recorded for Se as well as for Cd and Te data could be applied.

2.2. *Theoretical details*

Complementing our experimental work we have performed *ab-initio* calculations based on the density functional theory (DFT) with the WIEN97 package [6] which uses the linearised augmented plane wave (LAPW) method and with the FHI96md program [7] which uses first-principles pseudo-potentials (PP) and a plane-wave basis set. The latter was used to investigate the size dependence of the super-cells constructed around one substitutional As atom in CdTe. The calculations yielded good agreement with our EXAFS experiment (see Table I) so that the determined relaxations can be used as a solid basis for further interpretations of derived parameters such as hyperfine interaction parameters of defect complexes (for further details see [1, 8]).

3. Results and discussion

An example of our EXAFS result at low temperature is given in Fig. 1. As checked for two different samples, the main features of the absorption spectra at 20 K and at room temperature remain the same. Since our main concern was that the concentration may be too close to the doping limit, we checked the uniqueness of the As configuration. The mentioned temperature behaviour may be taken as a first, although weak proof for the structural uniqueness of the As configuration. Similarly, the detected PL corresponding to the As acceptor line in CdTe may not be a sufficient proof for the occurrence of the As-on-Te-site configuration as the main or sole As configuration either. As an additional test, we have inspected the XANES region of the absorption spectra and compared it to model spectra assuming As in various configurations (see Fig. 2). The modelling was performed according to [9]. Only the description of As being substitutionally at the Te site matches the experimental spectra. The occurrence of a "white line" in our experiment allows to safely state that the contribution from other As configurations cannot exceed a few percent of the total As concentration. We can therefore adopt the determined bond length as representative for As in CdTe at the substitional Te site.

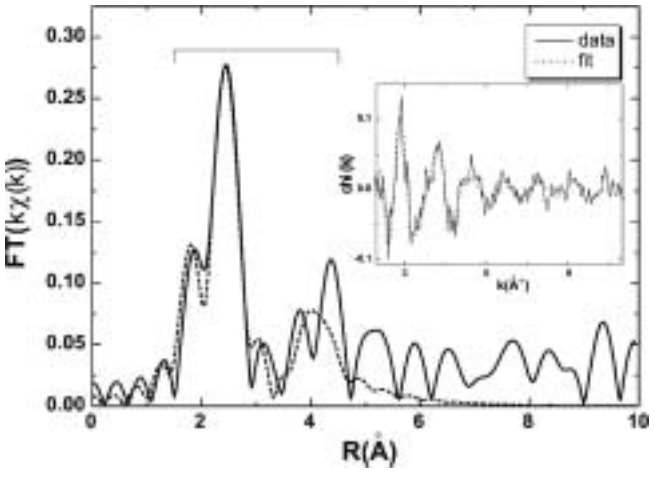

Fig. 1. Radial distribution function of As in CdTe obtained from the EXAFS spectrum, weighted linearly with k and Fourier transformed. The fit region in R-space is indicated by the bar. The insert shows the EXAFS spectrum $\chi(k)$.

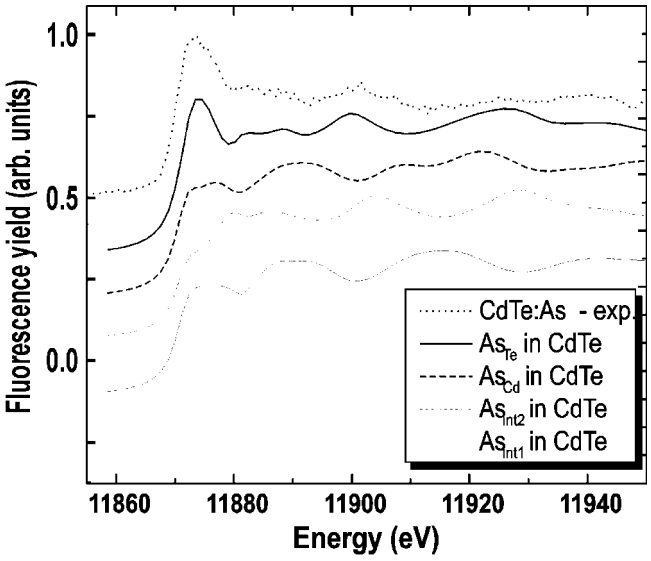

Fig. 2. Comparison of the experimental XAFS signal with XANES spectra calculated for different configurations around As in CdTe: (*i*) As substitutionally on the Te site (As_{Te}), (*ii*) As on the substitutional Cd site (As_{Cd}), and As located interstitially with (*iii*) either Te (As_{int1}) or (*iv*) Cd (As_{int2}) as first-shell neighbours. The theoretical spectra are normalised to the experimental edge step and shifted in y-direction for easier comparison.

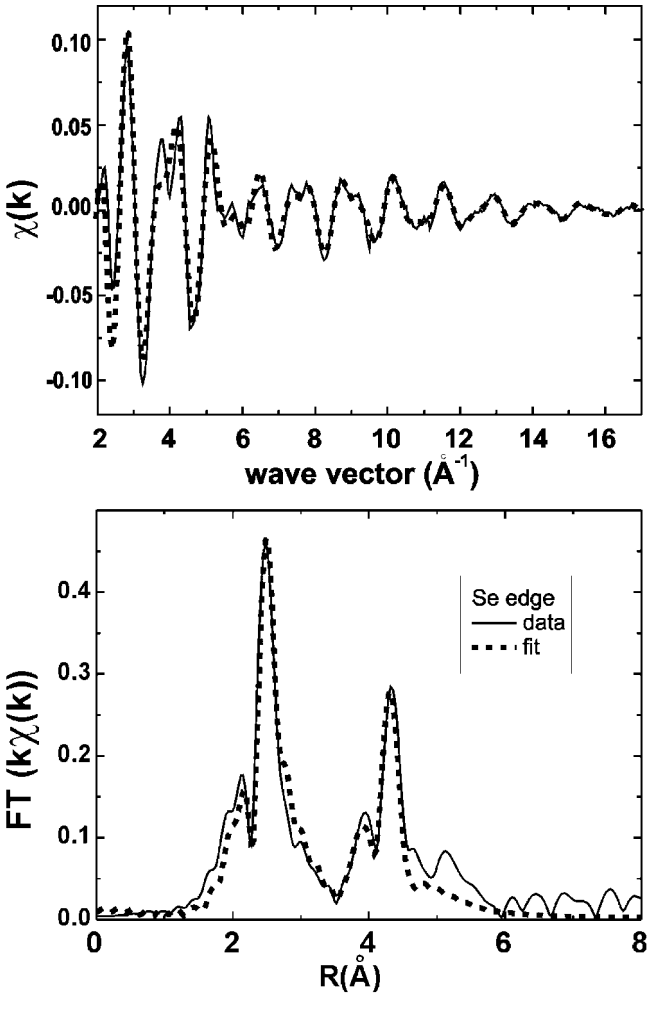

Fig. 3. EXAFS spectrum $\chi(k)$ (top) and radial distribution function (bottom) of Se in $CdTe_{1-x}Se_x$ for $x = 0.04$, obtained from the EXAFS spectrum, weighted linearly with k and Fourier transformed. The fitting range in R-space runs from 1.9 to 5 Å.

In Tab. I we compare our measured bond length with the results obained from the pseudo-potential calculations as well as the LAPW values according to ref. [1]. The agreement is very good. A distinction between the two possible impurity charge states cannot be made, the difference is too small to be noticeable in our data taken our experimental accuracy into account. There is, however, a tendency that the bond length extracted from our XAFS data is shorter by approximately 0.04 Å at room temperature than at 20 K which could be the result of a change of the charge state, or at least of a shift in the occupation of the possible impurity charge states.

Our EXAFS data on Se and the corresponding calculated values can be considered as an additional support to the good agreement obtained for As in CdTe between experiment and model calculation. The experimental results for Se in $CdTe_{1-x}Se_x$ are illustrated in Fig. 3. The extracted values are included in Tab. I. We have chosen a concentration of $x = 0.04$ which comes close to the super-cell size of 32 atoms. The agreement is very good and gives confidence to attack more sophisticated configurational doping problems both by modelling and the experimental verification of proposed model description. In this context we present our result of bond length calculation for the donor Br in CdTe, included in the Tab. I. Contrary to the As and Se case, it shows a sizeable increase in bond length. This prediction is awaiting experimental verification, which would probably help us to understand the formation of Br A-centre in CdTe.

Abstract

The temperature dependence of EXAFS Debye-Waller factors in $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ perovskite with cation deficiency was investigated with the cumulant expansion method. The measurements of the Ti and Nb K-edge and La L3-edge EXAFS spectra were carried out in the transmission mode at temperatures up to 800 K. The obtained local bond distances of 1.95(1) Å for Ti-O, 1.98(1) Å for Nb-O and 2.65(1) Å for La-O are significantly smaller than the expected values on Shannon's radii. This characteristic is attributable to the presence of the cation deficiency. The effective pair potentials, $V(u) = \alpha u^2/2 + \beta u^3/3$, were evaluated and the potential coefficients α and β for the Ti-O bond in $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ are 6.6(1) eV/Å^2 and −42(3) eV/Å^3, respectively. The Ti-O bond in the A-site-deficient $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ has relatively larger anharmonic and soft potential coefficient than that in ordinary $CaTiO_3$ perovskites.

1. Introduction

$La_{2/3}TiO_3$-based compounds with an *A*-site-deficient perovskite-type ABO_3 structure exhibit high ionic conductivities and dielectric constants. The orthorhombic (Cmmm) – tetragonal (P4/mmm) phase transition occurs reversibly and continuously at 623(2) K in $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ [1]. Cation vacancies in the compounds are ordered in a lattice site at lower temperature. Yashima *et al*. [2] determined the temperature dependence of the $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ structure by means of high-resolution synchrotron X-ray powder diffraction. The unit-cell parameters were found to change continuously with increasing temperature even near the phase transition. No hysteresis was observed in the lattice parameters between heating and cooling processes. Because La^{3+} and Nb^{5+} have larger valence than alkali earth elements and Ti^{4+} in ordinary $ATiO_3$ (A = Ca,Sr,Ba) perovskites, respectively, it is interesting to investigate its influence on the local structure, ionic conductivity and phase transition. The ionic conductivities are strongly dependent on the local structure.

Detailed knowledge of local structure and thermal properties for each atom in perovskite-type compounds is of great importance for understanding the mechanisms of favorable physical properties [3]. The analysis of the temperature-dependent EXAFS Debye-Waller factor allows us to evaluate the interatomic force constants for neighboring atoms [4, 5].

2. Experimental and analysis

$La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ perovskite was synthesized by a solid-state reaction reported previously [1, 2]. Starting materials were high-purity powders of La_2O_3, TiO_2 and Nb_2O_3 (>99.9%). The dried powders were weighted and well mixed. The mixture was calcined in air. The process of grinding and calcination was repeated four times. Obtained powders were ground and pressed into pellets under a uniaxial pressure of 150 MPa. The pellets were sintered at 1630 K for 12 hours in air. The sintered material was crushed and ground to obtain a fine powdered sample. The crystal of $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ perovskite was identified by X-ray diffraction.

The appropriate amount of fine powder sample and boron nitride powder was mixed and pressed into pellets of < 0.2 mm in thickness and 10.0 mm in diameter. Measurements of the Ti and Nb K-edge and La L3-edge EXAFS spectra were carried out in transmission mode at beam line BL-9A and BL-10B of the Photon Factory in KEK, Tsukuba (Proposal No. 2002G276). Because $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ contains a relatively small amount of Nb atoms, the sample for Nb K-edge had only edge-jumps with 0.2 ($\Delta\mu d$), where μ is the linear absorption coefficient and d is the thickness. X-ray absorption measurements were made in the temperature range from 300 to 800 K. The synchrotron radiation was monochromatized by a Si(111) double crystal monochromator. Mirrors are used to eliminate higher harmonics. Details of the measurement and analysis were given in references [5, 6].

The EXAFS interference function, $\chi(k)$, was extracted from the measured absorption spectra using the standard procedure [7]. The $\chi(k)$ was normalized using MacMaster coefficients according to the EXAFS workshop report [8]. Figure 1(a) shows the Ti K-edge EXAFS oscillation $k^3\chi$ at 333 K. Figure 1(b) shows examples of Fourier transforms of the Ti K-edge EXAFS spectra in the ranges of $2.5 < k < 10.7$. In quantitative analyses we carried out the Fourier-filtering technique and a nonlinear least-squares fitting method by comparing the observed $\chi(k)_{\mathrm{exp}}$ and calculated $\chi(k)_{\mathrm{calc}}$. We used the EXAFS formula in the single scattering theory with the cumulant expansion up to the fourth order term [9]:

$$\chi(k) = \sum_B (N_B/kR_{AB}^2)\,|f_B(k;\pi)|\exp(-2R_{AB}/(k/\pi)) \times \exp(-2\sigma 2k^2 + (2/3)\sigma 4k^4) \times \sin(2kR_{AB} - (2k/R_{AB}) \times(1 + 2R_{AB}/(k/\eta))\sigma 2 - (4/3)\sigma 3k^3 + \psi_{AB}(k))$$

where N_B is the coordination number of scattering atoms B at distance R_{AB} from the absorbing atom A, $|f_B(k;\pi)|$ the backscattering amplitude of photoelectrons and $\psi_{AB}(k)$ the phase shift function. Values of the function $|f_B(k;\pi)|$ and $\psi_{AB}(k)$ were calculated using the FEFF3 program [10]. σn denotes the nth cumulant. The mean free path λ of the photoelectron is assumed to depend on the wave number, $\lambda(k) = k/\eta$, where η is a constant.

*Corresponding author: Akira Yoshiasa: yoshiasa@sci.kumamoto-u.ac.jp

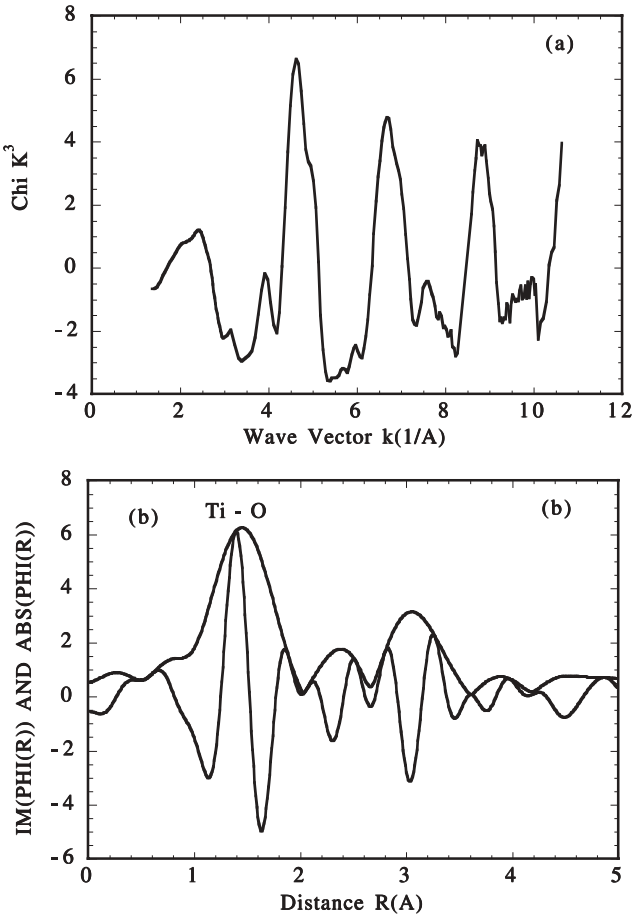

Fig. 1. (a) Observed Ti K-edge EXAFS oscillation $k^3\chi$ of $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ at 333 K. (b) Fourier transforms of the Ti K-edge EXAFS for $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ at 333 K. No phase shift corrections are made.

Single-shell fitting was carried out for each nearest-neighbor distance, where the number of neighboring atoms was fixed at the crystallographic value as $N_B = 6$ for the Ti-O and Nb-O distances and $N_B = 12$ for the La-O distances. We assumed that η and ΔE_0 have negligible temperature dependences. Here ΔE_0 is the difference between the theoretical and experimental threshold energies. The values of η and ΔE_0 are determined so as to give the best fit to the spectrum at the lowest temperatures. Because the fourth-order term was negligible, the refinement was performed to the structure parameters $R_{AB}, \sigma 2$ and $\sigma 3$ in each shell by use of the fixed η and ΔE_0 values. The reliability of the fit parameters,

$$R = \sum \left| {k_s}^3 \chi_s(k_s)_{\text{exp}} - {k_s}^3 \chi(k_s)_{\text{calc}} \right| / \left| {k_s}^3 \chi(k_s)_{\text{exp}} \right|,$$

between the experimental and calculated EXAFS functions was less than 0.032.

3. Results and Discussion

Figure 2 shows a portion of the crystal structure of $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ determined by X-ray diffraction experiment at room temperature [2]. There are two crystallographically nonequivalent La site (La1 and La2 sites) in the orthorhombic phase. The La1 sites are occupied 98% by La^{3+} and vacancies in the La1 sites are 2%. On the other hand, the La2 sites are occupied only 29% by La^{3+} and vacancies in the La2 sites are 71%. The average La1-O and La2-O distances determined by

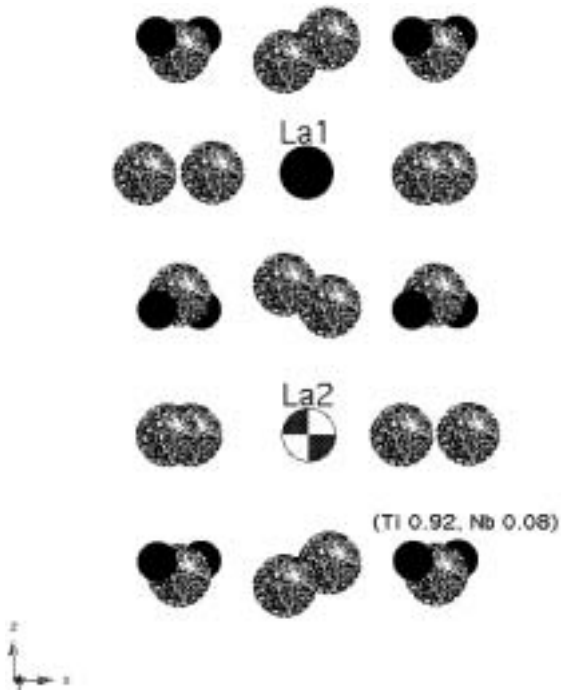

Fig. 2. Portion of the crystal structure (space group Cmmm) of *A*-site deficient $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ perovskite with double ideal cubic ABO_3 unit along the c-axis at room temperature.

diffraction are 2.691 and 2.802 Å, respectively. The deficient La2 site has significantly larger bond distance. EXAFS spectroscopy is effective for investigating the local environment around the La ions, while the average of the occupied and unoccupied sites is obtained by diffraction experiments. The local bond distance determined by EXAFS method is 2.65(1) Å for La-O bond, which is an average value for all La ions in both La1 and La2 sites. The La-O distance obtained by EXAFS represents the actual nearest-neighbor distance and is shorter than those obtained by diffraction experiments, indicating that the unoccupied sites are larger than the occupied sites.

The Ti and Nb ions in the orthorhombic phase are located at crystallographically equivalent positions. Diffraction method provide the $(Ti_{0.92}Nb_{0.08})$-O distance (1.950 Å), which is an average of Ti-O and Nb-O distances. The local bond distances obtained by EXAFS are 1.95(1) and 1.98(1) Å for Ti-O and Nb-O bonds, respectively.

Based on the ionic radii of Shannon, Ti-O, Nb-O and La-O distances are expected to be 1.985, 2.02 and 2.74 Å, respectively. The obtained local bond distances of 1.95(1) Å for Ti-O, 1.98(1) Å for Nb-O and 2.65(1) Å for La-O are significantly smaller than the expected values on the Shannon radii. The same tendency was observed by diffraction experiment [2], though diffraction method gives the averaged bond distances over occupied and unoccupied *A*-sites and over the Ti-O and Nb-O distances in the B-site. This characteristic is attributable to the cation deficiency. The coordination number of oxygen decreases with increasing cation deficiency, which leads to a decrease in ionic radii of O^{2-}. The O^{2-} ions shift from unoccupied sites toward occupied sites, and lattice sites become dilate around vacancies.

Figure 3 shows XANES spectra of Ti K-edge at 300 and 800 K. It is known that the relative peak intensity of the pre-edge peaks change with the local Ti atom distortion [10, 11]. No change in XANES spectra and in threshold energies of the Ti K-, Nb K- and La L3-edges was observed among the examined temperatures.

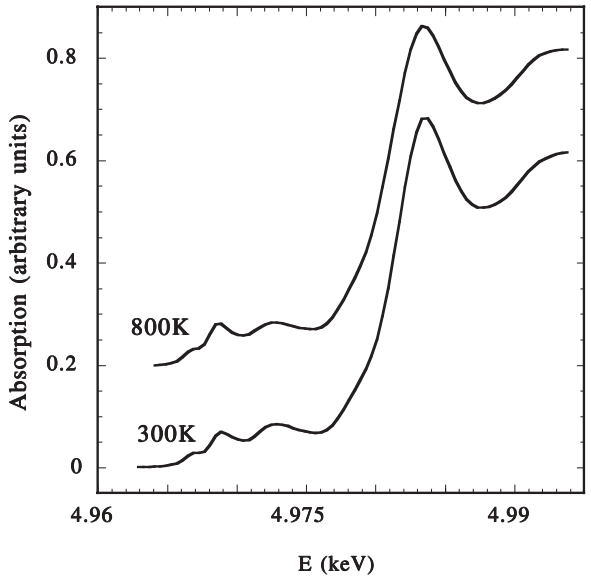

Fig. 3. XANES spectra of Ti K-edge in $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ at 300 K and 800 K.

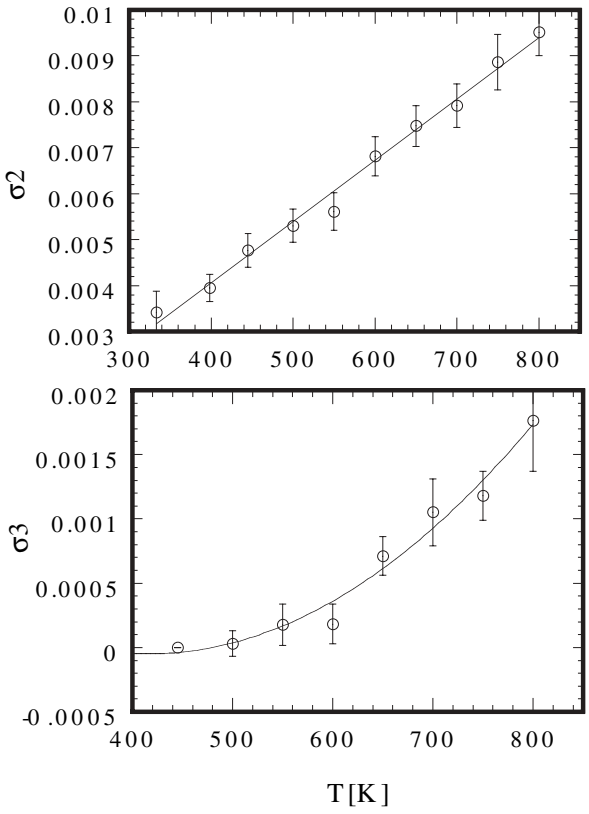

Fig. 4. Temperature (K) dependence of $\sigma 2$ and $\sigma 3$ for the Ti-O bond in $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ perovskite.

No significant difference in local distortion for each cation site near the phase transition point and at the higher temperatures is recognized.

Figure 4 shows the temperature dependence of $\sigma 2$ and $\sigma 3$ for Ti-O bond in $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$. The Debye-Waller type factor $\sigma 2$ includes the effects of static and dynamic disorders. The static disorder is configuration disorder, while the dynamic disorder arises from thermal vibrations of atoms. The contribution of thermal vibrations, σ_{thermal}, can be estimated under the assumption of classical statistical dynamics by the temperature dependence of $\sigma 2$ [5]. A steep slope in the figure represents a weak bonding. The gradient for the experimental $\sigma 2$ is equal to k_B/σ, if we evaluate the anharmonic effective pair potential $V(u) = \alpha u^2/2 + \beta u^3/3!$ from the contribution to the thermal vibration, where k_B is the Boltzmann constant, α and β are the potential coefficients and u is the deviation of the bond distance from the location of the potential minimum. β is calculated from the values of $\sigma 2$ and $\sigma 3$ [9].

The potential coefficients α and β for the Ti-O bond in $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ are $6.6(1)\,\text{eV}/\text{Å}^2$ and $-42(3)\,\text{eV}/\text{Å}^3$, respectively, while those for the Ti-O bonds in $CaTiO_3$ [6] are $6.9(1)\,\text{eV}/\text{Å}^2$ and $-38(2)\,\text{eV}/\text{Å}^3$, respectively. The Ti-O bond in the *A*-site-deficient $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ has relatively larger anharmonic and soft potential coefficient than that in ordinary $CaTiO_3$ perovskites. The potential coefficient α for the Nb-O bond in $La_{0.63}Ti_{0.92}Nb_{0.08}O_3$ is estimated as $27(7)\,\text{eV}/\text{Å}^2$ with large error. The Nb^{5+}-O bond is considerably stronger than the Ti^4-O bond.

Abstract

Temperature dependence of XAFS spectra of the Perovskite-type proton conductor $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ at Sr and Zr K-edges and Yb L3, L2 and L1-edges have been investigated. Chemical shifts to lower energy and change in XANES spectra are observed with increasing temperature. No change in the XANES spectra and in the threshold energies of the Yb L3-, L2- and L1-edge was observed. This indicates that the effective charges (oxidation states) of the Sr and Zr ions change with oxygen loss while the effective charge of the Yb ions were maintained. The unit cell volumes increase with increasing temperature with a slight bend between 700 and 950 K. This bend of the unit cell volumes vs. temperature is considered to be due to the loss of oxygen, which is consistent with the result of a weight loss in TGA observed in the same temperature range. The mean-square relative displacements (MSRD) of the backscattering atoms with respect to the absorbing atom were also determined by EXAFS. Its temperature dependence increases with a slight bend between 700 and 950 K, which is considered to be due to a local structure change accompanied by the loss of oxygen rather than that by the phase transition at 948 K. It is proposed that the changes of local structure and effective charges of Sr and Zr ions must play an important role in the protonic conductivity.

1. Introduction

Perovskite-type oxides such as Ln^{3+} doped $SrCeO_3$ and $BaCeO_3$, where Ln^{3+} represents trivalent lanthanide elements, have been found to exhibit appreciable proton conduction in hydrogen-containing atmospheres at high temperature [1, 2, 3, 4, 5]. Among these, the chemical stability of $SrZrO_3$-based oxides is much better, and Yb-doped $SrZrO_3$ oxide shows the highest proton conductivity. The proton conductivity depends on the amount of dopant Yb ions and shows a maximum value when substituted for Yb ions by 10 mol%. The oxide ion vacancies and/or electron holes are produced by substitution of tetravalent zirconium ions by trivalent ytterbium ions. In our previous studies [6, 7], the mass loss and gain of oxygen in the Yb-doped $SrZrO_3$ was observed in the heating and cooling processes, respectively. Four polymorphs of SrZrO3 were reported [8]. The temperature dependence of local structure in $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ is not known yet. Detailed knowledge of the local structure and thermal properties for each atom in $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ perovskite is of great importance for understanding the mechanisms of protonic conduction.

2. Experimental and analysis

The $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ perovskite was synthesized by the solid-state reaction reported previously [6, 7]. The sample were sintered at 1975 K for 30 h and kept in air for a week. The crystals were characterized by high temperature X-ray powder diffraction analyses. Space group and detail structure for each phase are determined using synchrotron radiation and Rietveld refinements.

The measurements of Sr K-, Zr K-, Yb L3-, Yb L2- and Yb L1-edges EXAFS spectra were carried out in the transmission mode at beam line BL-10B of the Photon Factory, KEK. X-ray absorption measurements were made in the temperature range from 300 to 1250 K. Details of the measurement and analysis were given in reference [9, 10].

The EXAFS interference function was extracted from the measured absorption spectra and was normalized MacMaster coefficients according to the EXAFS workshop report. The radial structure function was obtained by the Fourier transform over the k range of 3.5–12.5 $Å^{-1}$ for the Sr K- and Zr K-edge and of 3.5–11 $Å^{-1}$ for the Yb L3-edge. In quantitative analyses, we carried out the Fourier-filtering technique and a nonlinear least squares fitting method by comparing the observed and calculated EXAFS interference function. We used the EXAFS formula in

the single scattering theory with the cumulant expansion up to the fourth order term.

3. Results and Discussion

The unit cell volumes increase with increasing temperature with a slight bend between 700 and 950 K (Fig. 1). This bend of the unit cell volumes vs. temperature is considered to be due to loss of oxygen, which is consistent with the result of a weight loss in TGA observed in the same temperature range [7]. The amount of oxide ion vacancies was estimated to be 3.3 atom% [7]. In $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$, the Pnma-Imma-I4/mcm-Pm-3m phase transitions were observed reversibly at 948, 993 and 1223 K, respectively, in our detail structure analyses. The weight loss of oxygen occurs at a lower temperature than phase transition temperatures.

Figure 2 shows the temperature dependence of XANES spectra of $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ at the Sr K- and Zr K-edges. Chemical shifts to lower energy and changes in XANES spectra are observed with increasing temperature and are considered due to the mass loss of oxygen. Changes of the oxidation states of Sr and Zr ions can be expected above the temperature of a mass loss of oxygen. No change in XANES spectra and in threshold energies of the Yb L3-, L2- and L1-edge was observed (Fig. 3).

This indicates that the effective charges (oxidation states) of Sr and Zr ions change with oxygen loss while the effective charge of Yb ions were maintained. The shifts of threshold energies for Sr K- and Zr K-edges are 1.4 and 1.2 eV, respectively. The data suggests that the total electric charges for Sr and Zr ions are less than 2 and 4, respectively. It is considered that the changes of local structure and effective charge of Sr and Zr ions must play an important role in the protonic conductivity.

At room temperature, the Zr-O distance of 2.094 (3) Å in $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ by EXAFS is in good agreement with that of 2.091(1) Å in $SrZrO_3$ by diffraction. The obtained Sr-O distance of 2.735(5) Å in $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ is larger than that of 2.698(4) Å in $SrZrO_3$. The sum of the effective ionic radii [11] between 4-coordinated oxide ions and 6-coordinated Yb ions is 2.248 for Yb-O distance. The Yb-O distance of 2.168(3) Å in $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ obtained by EXAFS is 0.08 Å smaller than expected value from ionic radii. This suggests that Yb ion is less than 6-coordination of oxygen and the oxide ion vacancies are localized around Yb ions at lower temperature. No significant difference in local bond distance for each cation at the higher temperatures is seen within the experimental error.

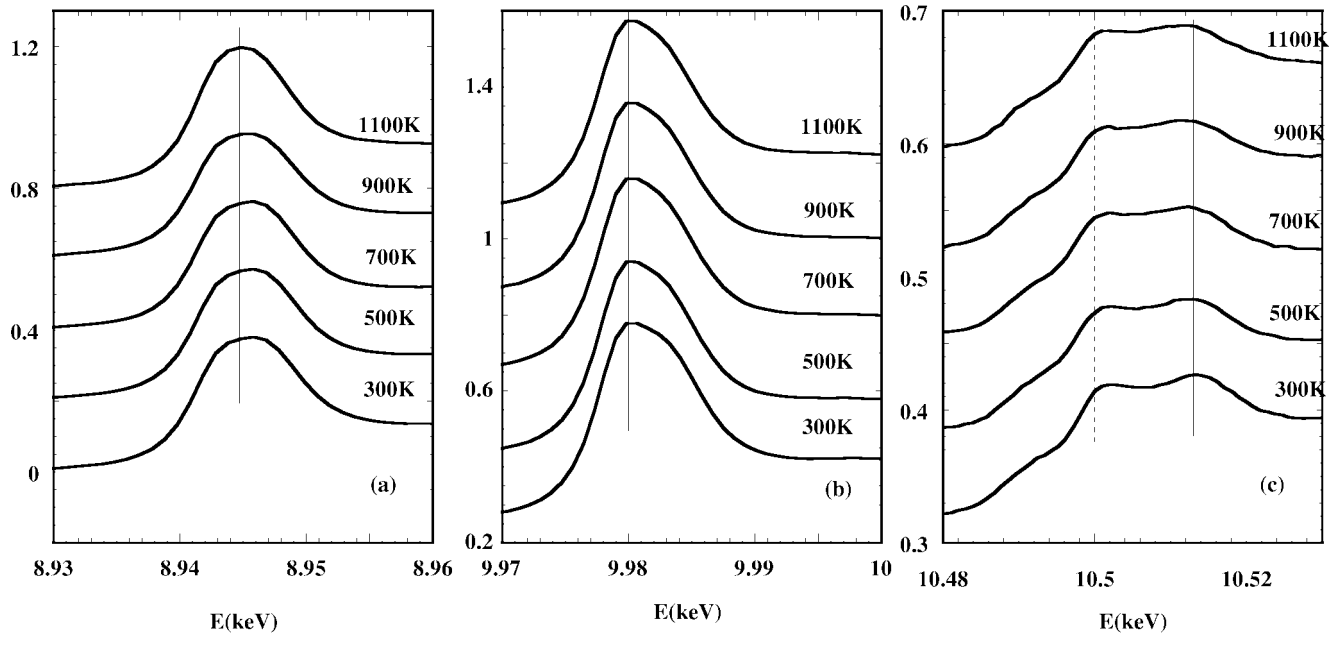

Fig. 3. Temperature (K) dependence of XAFS spectra of $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ at the Yb L3, L2 and L1 edges.

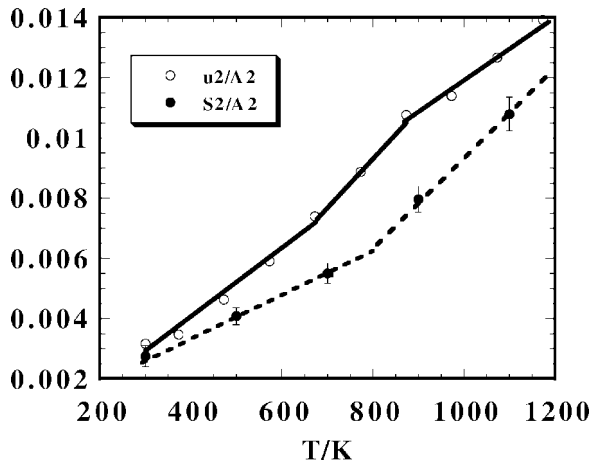

Fig. 4. Temperature (K) dependence of the Debye-Waller factor of EXAFS analysis (σ_2) for the Zr-O bond and that of diffraction analysis (u^2) for Zr(+Yb) atom in $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$.

The Debye-Waller factor determined by EXAFS spectroscopy (σ_2) is sensitive to short-range correlations of the atomic motion. The mean-square relative displacement (MSRD) of the backscattering atoms with respect to the absorbing atom can be determined by EXAFS. The mean-square displacement (MSD: u^2) of each atom at crystallographically equivalent positions is determined by diffraction methods. The MSRD contains the contribution from the MSD of both absorbing and backscattering atoms and the displacement correlation function (DCF) [12, 13]: $\mathrm{MSRD_{AB}} = \mathrm{MSD_A} + \mathrm{MSD_B} - 2\mathrm{DCF}$.

Figure 4 shows the temperature dependence of σ_2 for the Zr-O bond and u^2 for the Zr (+10%Yb) atoms in $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$. The amplitudes of both Debye-Waller factors are nearly the same. The amplitude of u^2 for Zr atom increases with increasing temperature with a slight bend between 700 and 950 K. This bend may be correlated to the loss of oxygen and to the change of effective charge of the Zr ion. The bend of the amplitude of σ_2 versus temperature is also observed at temperatures higher than 700 K, which is considered to be due to a local structure change accompanied by the loss of oxygen rather than the phase transition at 948 K. A detailed study on thermal properties for each atom in $SrZr_{1-x}Yb_xO_{3-\delta}$ ($x = 0.0$, 0.05 and 0.1) perovskite is now in progress. The gradient for the experimental σ_2 is equal to k_B/α, if we evaluate the harmonic effective pair potential $V(u) = \sigma u^2/2$ from the contribution to the thermal vibration, where k_B is the Boltzmann constant, α is the potential coefficient and u is the deviation of the bond distance from the location of the potential minimum [14]. The potential coefficient α for the Zr-O bonds in $SrZr_{0.9}Yb_{0.1}O_{3-\delta}$ at lower temperature is 9.1 eV/Å^2, which is larger than the potential coefficients for the Ti-O bonds (7.0 eV/Å^2) in $SrTiO_3$ and $CaTiO_3$ [15]. This is consistent with properties such as the melting temperature.

4. Conclusion

The effective charges (oxidation states) of both Sr and Zr ions change with oxygen loss while the effective charge of the Yb ions were maintained.

The oxide ion vacancies produced by trivalent Yb substituted for tetravalent Zr are localized near Yb ions. The oxygen vacancies derived by oxygen loss at the high temperature are considered to be localized Sr ions and Zr ions. The changes of local structure and effective charge of Sr and Zr ions play an important role in the protonic conductivity.

Abstract

X-ray absorption spectroscopy was used to probe the short-range structure in lanthanum-doped lead titanate ceramics ($Pb_{1-x}La_xTiO_3$) for x ranging from 0.0 to 0.30. A comparison of the XANES spectra and the X-ray diffraction (XRD) results indicates that the local structure around Ti atoms had a different compositional dependence. According to the XANES data, even for the sample containing 30% of lanthanum, for which the XRD analysis indicated the existence of a cubic structure, a local distortion around Ti atoms persisted. The intensity of the pre-edge feature of the PLT30 sample decreased by a factor of only two when compared with the lanthanum-free sample.

1. Introduction

$Pb_{1-x}La_xTiO_3$ (PLT) ceramic materials have been studied extensively due to their interesting physical properties [1]. The isomorphic replacement of lead atoms by lanthanum atoms induces some interesting changes in the physical properties. Upon increasing the lanthanum content ($x > 0.25$), a diffuse character of the ferroelectric-paraelectric phase transition (DPT) is observed. This variation in the phase transition character is followed by a linear decrease of the Curie temperature (T_c) to room temperature [1, 3]. It has been suggested that the lanthanum-induced modification of $PbTiO_3$ causes structural changes that can be directly related to the nature of the phase transition [4]. Although the physical properties of the PLT system have been studied in some detail [1–7], the literature contains few reports concerning the structural characteristics of the PLT system.

The $PbTiO_3$ crystal structure has been exhaustively studied [8–10]. Its room temperature structure is tetragonal P4mm ($a = 3.902(3)$ and $c = 4.156(3)$ Å) [11]. The notation on perovskite structures labels the Pb and Ti sites *A* and *B*, respectively and according to the literature, the La^{3+} ion replaces the Pb^{2+} ion rather than the Ti^{4+} ion in Pb-based perovskites [12]. To maintain the neutrality of the charge when lead atoms are replaced by lanthanum atoms, *A* site vacancies are created [12].

Using the Raman scattering technique, E.C.S. Tavares *et al.* [13] probed the short-range structure in lanthanum-doped lead titanate ceramics for x ranging from 0.0 to 0.30. According to their report, X-ray diffraction measurements of highly doped samples ($x>0.27$) indicated a cubic structure. On the other hand, in highly doped samples ($x>0.27$), measurements of Raman scattering at temperatures above and below the tetragonal phase transition showed a residual short-range structural disorder in the cubic phase. These authors suggested that the existence of this short-range structural disorder may be correlated to the relaxor behavior in highly doped samples.

Despite this system's scientific and technological importance, there is still a paucity of conclusive investigations regarding its crystalline structure. In this paper, we discuss a short-range structural study of $Pb_{1-x}La_xTiO_3$ ceramic samples as a function of the lanthanum content. X-ray Absorption Spectroscopy (XAS) was used to probe the local structure around Ti atoms.

2. Sample Preparation and Experimental Details

Polycrystalline $Pb_{1-x}La_xTiO_3$ (PLTx) samples with $0.0 \leq x \leq 0.30$ were prepared by the conventional mixed oxides method. PbO, TiO_2 and La_2O_3 were mixed with distilled water in an alumina ball mill. Monophasic PLT powders were obtained after calcination in air for 3 h at 1123 K. The calcined powders, pressed into pellets, were sintered in a covered alumina crucible at 1473 K for 3 h. Further details of sample preparation are reported elsewhere [2].

The titanium K-edge X-Ray absorption spectra were collected at the LNLS (National Laboratory of Synchrotron Light) in Campinas, Brazil, a facility that uses the D04B-XAS1 beam line [14]. The LNLS storage ring was operated at 1.36 GeV and 100–160 mA. The pelletized samples obtained after sintering were ground for XAS measurements. XAS data were collected at the Ti K-edge (4966 eV) in transmission mode and at room temperature, using a Si(111) channel-cut monochromator. Ionization chambers were used to detect the incident and transmitted flux. XANES (X-ray absorption near edge structures) at the Ti K-edge were recorded for each sample between 4910 and 5200 eV, using energy steps of 0.5 eV. A qualitative interpretation of XANES spectra obtained at the Ti K-edge was performed using the software package developed by Michalowicz and Noinville [15]. For purposes of comparison among different samples, all the spectra were background removed and normalized, using as unity the first EXAFS oscillation.

3. Results and Discussion

Figure 1 shows the XANES spectra obtained at the Ti K-edge of PLT samples. The pre-edge region of the K-edge XANES spectra of some transition metal oxides are characterized by a pronounced feature several volts before the main rising edge [16–18]. In transition metal oxides that crystallize in centrosymmetric structures, this pre-edge feature is very small or absent; in noncentrosymmetric structures it can be quite large [16–18]. According to the literature, the physical origin of the peak labeled A in Figure 1 is the transition of the metallic 1s electron to an unfilled d state [16]. This forbidden electronic dipole transition is normally allowed by the mixture of p character from surrounding oxygen atoms in the unfilled d states. On the other

*e-mail: valmor@if.sc.usp.Br

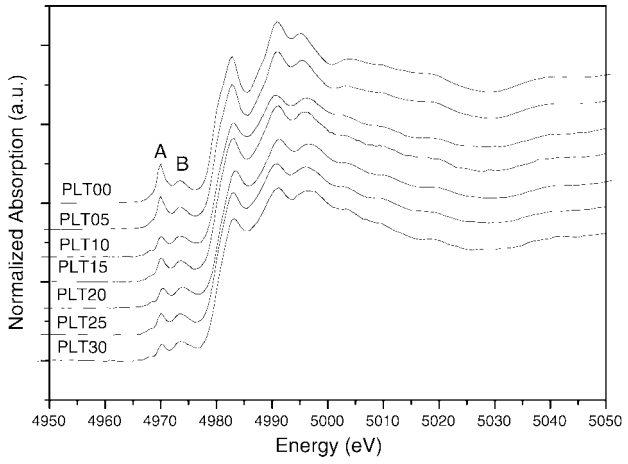

Fig. 1. Ti K-edge XANES spectra of PLTx powder samples with $0.0 \leq x \leq 0.30$.

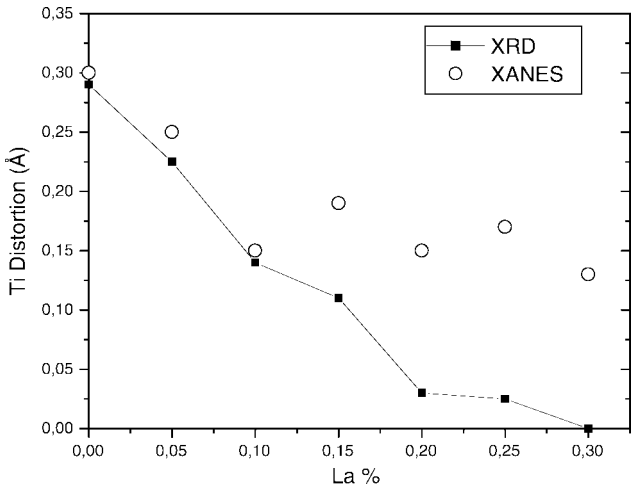

Fig. 2. Variation of the intensity of A pre-edge peak in XANES spectra and Ti atom distortion along the c-axis obtained from XRD data.

hand, the peak labeled B in Figure 1 was found to be caused by Ti 1s electron transition to the unoccupied 3d-originated e_g-type molecular orbitals of TiO_6 polyhedra neighboring the absorbing Ti atoms, which are weakly affected by the core hole potential [18]. The peak B area does not depend strongly on small displacements of the atoms from their sites in a cubic crystal lattice, but it changes significantly when 4d atoms appear in the vicinity of the absorbing Ti atom, for instance, Zr atoms in the PZT solid solution [18].

As can be seen in Figure 1, the intensity of the A feature in the PLT05 sample is similar to that of the undoped sample. A 10% increase in the amount of lanthanum causes a significant drop in the intensity of the A feature. A further increase of lanthanum to a concentration of up to 30% shows a slight variation in the intensity of the A feature, indicating a slight dependence of the A feature's intensity on the concentration of lanthanum. The intensity of the A feature was compared with that of the undistorted $EuTiO_3$ cubic compound. In $EuTiO_3$, which is centrosymmetric, the intensity of the pre-edge A feature is very small [16]. This comparison PLT suggests that the local distortion around Ti atoms persisted as the amount of lanthanum increased, even in the PLT30 sample. Thus, the XANES results of all the samples containing lanthanum shows that Ti atoms were located in distorted sites.

With regard to the analysis of the B pre-edge feature, since we found no significant variation in its shape and amplitude when the content of lanthanum was increased, it is reasonable to assume that La atoms preferably replaced Pb atoms rather than Ti atoms. This assumption is in good agreement with our XRD results.

The magnitude of Ti atom distortion from the center of the oxygen octahedron can be evaluated by measuring the intensity of the A feature [16, 19]. The intensity of the A feature was extracted from the XANES spectra by least-square fitting in the interval from 4965 to 4980 eV. A single Gaussian function was used to model the A pre-edge feature. The results have an uncertainty of 0.1 eV in energy and 0.02 in intensity. Figure 2 compares the magnitude of Ti atoms distortion by measuring the intensity of the A feature present in the XANES spectra with the Ti atom distortion obtained from XRD data. The values of Ti atom distortion obtained from XRD data were obtained by making a difference between Ti-O distances situated along the c-axis divided by 2.

As illustrated in Figure 2, the amplitude of the distortion of Ti atoms decreased as the content of lanthanum increased and was in good agreement with Ti atom distortion obtained from XRD data for compositions containing up to 10% of La. For the PLT00 sample, the amplitude of Ti distortion was found to be equal to 0.29 Å, a very close value to that found by other authors [16, 19]. For the samples containing more than 10% of La, the amplitude of Ti atom distortion obtained by measuring the intensity of the pre-edge A feature indicate that a local distortion around Ti persisted, whereas the analysis of XRD data suggested that Ti atoms returned to the center of the TiO_6 octahedron, presenting a point $m\bar{3}m$ symmetry in the sample containing 30% of La. A certain structural discrepancy exists between XAS and XRD results concerning the PLT30 sample.

The same kind of discrepancy between XAS and XRD results involving local and long-range structural data was observed by Sicron *et al*. in their study of the nature of the ferroelectric phase transition in the $PbTiO_3$ compound [20]. Whereas the XAS results showed that the local distortion around lead and titanium atoms were nonzero above the transition temperature, the XRD data suggested that Ti and Pb atoms returned to the center of the atom site [20].

According to the literature, as long as some long-range order is present, the diffraction pattern is composed essentially of δ functions, even if structural disorder is present [16]. In this case, there is also a weak broad background, which is usually ignored. The disorder does, however, affect the relative integrated intensities of the various δ functions. Thus, in principle, the diffractogram do contain information on the disordered structural distortions. To obtain this information, it is necessary to introduce the disordered distortions to the fitting model and to have a sufficient range of k space to solve the disordered distortions. Since most X-ray diffraction powder models do not take disordered distortions into account, these experiments provided information only on the average structure.

4. Conclusions

The qualitative analysis of the XANES spectra indicated that the local structure around Ti atoms had a different compositional dependence than that indicated by the results obtained from the X-ray diffraction analysis. According to the XANES data, for the sample containing 30% of lanthanum, for which the XRD analysis clearly indicated the existence of a cubic structure, a local distortion around Ti atoms persisted. The intensity of the A feature of this sample decreased by a factor of only two when compared to the lanthanum-free sample. Our results are in good

agreement with the results obtained by Raman Spectroscopy, in which the existence of a local disorder in highly doped lanthanum samples was observed.

Abstract

Amorphous germanium (a-Ge) structure is known to show a complex behavior upon pressurization. Here an XAS experiment on a-Ge at high pressure and temperature is presented, which is aimed to investigate such behavior and verify the presence of "polyamorphism". High quality a-Ge EXAFS spectra (Ge K-edge) have been collected up to 8.3 GPa. The data analysis, realized using the GNXAS package, gives precise values of the first neighbor bond lengths at various pressures. Two well defined behaviors of the a-Ge local atomic structure have been observed, depending on the sample temperature. At 475 K a-Ge starts to crystallize above 8 GPa. On the other hand, at room temperature, the data seem to indicate the occurrence of a transition toward a different amorphous structure, well before the start of the process of crystallization.

1. Introduction

Elemental amorphous semiconductors (a-Si, a-Ge) play an important role in scientific and technological research since the 1960s. Great progresses have been made in the industrial applications of semiconducting materials, which are at the basis of the modern integrated device technology. Nevertheless the structural characteristics of these systems and their response to temperature and pressure are still subject of debate in condensed matter physics. Still today several questions are open, for example the existence of different pressure-induced amorphous phases (termed "polyamorphism") is not experimentally confirmed.

Here we focus our attention on amorphous Ge. a-Ge is known to undergo an abrupt decrease of the resistivity at 6 GPa and room temperature [1] due to a semiconductor-metal transition. This experimental result can be explained by a "two-fluid" model [2] based on thermodynamical calculations. Nevertheless there is still no experimental confirmation that the resistivity change is associated with a first order structural transition between a low density (LDA) and a high density (HDA) amorphous phase as obtained by numerical simulations. In the last 15 years several experimental and theoretical efforts have been devoted to shed light onto this matter, but no definitive results have been obtained [3, 4, 5, 6, 7, 8]. Differences in the results collected so far, could be related to the processes of "amorphization" used to obtain the a-Ge samples (melt quenching, ions sputtering, glow discharge, evaporation onto substrate). Depending on the preparation methods, different kinds of amorphous Ge structures can be generated which are characterized by different bulk densities [9], voids distributions and impurities concentration. Similar problems can affect computational models, because there are several ways to define the initial amorphous configuration in numerical simulations [10, 11].

Accurate experimental investigations on a-Ge polyamorphism are possible using X-ray absorption spectroscopy (XAS) which allows the study of subtle variations of local order. XAS is particularly suited to this scope due to its unique structural sensitivity. In the next sections we present a preliminary study of a-Ge local structure probed by XAS technique, covering a wide range of pressures between 0 and 8.3 GPa, at room temperature and at 495 K.

2. Experimental

The a-Ge measurements have been carried out at the ESRF, using the advanced set up available at the BM29 beamline [12] which is designed to collect simultaneously both X-ray absorption spectroscopy (XAS) data and energy-scanning X-ray diffraction (ESXD) patterns.

a-Ge samples of suitable thickness have been prepared by evaporation onto Kapton polyimide films of high-purity Ge. The deposition has been performed under high vacuum conditions (10^{-5} mbar) and the Kapton substrate was placed at about 5 cm from the Ge source. A mixture of BN and LiF powders, used as pressure markers, has been compacted in a 1.5 mm diameter cylinder with a small piece of wrapped Kapton/a-Ge foil, placed in a 2 mm graphite hollow cylinder and in a 7 mm boron-epoxy gasket to be used in the "Paris-Edinburgh" large-volume press.

High quality a-Ge XAS spectra (Ge K-edge) and related ESXD patterns have been collected up to 8.3 GPa, both at room temperature and at 475 K. The absence of Bragg peaks associated with Ge crystalline phases was confirmed by the powerful seven-channel collimator system available at BM29 (see [13] and ref. therein). Absence of sample oxidation was also confirmed by near-edge XAS spectra. The experimental XAS data have been analyzed using the GNXAS package [14, 15], taking into account the presence of double electron excitations in the atomic background and multiple scattering in the EXAFS signal [16].

3. Results and discussion

Two sets of EXAFS signals collected at various pressures up to 8.3 GPa are presented in figure 1, for two different sample temperatures (295 K and 475 K). The quality of the raw EXAFS signals is very good, also higher pressures, thanks to the advanced XAS set-up installed at the beamline BM29 (ESRF) [12]. The high sensitivity to the local structure which characterizes the XAS technique, make us able to detect very small variations in the a-Ge bond length and variance.

At room temperature (fig. 1 upper panel) the smooth decrease of the EXAFS frequency is associated with the compression of the first neighbor distance upon pressurization. Nevertheless, a clear increase of frequency, is observable above 8.0 GPa (P_c).

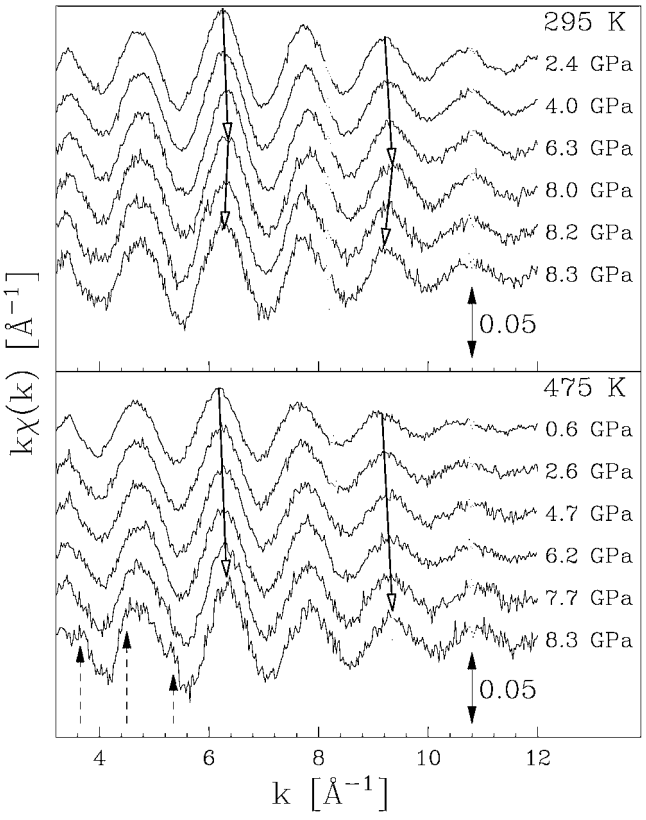

Fig. 1. EXAFS signals collected at 295 K and 475 K are shown at various pressures. The long arrows are drawn as guides for the eyes. At 295 K (upper panel) the signal frequency decreases gradually up to 8.0 GPa (P_c), then an increase of the frequency can be observed. At 475 K (lower panel) the signal frequency decreases gradually up to 8.3 GPa. The dashed arrows at low wave numbers (k) indicate the appearance of high frequency signals at 8.3 GPa.

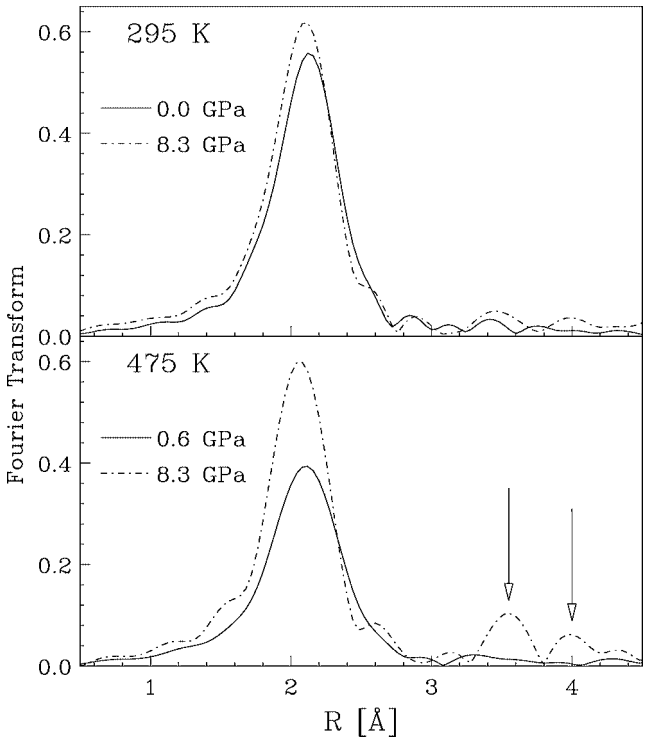

Fig. 2. Fourier transforms of selected experimental EXAFS signals. At 475 K (lower panel) the high frequency present in the total signal, causes the growth of two small peaks in the transform at $R \simeq 3.5$ Å, 4.0 Å (vertical arrows) which are not present at room temperature (upper panel). The position of the principal peaks is shifted due to the decrease of the main signal frequency.

This indicates the presence of a structural change. In order to investigate the nature of this change, the ESXD patterns collected above the transition pressure P_c have been analyzed confirming the absence of c-Ge diffraction peaks. Moreover high frequency multiple scattering signals usually present in ordered c-Ge crystals [16] have not been detected in the low k region of the EXAFS signals. A possible explanation of these findings is that at P_c a-Ge undergoes a structural phase transition toward another (denser) amorphous phase, as recently obtained by numerical calculations [5].

At 475 K the a-Ge structure shows a different response to the pressure (fig. 1 lower panel). In fact there is no sign of sudden modifications in the first neighbor distance, which gradually decreases upon compression. In the same figure a high frequency oscillation becomes evident in the EXAFS signal at 8.3 GPa for $k < 6\,\text{Å}^{-1}$ (dashed arrows in fig. 1 lower panel). This high frequency signal is probably due to the medium range order in the amorphous structure, which starts to increase above 8 GPa, but similarly to the room temperature case, the diffraction patterns do not show any evidence of c-Ge peaks at 475 K and 8.3 GPa.

In figure 2 the Fourier transforms of selected EXAFS signals are shown. The main difference between the room temperture (upper panel) and the high temperature (lower panel) results, is the presence of small peaks ($R \simeq 3.5$ Å, 4.0 Å) at 475 K and 8.3 GPa, which are due to the multiple scattering high frequency in the total EXAFS signal. Similar peaks have been detected in previous EXAFS experiments [7, 17] which studied the gradual crystallization of a-Ge at ambient pressure induced by high temperature annealing. In agreement with those experiments, we deduce that above P_c the simultaneous action of pressure and temperature has induced the ordering of the a-Ge structure. In our data the crystallization process is probably at the first stage and limited to small c-Ge embryos, noticeable only by the extreme sensitivity to the local environment of EXAFS and not visible by diffraction. Increasing the pressure further, we expect that the final process of crystallization can take place starting from these small crystalline clusters similarly to a nucleation process. It is remarkable that a limited increase of the temperature ($\Delta T \sim 200$ K), induces clear differences in the evolutions of the a-Ge structure upon pressurization. In fact in previous experiments [7, 17] traces of crystallization have been detected after annealing above $T = 675$ K.

In figure 3 the whole set of measured first neighbor Ge–Ge distances is presented. EXAFS offers a very accurate evaluation of these distances, which have been measured with a maximum uncertainty of ± 0.005 Å at both temperatures. As expected the average Ge–Ge distance in the hotter sample is larger. Also the overall trend of the experimental points in figure 3 as a function of pressure is comparable, indicating that the a-Ge bulk compressibility values at 295 K and 475 K are similar. The most remarkable difference is the sudden change in the Ge-Ge distance ($\Delta d_{\text{Ge-Ge}} \simeq 0.02$ Å) at P_c at room temperature, which is totally absent at 475 K. Although the first shell distance undergoes this unexpected elongation, the bulk density upon pressurization is expected to increase. This happens to c-Ge which changes at higher pressures from diamond ($N = 4$) to a denser β-tin structure ($N = 6$), characterizated by a longer first neighbor distance. Also a-Ge has been seen to crystallize at high pressure in the β-tin phase [4, 8]. Nevertheless in our case the coordination number of a-Ge increases only slightly ($N_0 = 4.0 \rightarrow N_{P_c} \sim 4.5$). Therefore one can conjecture that the HDA phase packing is more similar to

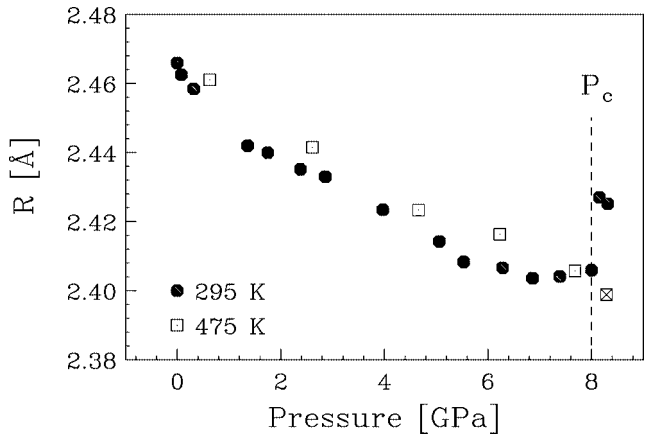

Fig. 3. First neighbor Ge–Ge distance in a-Ge obtained from EXAFS analysis at 295 K and 475 K. Above the transition pressure P_c structural changes take place at both temperatures: at room temperature the Ge-Ge distance becomes suddenly shorter indicating a drastic change of the amorphous structure, on the contrary at 475 K multiple scattering signals are detectable (crossed square) which could be associated to the starting of the process of crystallization. The maximum uncertainty affecting the data is ±0.005 Å at both temperatures.

a disordered ST12 [18] structure ($N = 4$), than a β-tin structure ($N = 6$), but more work is necessary to confirm this hypothesis.

4. Conclusions

Amorphous Ge structure has been analyzed at high pressure and temperature and the presence of a phase transition (at $P_c \simeq 8$ GPa) has been observed at room temperature, well before the crystallization. Upon this transition the a-Ge structure remains amorphous in agreement with existing numerical simulations. Other investigations are necessary for the high pressure phase in order to clarify its structural and electronic properties. At 475 K the a-Ge structure shows a different response to the pressure. The higher thermal energy, combined with pressurization, seems to favor crystallization at a pressure close to P_c, above which our results indicate the starting of the crystallization process. All these results have been obtained using the XAS technique which is a unique tool to investigate amorphous systems due to its high sensitivity to subtle modifications of the local atomic structure.

Abstract

Er doped Si represent an interesting class of materials for the realization of light emitting devices based on Si technology. The local structure around Er ions is known to strongly affect the luminescence properties of the Rare Earth. In this work the Er site in Er + O doped silicon samples prepared by Molecular Beam Epitaxy has been investigated by X-ray Absorption Spectroscopy at the Er L_{III} edge. Samples with different preparation parameters such as the O/Er ratio and thermal treatments were investigated. Data were fitted using a model consisting in a first shell of O atoms and a second shell of Si atoms and accounting for multiple scattering effects. The rare earth is found to be linked to 5–6 O atoms at around 2.23 Å whereas a well defined Er-O-Si bond angle of ≈136 deg is evidenced.

1. Introduction

Er doped Si has been extensively studied in the recent years due to its potential application in optoelectronics [1]. The $^4I_{13/2} \rightarrow 4I_{153/2}$ transition indeed occurs at 1.54 μm coinciding with one of the minimum absorption windows of commercial silica based optical fibers. This transition is forbidden by electrical dipole selection rules, but becomes possible whenever the Er ions is embedded in a non centrosymmetric environment and can be excited both optically [2] and electrically [3] in such systems. The major problem with the Er : Si system is the low solubility of this rare earth ion in the matrix being of the order of 2×10^6 Er/cm^2 [4]. Using non-equilibrium techniques to raise the Er concentration above the solubility limit (namely ion implantation) leads to the precipitation of Er in Er silicide [5, 6]. This compound, having cubic symmetry around the Er ion produces no luminescence from the Rare Earth. An efficient way to enhance the solubility of Er is in Si is the co-doping with O. In this way Er binds to O ions and concentrations as high as 10^{19} Er/cm^3 can be incorporated in crystalline Si [7]. In samples with Er : O ratio equal to 1 : 10, strong luminescence at 1.54 μm has been observed at 77 K, with a moderate quenching as the temperature is increased. The X-ray Absorption Fine Structure (EXAFS) technique [8] has revealed to be effective in describing the local site of Er in crystalline Si [5, 6, 9–11], and amorphous hydrogenated Si [12, 13]. These studies show that Er is generally 6-coordinated to O ions at a distance of 2.24–2.26 Å. When Er is coordinated to less O ions [12] the Er-O bond lengths shrink to 2.09–2.14 Å. The use of the Multiple Scattering formalism on the other hand, revealed extremely effective in describing the site of Er and Yb beyond the O shell in glassy matrices like silicate [14, 15] and phosphate [16] glasses. The aim of this study was to determine, the site of the Er ion in differently prepared Er + O doped crystalline Si samples by EXAFS.

Table I. *Description of the preparation and thermal treatments of the samples used in the present investigations.*

Sample	Nominal molar ratio O/Er	Annealing temperature	Annealing time
33	1.8	—	—
33E	1.8	900 °C	30 s
49	5	—	—
49E	5	900 °C	30 s

2. Sample Preparation

Samples were prepared by Molecular Beam Epitaxy (MBE) onto (001) oriented Czochralsky Si wafers. Si evaporation was carried out by electron gun in presence of an Er flux arising from an effusion cell and a molecular oxygen leak into the MBE chamber. A pure Si buffer layer 100 nm thick was always deposited prior to the Er : O co-doped layer whose thickness was in the range 240–270 nm. The substrate temperature during the growth was kept at 550 °C to ensure a good epitaxy. Two samples were also annealed to check the stability of the obtained layers. With this procedure $Si : Er_x : O_y$ layers with $x \approx 10^{-3}$ and $y/x = 1.8$ and 5 were grown as resumed in Tab. I.

3. Experimental Details and Results

The experiments at the Er L_{III} edge were carried out at the GILDA CRG beamline at the European Synchrotron Radiation Facility. The monochromator was equipped with a pair of Si(311) crystals and was run in the so-called *Dynamic Focusing* Mode [17]. This means that at each energy point the radius of curvature of the second crystal is changed in order to fix the focal position on the sample spot. Harmonic rejection was achieved by using a pair of Pd coated mirrors with an energy cutoff of 21 keV. The absorption coefficient was measured by collecting the fluorescence yield from the samples using a 13 elements Hyper Pure Ge detector at Liquid Nitrogen Temperature. For each sample 2 to 4 scans were collected and averaged to increase the Signal to Noise (S/N) ratio. Finally a spectrum on Er_2O_3 finely powdered and deposited on a millipore membrane was collected in transmission mode as reference compound. EXAFS spectra with the relative fits are shown in Fig. 1 whereas the Fourier Transforms (FT) are shown in Fig. 2. From these spectra it is evident the presence of a coordination peak at an apparent distance just below 2 Å due to the Er-O bond plus a further peak at ≈ 3.0 Å that can be ascribed to an Er-Si coordination. This is reasonably not due to a direct Er-Si bond, because in this case the related peak is usually observed at a somewhat shorter apparent distance, ≈2.5 Å as shown in the FT shown in [6, 10]. Thus, the hypothesis is made that Er is not

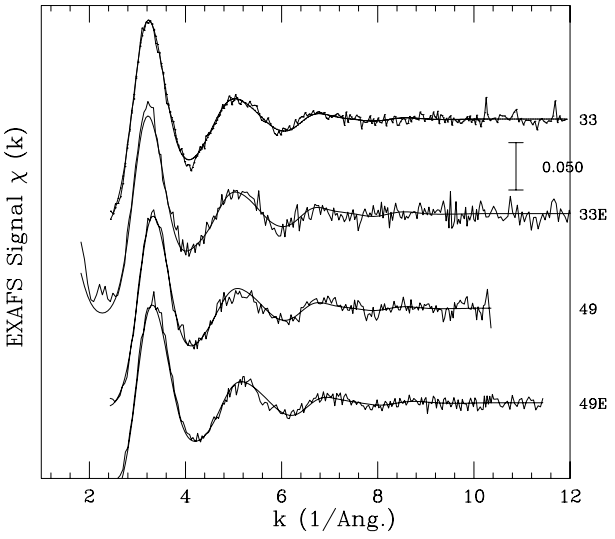

Fig. 1. EXAFS spectra of the samples with the fitting function superimposed.

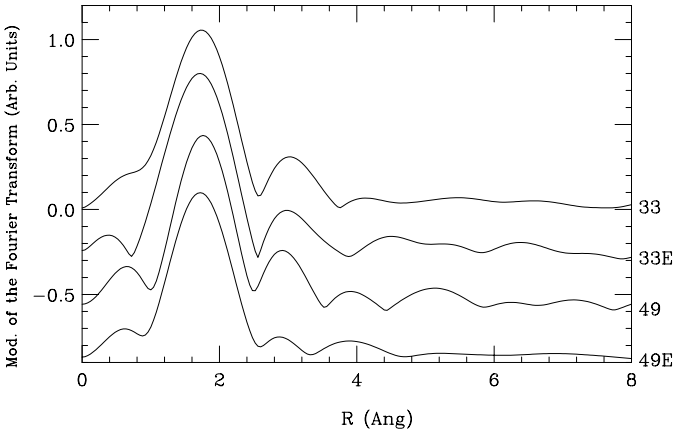

Fig. 2. Fourier Transforms of the EXAFS spectra. The transform was carried out in the range $k = 2.5 \ldots 9\,\text{Å}^{-1}$ using a k^2 weight.

directly bound to si but the interaction happens *via* the O nearest neighbor. Data analysis was carried out by using the GNXAS code [18, 19]. The theoretical signals were calculated from a cluster derived from the crystalline structure of $Er_2Si_2O_7$ [20]. Data were analyzed in an average range $k = 2.5 \ldots 11\,\text{Å}^{-1}$ working directly on the absorption spectrum. To reproduce the spectra we considered a Single Scattering (SS) Er-O path described by a bond length R_{Er-O} and Debye-Waller factor σ^2_{Er-O} and Multiple Scattering (MS) Er-O-Si path (that includes both the MS and the Er-Si SS path) described by the Er-O SS parameters plus the Si-O bond length R_{O-Si}, the Debye-Waller factor σ^2_{Si-O} and the angular parameters $\Theta_{Er-O-Si}$ and $\sigma^2_{\Theta Er-O-Si}$. The Er-Si bond length and Debye-Waller factors are derived automatically from these data by the program code. At each Er-O bond is thus associated one Er-Si and one triangular Er-O-Si bond. This comes from the fact that, being O bound to both Er and Si, a well defined Er-O-Si bond angle should exist as indeed found in glassy matrices [14, 16]. In the fitting procedure all the cited parameters plus the Er-O coordination number N_{Er-O} and the edge position E_0 were varied with the exception of σ^2_{Si-O} (fixed to literature data $0.0001\,\text{Å}^2$ [21]), and the R_{O-Si} and $\sigma^2_{\Theta Er-O-Si}$ parameters, defined in the fit of sample 33 and then fixed for the others. The s_0^2 parameter was defined in the fit of the Er_2O_3 compound ($s_0^2 = 0.92$) and then kept fixed. The results are shown in Tab II.

Table II. *Results of the quantitative fits. For all spectra $R_{O-Si} = 1.60$ Å, $\sigma^2_{Si-O} = 0.0001\,\text{Å}^2$ and $\sigma^2_{\Theta Er-O-Si} = 30\,\text{deg}^2$. Errors were determined by a χ^2 analysis with a confidence level of 95%.*

Sample	N_{Er-O} ±0.6	R_{Er-O} ±0.02 Å	σ^2_{Er-O} ±0.003 Å^2	$\Theta_{Er-O-Si}$ ±4 deg	R_{Er-Si} ±0.03 Å	σ^2_{Er-Si} ±0.007 Å^2
33	5.7	2.22	0.015	134	3.55	0.020
33E	5.5	2.23	0.014	137	3.60	0.018
49	5.0	2.23	0.013	135	3.58	0.019
49E	4.8	2.24	0.013	136	3.59	0.017

4. Discussion

All the samples exhibit the same local environment despite the different preparation conditions. This means that an equilibrium configuration is attained already during the growth and that successive thermal treatments have only minor effects on the local structure. An opposite situation was found in similar systems obtained by ion implantation [6] where the Er environment was found to progressively evolve from a silicide structure to an oxide structure under thermal annealing. In all samples the average site appears to be a 5–6 fold oxygen-coordinated Rare Earth ion with a first coordination shell of ≈2.23 Å. A high Er-O coordination is present also in samples with a nominal low O/Er ratio (33) and its origin is under investigation at present. A possible explanation could be the diffusion of O species present in the Si substrate that came in contact with Er like already found in Er implanted Czochralsky Si [5]. Further studies will be devoted to the elucidation of this point. A well defined Er-O-Si bond angle is found, of around 135 deg, leading to an Er-Si distance of ≈3.5 Å. The Er-O bond length falls in the typical range of previous investigations [5, 6, 9, 11] whereas the Er-Si distance and Er-O-Si the bond angle approach the values found in silicate ($R_{ErSi} = 3.59$ Å and $\Theta_{Er-O-Si} = 140$ deg) [14] and phosphate ($R_{ErSi} = 3.61$ Å and $\Theta_{Er-O-Si} = 143$ deg) [16] glasses. No evidence of a possible Er-Er coordination is found due to the dilution of the Er species in the matrix.

5. Conclusion

In this work the site of Er in Er + O doped Si samples obtained by MBE has been studied by EXAFS. Er is bound to 5 to 6 O neighbors linked in turn to Si atoms from the matrix. A well defined Er-O-Si bond angle of around 136 deg is found as already pointed out for glassy matrices.

Abstract

A number of Ag-bearing galena samples (PbS) has been investigated by Ag K-edge XAS in order to determine the Ag structural role within the host galena structure. Despite the very low absorber concentration and the high absorbance of the PbS matrix, XANES spectra were successfully collected for samples with Ag content down to 500 ppm. Theoretical spectra have been calculated with the CONTINUUM code in order to discriminate the contributions from Ag located in the two possible sites in the galena structure: the Pb site (located at Wyckoff position 4b, octahedral S coordination, site symmetry m3m), and an interstitial site (located at Wyckoff position 8c, tetrahedral S plus tetrahedral Pb coordination, site symmetry $\underline{4}3m$). Experimental spectrum of diaphorite (a Ag-bearing mineral phase forming nano- to micro inclusions in Ag-rich galena) have been used for comparison.

The XANES experimental spectra show two different types of Ag environment:

a) the samples with high Ag content display spectra similar to that of diaphorite, as evidenced by the theoretical spectra, suggesting that, when present in considerable amount, most of the Ag partitions into the diaphorite inclusions rather than entering the galena structure;
b) trace level Ag-bearing samples display spectra very different from that of diaphorite. In view of the absence of micro- and nano-inclusions in the latter samples (confirmed by electron microscopy), these spectra are taken as representative of the Ag environment in the host galena structure. In these samples the comparison between experimental and theoretical spectra shows that the spectrum can be interpreted as the sum of the two contributions from Ag located in the 8c and 4b positions in the galena structure, in approximately the same proportions. Therefore, the data suggest that in this type of galena sample, half of the Ag occupies the vacant Pb site whereas the remaining part is located in the interstitial 4b site.

1. Introduction

In spite of its precious metal nature, Ag can be present in sulphides as a trace impurity in solid solution. Of particular economical importance is the presence of Ag in natural galena (PbS), as this represents the major ore for the extraction of Ag world-wide. In galena, PbS, whose structure is NaCl-type, Ag partly can substitute for Pb, and partly can form micro-inclusions of diaphorite, a mineral phase of composition $Pb_2Ag_3Sb_3S_8$ where Ag is located in octahedral sites. Substitution mechanism in the galena structure can be attained by two exchange reactions [1]: the first, $2Ag^+ = Pb^{2+}$, can lead only to modest Ag content because at least half of the Ag should be located in interstitial sites; the second exchange reaction, $Ag^+ + (Sb, Bi)^{3+} = 2Pb^{2+}$, can lead to higher Ag contents. The investigation of the type of mechanism for Ag incorporation in the PbS structure is the aim of this study, which has been carried out on selected samples of natural galena, already chemically and structurally well characterized. The major analytical difficulty in this study is the very low amount of Ag in the galena matrix, below the electron microprobe detection limit (500 ppm) coupled with the presence of a heavy matrix (Pb). The determination of the role of Ag requires therefore the use of methods which are able to overcome this problems.

X-ray Absorption Spectroscopy (XAS) can give insight on the Ag structural role in the galena structure thanks to such characteristics as element-selectivity and sensitivity to the local structural and chemical environment around the absorber, even at low concentrations of the absorber and in presence of a matrix composed of heavy elements. However, the determination of Ag location in the galena host structure is an experimentally challenging task because of the very low Ag content involved, a problem we tried to overcome by using fluorescence detectors and very long acquiring time. To better characterize the experimental data and obtain structural information on the Ag location in the galena host structure we made use of theoretical XAS spectra, calculated using the structure refinements available.

2. Experimental methods

2.1. *Samples and their characterization*

A group of Ag-bearing galena samples has been selected among those currently available at the "Museo di Mineralogia e Litologia" of the University of Firenze (I) and the mineralogical collection of the "Dip. Scienze della Terra" of the University of Camerino (I). The samples were checked for purity by powder X-ray diffraction, whereas polished sections were examined by Scanning Electron Microscopy in order to check for the eventual presence of micro inclusions. Chemical compositions were obtained by means of a JEOL JXA 8600 electron microprobe operating at 15.0 kV and 10.0 nA, and with the electron beam focused to a radius of 10 μm. Data were corrected according to the method by Bence and Albee [2]. The data are averages of eight individual analyses, and show the GalYuk to contain 0.23 wt% Ag, whereas all the other samples contain less than 500 ppm Ag (which is the detection limit of Ag as measured with electron microprobe).

2.2. *Data collection and reduction*

Samples for XAS measurement were prepared by smearing finely ground powder on a kapton tape. XANES spectra were collected at the beamline BM-29 of the ESRF (European Synchrotron Radiation Facility) storage ring (Grenoble, F) operating at 6 GeV and with the ring current ranging from 150 to 200 mA. Radiation was monochromatised by means of two channel-cut Si (311) crystals. Spectra were recorded in step-scan mode measuring the incident beam intensity with a ionisation-chamber and the fluorescence yield with a high purity Ge detector. Scans ranged from 25200 eV to 25700 eV with a variable energy step in order to get a constant energy step in the XANES region and a constant K step in the EXAFS region. The reported spectra are the average of three different scans. A Ga filter was placed in front of the Ge detector in order to reduce the Pb fluorescence, thus avoiding the detector saturation and allow to analyze the trace amounts of Ag in the samples.

Experimental XANES spectra were reduced by background subtraction with a linear function and then normalised for atomic absorption on the average absorption coefficient of the spectral

region from 25600 to 25700 eV. Energy was calibrated against a standard of Ag metal (25514 eV). The threshold energy was taken as the first maximum of the first derivative of the spectra, whereas peak positions were obtained by calculating the second derivative of the spectra.

2.3. *Theoretical spectra*

Theoretical XANES spectra were calculated in the frame of the one-electron multiple-scattering theory of Lee & Pendry [3], with refinements and computational methods progressively introduced by Natoli *et al*. [4], Durham *et al*. [5], Natoli & Benfatto [6], Durham [7]. The calculations were carried out by means of the CONTINUUM code [4, 6] using clusters of increasing size till convergence was achieved (at about 5 Å from the absorber in this case). The cluster density has been defined according to Mattheiss [8] and the Coulomb part of the potential was obtained by superposition of neutral atomic charge densities using the Clementi & Roetti basis set [9]. We used the $Z + 1$ approximation (final state rule) to simulate the charge relaxation around the core hole in the absorber, and for the exchange-correlation part of the potential we used the energy- and position-dependent complex Hedin-Lundquist potential. Muffin-Tin radii were chosen according to Norman's criterion, and allowing a 10% overlap between contiguous spheres to simulate the atomic bond. Convolution has been obtained with a Lorentzian shaped function to account for the core hole lifetime.

3. Results and discussion

3.1. *Experimental spectra*

Representative Ag K-edge experimental spectra of the Ag- bearing PbS samples are shown in Fig. 1 along with the spectrum of a diaphorite sample, used for comparison. It is evident that the spectra can be divided into two groups: 1) spectra like that of GalYuk sample closely resembles that of diaphorite both in peak positions and intensity; 2) spectra like those of G-1786 (G-15653 and GaIBg) have a more complex shape than that of diaphorite, and display a larger number of more resolved peaks.

The resemblance of the GalYuk spectrum to that of diaphorite can be easily explained by the presence of diaphorite inclusions in this sample in the form of needles up to 200 μm long. The presence of diaphorite in this sample was known before XAS analysis and this sample was chosen and used therefore to indicate the effect on the XANES spectrum due to the local environment of Ag in diaphorite included in the galena structure. However, it must be noted that SEM microchemical analysis of the same sample revealed the presence of small amounts (below the electron microprobe detection limit) of Ag also in the PbS matrix, away from the diaphorite needles. The XANES spectra clearly indicates that most of the contributions to the spectrum are due to Ag located in the diaphorite inclusions, whereas the Ag diluted in the galena matrix, as expected, shows negligible contributions to the XANES spectrum.

The second type of spectra (G-1786 type) is certainly different from the diaphorite-bearing galena spectra. However, a more detailed interpretation, given the absence of standard materials, requires the use of theoretical spectra. This procedure will allow to give information on the site preference of Ag in the galena structure and how the individual Ag sites contribute to the total spectrum [10].

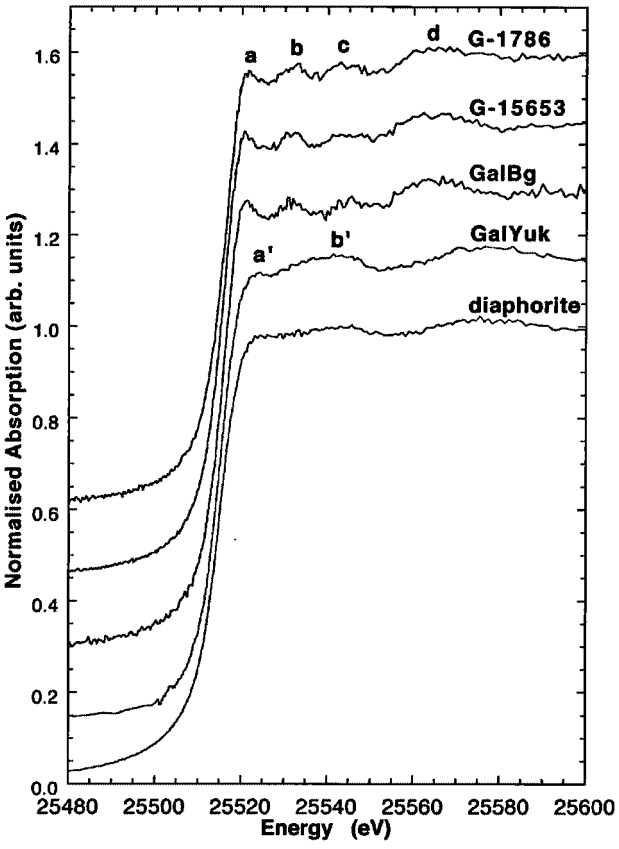

Fig. 1. Experimental Ag K-edge XANES spectra of Ag-bearing PbS samples along with a diaphorite standard.

3.2. *Theoretical spectra*

The theoretical Ag K-edge XANES have been calculated for two clusters of about 80 atoms up to 7.3 Å from the absorber. The calculations for Ag in the octahedral (Oh) and tetrahedral (Td) sites are shown in Fig. 2a. The spectra (dotted line) have been convoluted with a 6.75 eV wide lorentzian [11] in order to account for core-hole lifetime (solid line). Despite the severe dumping of the spectral features after convolution, the two spectra still differ significantly in shape, thus allowing to discriminate the contribution of each Ag site to the total spectrum. In particular, the contributions from the two sites differ both for energy position and intensity of the peaks in the edge region (about + 10 eV in the energy of the main peak between Oh and Td configurations), reflecting the different coordination environment, but also differ for the overall shape at high energy, due to the different structural and chemical composition of the two clusters used in the calculations.

3.3. *Discussion and conclusions*

The comparison of the experimental spectrum of Ag-bearing galena sample with the theoretical single site spectrum (Oh or Td) does not show a good agreement, suggesting that the substitution mechanism of Ag in the galena host structure cannot be related to a single site partitioning (Ag in Oh or in Td). Therefore, we can be certain that Ag in the galena structure cannot be located in only one site. Infact, a better agreement between experimental and theoretical spectra is obtained when using theoretical spectra calculated by combination of the two single site contributions in different proportions (Fig. 2b). The best fit has been found when comparing the experimental spectra with the weighted sum of 50% of Ag in the octahedral and 50% in the tetrahedral site (Fig. 3)

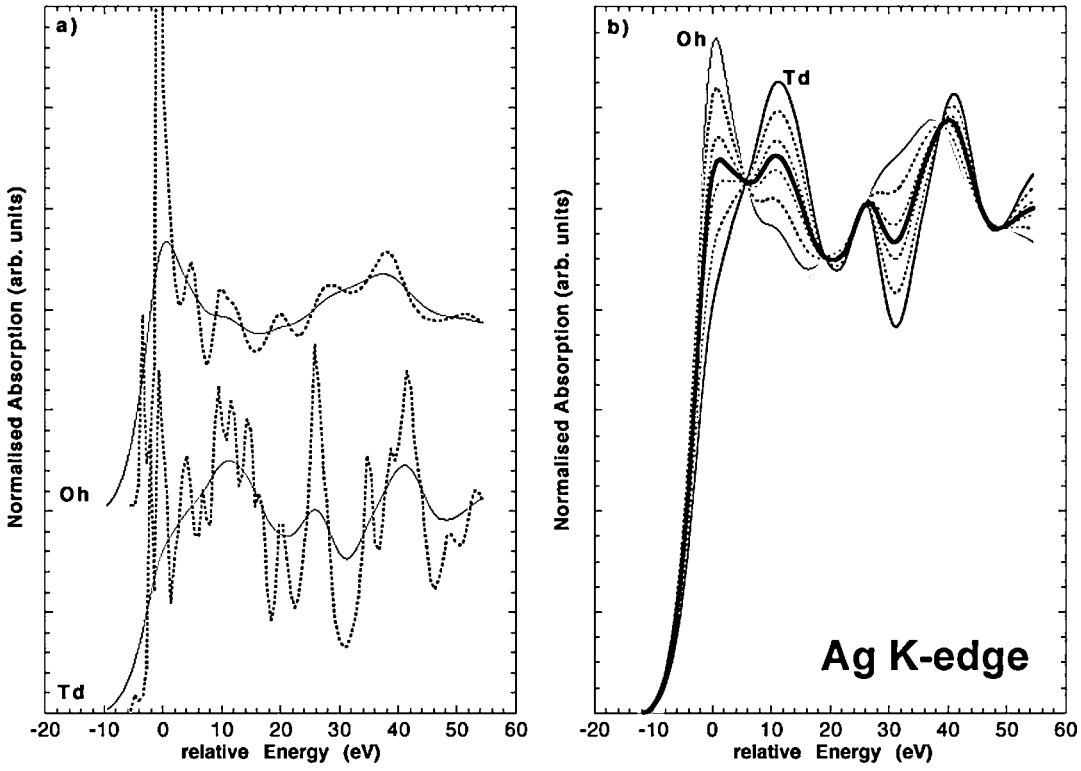

Fig. 2. a) Theoretical Ag K-edge XANES spectra for Ag located in the octahedral (Oh) and tetrahedral (Td) site in the PbS structure (see text). The theoretical spectra (dotted lines) have been convoluted by a 6.75 eV wide Lorentian to take into account Ag K-edge core-hole lifetime; b) weighted sums of the theoretical spectra: it can be clearly noted that the relative intensity of the two peaks at the low energy side change dramatically as a function of Ag partition in the two sites.

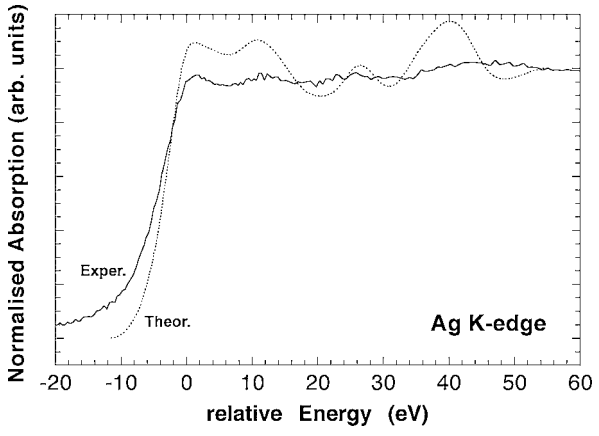

Fig. 3. Comparison between the theoretical and experimental Ag K-edge spectra. The relative position and intensity of the XANES features a and b are satisfactorily reproduced by a theoretical spectrum obtained by taking into account equal amounts of octahedrally and tetrahedrally coordinated Ag.

showing that the peak energy and intensity are well reproduced (peak b-peak a energy difference is 10.5 eV for the experimental and 11.2 eV for the theoretical). If we look at the ratio between the intensity of peaks b and a as another indication of similarity between the spectra [12, 13], we find that the values of this ratio in the experimental and in the theoretical spectrum are very close. These information are in favor of the goodness of the fit and strongly support the hypothesis that the $2Ag^{+} = Pb^{2+}$ exchange reaction can be considered appropriate for describing the presence of Ag in galena in the samples studied. In fact, from the XANES spectra we found the direct evidence that half of the Ag atoms is located in the octahedral sites, whereas the other half of the Ag atoms is located in the interstitial sites. This type of distribution appears to be realistic when Ag is in trace amounts in galena, whereas when Ag is more concentrated a Ag-rich phase like diaphorite segregates and the $2Ag^{+} = Pb^{2+}$ exchange reaction cannot take into account a higher proportion of Ag in the structure, as evidencd by the spectrum of sample GalYuk.

Regarding the second possible exchange reaction $Ag^{+} + (Sb,Bi)^{3+} = 2Pb^{2+}$, we did not detect Sb or Bi in our samples, not even in trace amounts. Therefore the investigation of this type of substitution has to be postponed until suitable samples will be found.

Abstract

Lithium intercalation and deintercalation in crystalline TiO_2-electrodes (rutile and anatase modifications) was investigated ex situ using grazing incidence reflection mode X-ray absorption spectroscopy in a specialized cell which permits the removal of the electrolyte and the subsequent measurement of grazing incidence X-ray absorption spectra under a protecting noble gas atmosphere. Small changes observed in near edge X-ray absorption spectra indicated that the Ti^{4+} ions are reduced by the electrochemical lithiation, depending on the TiO_2 modification, $Ti^{3.5+}$ states as well as Ti^{3+} states are observed for rutile and anatase, respectively. Angle dependent experiments reveal that the intercalation is not complete for rutile, while anatase seems to be fully intercalated. In addition, a certain amount of Li remains in the anatase electrode after a complete intercalation – deintercalation cycle. The results suggest that Li-ions are generally accumulated at the electrode/electrolyte interface during both intercalation and deintercalation.

1. Introduction

Rechargeable lithium ion batteries are attractive for their potential use as lightweight, compact energy storage device in applications ranging from portable electronics to vehicles. Therefore lithium ion insertion into metal oxides is one of the main objectives of recent battery research. In this contribution, we will report on ex-situ EXAFS studies of the electrochemical insertion of Li into smooth thin film TiO_2 rutile electrodes. The reversible storage of Li in TiO_2 finds its application in the use as anode material in non-aqueous rechargeable lithium batteries [1, 2]. Based on the change in color from transparent to dark blue when lithium is inserted, electrochromic devices can be realized using lithiated TiO_2 electrodes [3, 4]. In spite of the large number of studies, the origin of the electrochromic effect in Li- inserted TiO_2 remains unclear up to date. Compared to rutile, TiO_2 anatase can accommodate much more Li in its crystal lattice [5–8]. In fact, most of these studies report that hardly any Li inserts into bulk rutile at room temperature [5, 7, 8]. While the originally tetragonal anatase bulk phase undergoes an orthorhombic distortion upon Li insertion resulting in a lithium titanate structure characterised by the *Imma* space-group [9], the structure of Li-intercalated rutile has not yet been investigated in detail.

In this context, grazing incidence X-ray absorption spectroscopy is a well suited technique to obtain structural and electronic information about the electrode surfaces during the intercalation and deintercalation. Unfortunately, the parasitic absorption of the electrolyte is a significant drawback for real in situ studies at energies in the vicinity of the Ti K-edge (4966.4 eV) even if sophisticated detector equipment is employed at 3rd generation synchrotron sources. We therefore designed a new cell, which enables the electrochemical processing of samples which are sensitive towards oxidation by air or humidity. Additionally, it permits grazing incidence X-ray absorption experiments after the controlled emersion of the electrodes from the electrolyte; first results have been published recently [10, 11]. In this contribution, we will address the electrochemical intercalation of Li in two different TiO_2 modifications (rutile and anatase) and compare the observed structures.

2. Experimental

The X-ray absorption experiments were performed at the X-ray undulator beamline BW1 [12] at the DORIS III storage ring at HASYLAB (Hamburg, Germany) operating with 4.45 GeV positrons and injection currents of about 150 mA. The incident monochromatic X-ray beam from a Si(111) double-crystal monochromator with an energy resolution of about 0.9 eV was collimated to a vertical size of about 240 μm and 10 mm horizontally. Incident and reflected intensities were measured by means of argon filled ionization chambers. A second slit system in front of the second ionization chamber suppresses the intensity of non specularly reflected X-rays and shields this detector from the direct beam. All components of the reflectometer, i.e. the sample position, the angle of the detector arm and the slit system can be adjusted by stepper motors. The reflection mode XANES and EXAFS data were collected in the vicinity of the Ti K-edge (4966.4 eV) at ambient temperature. A Ti metal foil was measured in transmission between the second and a third ionization chamber in order to calibrate the energy scale of the monochromator simultaneously with each of the samples. Thin film TiO_2 working electrodes (thickness ≈25 nm, length 40 mm, width ≈25 mm) were prepared by RF sputter deposition on gold covered single crystal quartz substrates. Li intercalation was performed in an electrolyte consisting of 1 M $LiClO_4$ in propylene carbonate (PC). High purity copper wires served both as counter and reference electrodes in a three electrode compartment which is controlled by a potentiostat. Li intercalation and deintercalation was performed under potentiostatic conditions. After the electrochemical treatment, the electrolyte was removed from the samples surface and remaining electrolyte drops were removed by a jet of high purity He prior to the X-ray investigations. Rutile as well as anatase TiO_2, TiO, Ti_2O_3, $Li_4Ti_5O_{12}$ (Li-Ti-spinell) and $Li_{0.6}TiO_2$ samples – the latter with space group *Imma* (nr. 74, [9]) – were investigated in transmission geometry to obtain reference spectra. Further details are given elsewhere [10, 11].

3. Results and Discussion

In Figure 1(a), near edge XANES data determined from reflection mode spectra from a rutile electrode are presented for different

*e-mail: dirklh@uni-wuppertal.de

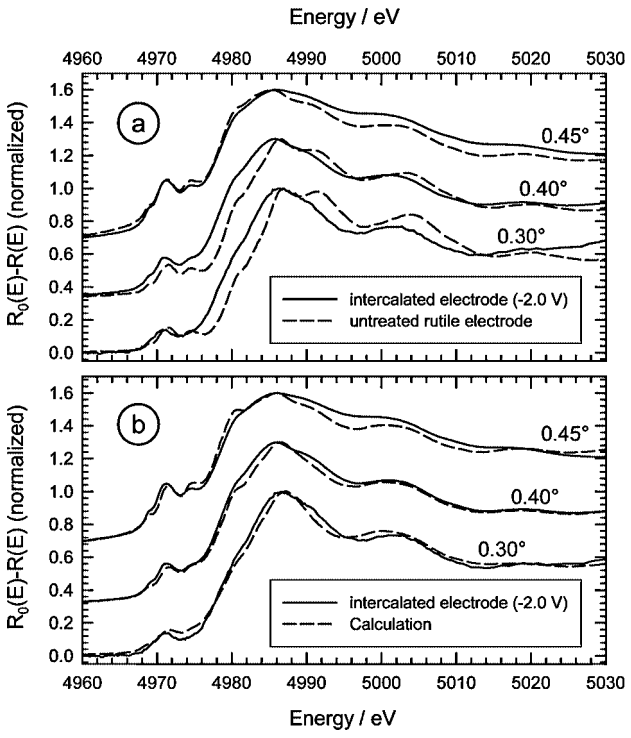

Fig. 1. (a) Comparison of absorption spectra determined as the normalized difference $|R_0(E) - R(E)|$ for the intercalated (-2.0 V for 1 h) and the untreated electrode for several glancing angles. (b) Comparison of the experimental XANES spectra of the intercalated electrode (full lines) to calculations for a multilayered structure (dashed lines) for different grazing angles as indicated. Assumed was a top layer of 5.7 nm $Li_{0.6}TiO_2$ on an underlying rutile TiO_2 layer with a thickness of 20 nm and a 12.5 nm thick gold backing electrode on the quartz substrate. (The spectra are shifted vertically by 0.3 for each angle for a better visualization.)

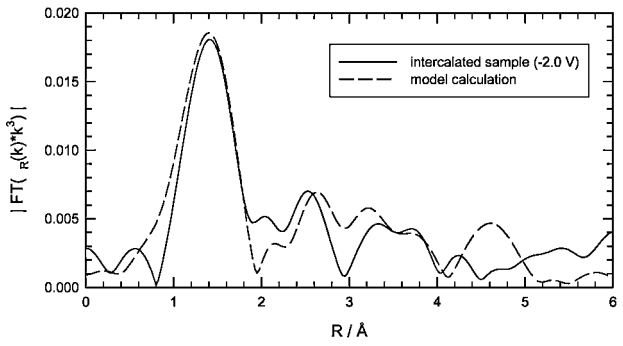

Fig. 2. Comparison of the magnitude of the Fourier- transform of the reflection mode fine structure spectrum of the intercalated rutile electrode ($\Theta = 0.30°$, full line) with that of a model calculation assuming a multilayered structure consisting of 5.7 nm $Li_{0.6}TiO_2$ on 20 nm rutile layer and 12.5 nm gold on the quartz substrate (dashed lines) (Data are not corrected for phase shifts. The k-range for the Fourier-transform is $2.2\,\text{Å}^{-1} \leq k \leq 10.2\,\text{Å}^{-1}$).

grazing angles. The spectra were calculated as the normalized difference between a linear pre-edge background $R_0(E)$ and the reflection mode XANES spectrum $R(E)$ in order to obtain a measure of the absorption (see ref. [10]). Spectra from the untreated electrode and intercalated rutile (-2.0 V vs. Cu) are shown.

Obviously, distinct differences between both data sets were observed, especially for $\Theta = 0.30°$ and $\Theta = 0.40°$. The most prominent is the shift of the absorption edge from about 4979.4 eV to about 4978.0 eV after the intercalation. The critical angle of total reflection is about 0.42°. Accordingly, the penetration depth of the X-rays amounts to ca. 3–4 nm at 0.30°, 5–10 nm at 0.40° to more than 50 nm at 0.45°. We can therefore conclude that the near surface region of the rutile is modified by the intercalation. The observed edge shift corresponds to a reduction of the rutile Ti^{4+} states to a Ti-valence of ca. 3.6 [10]. Thus a spinell type Li-Ti-O compound such as $Li_2Ti_2O_4$ [9] is very unlikely present due to its Ti^{2+} valence. Furthermore, significant changes can be observed above the edge, for example the double peaked structure in the spectrum of the untreated rutile electrode between ca. 4985 eV and 4992 eV was transformed to a single peak centered at about 4986 eV after the Li insertion. The comparison of the XANES spectra of the intercalated rutile electrode with those of other Li-Ti-oxide reference compounds and Ti-oxides shows that the near edge structures are very similar to those of $Li_{0.6}TiO_2$ [10].

We therefore conducted model calculations, results of which are presented in Fig. 1(b). For these calculations, the complex refractive index $n = 1 - \delta - i * \beta$ was extracted from transmission mode EXAFS spectra of the reference compounds by means of a Kramers-Kronig analysis, and the reflection mode spectra were calculated by applying the Fresnel theory for multilayered systems [13]. For the calculations shown in Fig. 1(b), a $Li_{0.6}TiO_2$ top layer with 5.7 nm thickness (t) on an underlying rutile TiO_2 layer ($t = 20$ nm) and a thin film gold backing electrode ($t = 12.5$) on the quartz substrate (dashed lines) was assumed. As can be seen, a good fit to the experimental data was achieved for all grazing angles. Therefore the structure of the Li intercalated rutile seems to be at least very similar to that of $Li_{0.6}TiO_2$. This is further supported by the results of reflection mode extended X-ray absorption spectra of the intercalated electrode. A typical result is presented in Fig. 2. Here, the Fourier-Transform of the reflectivity fine structure $\chi_R(E)$ extracted from the experimental data is compared to that of a model calculation. It has to be mentioned that similar calculations were performed using multilayered systems with different Li-Ti-O compounds and Ti-oxides such as $Li_2Ti_2O_4$, $Li_4Ti_5O_{12}$, TiO and Ti_2O_3. However, these calculations only fit poorly to the experimental data. Therefore it can be concluded that the structure of the lithiated rutile layer is very similar to that of $Li_{0.6}TiO_2$ (anatase type space group imma, [9]) in which Ti has a valence of 3.5 and Ti is surrounded by 6 nearest neighbour oxygen atoms in a strongly distorted octahedron with bond distances between 1.94 Å and 2.13 Å, and two different Ti-Ti coordination distances at 2.89 Å and 3.13 Å.

A completely different picture was observed for Li intercalation in anatase TiO_2. First of all, the electrochemical intercalation occurs for a significantly smaller negative potential, i.e. the intercalation requires a significantly smaller overpotential compared to Li intercalation in rutile. XANES spectra calculated from reflection mode EXAFS spectra measured after lithiation at -1.6 V (vs. Cu) for 1 h are presented in Fig. 3(a). In this figure, we also show XANES data of the untreated anatase electrode and data measured after a galvanostatic deintercalation (20 min with a current density of about $1\,\mu A/\text{cm}^2$).

The dramatic shift of the absorption edge towards smaller energies after the intercalation is evident. We obtained a value of 4976.2 eV compared to 4979.0 eV for the untreated electrode. This value corresponds well to the position of the Ti_2O_3 absorption edge at 4976.0 eV, i.e. the presence of a Ti^{3+} species is very likely after the intercalation. To our best knowledge, Li-Ti-oxide reference compounds with a Ti^{3+} valence have not been reported up to now. Therefore we simply compared the derivative spectrum of the intercalated anatase electrode with that of polycrystalline Ti_2O_3 measured in transmission in Fig. 3(b). The similarity of both derivative spectra is evident: Both derivative spectra show

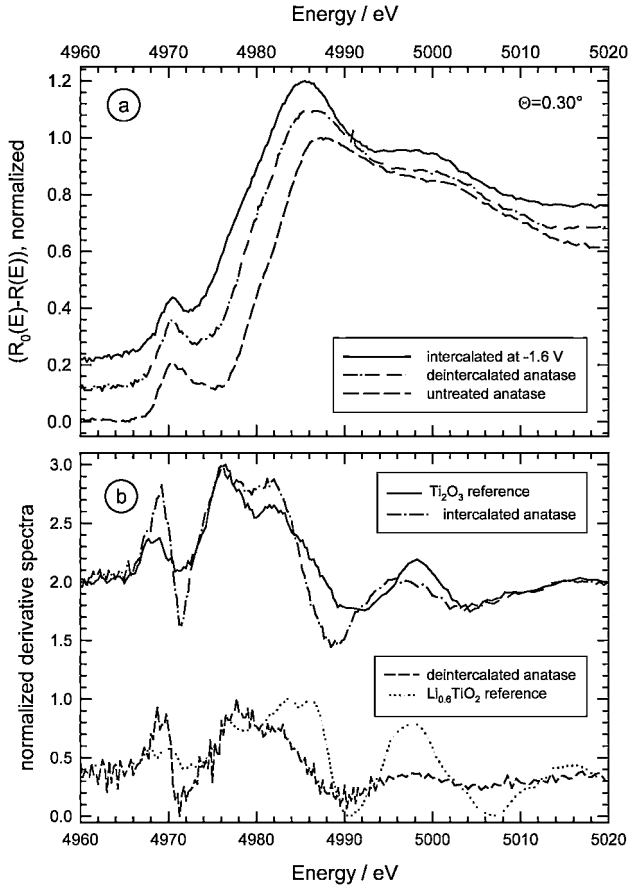

Fig. 3. (a): Normalized difference spectra $(R_0(E) - R(E))$ obtained ex situ from an anatase TiO_2 electrode in 1 M $LiClO_4$ in propylene carbonate for a glancing angle $\Theta = 0.30^\circ$ for untreated anatase, the intercalated and the deintercalated electrode. (b): Comparison of derivative spectra of the intercalated and deintercalated anatase sample with those of reference compounds measured in transmission.

minima and maxima at very similar energies. It should be noted at this point, that the effect of the anomalous dispersion influences the intensities of the peaks derived from the reflection data which might therefore be different [10]. Nevertheless, we can conclude from our measurements that the Ti atoms at the surface of the intercalated anatase electrode have a very similar electronic structure compared to Ti_2O_3 as was proved by preliminary model calculations using a layered structure with a Ti_2O_3 top layer of 4–5 nm thickness.

After deintercalation, an edge position of about 4978.2 eV was found. This energy corresponds well to that of the $Li_{0.6}TiO_2$ reference (4977.6 eV). Also the derivative spectrum of the deintercalated electrode is very similar to that of $Li_{0.6}TiO_2$. Thus the anatase electrode is not completely discharged but some of the intercalated Li remains within the sample. Angle dependent measurements show that the edge shifts to higher values for higher grazing angles, i.e. a larger X-ray penetration depth. Thus it can be concluded that the inserted Li is accumulated at the outer surface towards the electrolyte during deintercalation. The same observation was made for the intercalated material, i.e. the oxidation state seems to increase with increasing distance from the electrode/electrolyte interface. Therefore it can be deduced that only a surface layer of the lithiated material is in the Ti^{3+} state. More detailed model calculations are however necessary to clarify this point.

Abstract

The structures of polyacetylene (PA) films with oriented chains have been intensively investigated with linearly polarized carbon K-edge near edge X-ray absorption fine structure (NEXAFS) for the first time. The angular dependence of linearly polarized peak feature has been observed from normal to glancing incidence, with respect to the stretched direction of the PA film. The polymeric chain orientation of the stretched *trans*-PA has been determined with the strong angular dependence of $\pi^*_{C-C}, \sigma^*_{C-H}$, and π^*_{C-C} resonance. Heavily doped PA films with 6% $FeCl_4^-$ or ClO_4^- show different near-edge peak features from the undoped PA films, especially in the energy region of ~285 eV corresponding to electronic transition of C ls electron to unoccupied π^*_{C-C} molecular level. Upon doping, the resonance peak position for sp^2 hybridization of unsaturated C−C bonding is shifted to higher energy and the peak intensity is reduced significantly, which indicates that the cleavage of conjugated π bonds by p-doping occurs in the *trans* polymeric chain reducing the alternating double bond chain length. Although the peak features for σ^*_{C-H} and σ^*_{C-C} have been effectively changed, no angular dependence of the NEXAFS spectra are observed in the doped PAs.

Polyacetylene (PA) is the simplest sp^2-hybridized conjugated system and is therefore of special fundamental importance. From the first discovery of the insulator-metal transition by doping [1], PA has been widely studied both experimentally and theoretically [2]. At low doping level, the soliton-based conduction process is known to be dominant and yet the electronic structure in the heavily doped regime is not well understood due to the complex morphology of the randomly entangled fibrillar morphology of PA film [3]. Recently, the photo generation of soliton pairs has been well demonstrated in femto-second spectroscopy study [4]. Also the low temperature *I–V* characteristics of PA nanofiber has been investigated under magnetic field to understand the intrinsic conduction mechanism [5].

On the one hand, spectroscopic research of soft X-ray absorption, mostly concentrated on carbon K-edge, has been carried out for the quantitative study of the local structure in various organic-inorganic materials, such as chemisorbed molecules [6, 7, 8] and polymeric systems [9, 10, 11]. Direct information of unoccupied molecular level can be obtained from the intensive absorption peaks of carbon K-edge near-edge X-ray absorption fine structure (NEXAFS). The electric dipole-allowed transitions of ls electron to molecular orbitals provide a direct spectral probe of nature as well as the orientation for various chemical bonds in the materials. In the present study, spectroscopic studies of p-doped PA films with oriented chains have been carried out with linearly polarized carbon K-edge NEXAFS for the first time to investigate the local distortion of polymer chains around the dopant ions.

High-density PA films are synthesized according to the modified Shirakawa method [12], which is described elsewhere in detail [13, 14]. The PA films were oriented by stretching with $l/l_0 \sim 2$–3 or $l/l_0 \sim 5$–6, where l is the final stretched length and l_0 is the unstretched length. The oriented samples were doped with $FeCl_4^-$ or ClO_4^- from solution up to a saturation level of ~ 7–8 *molar%* Carbon K-edge NEXAFS measurements on the PA films were performed on the BL2B1 beamline in the storage

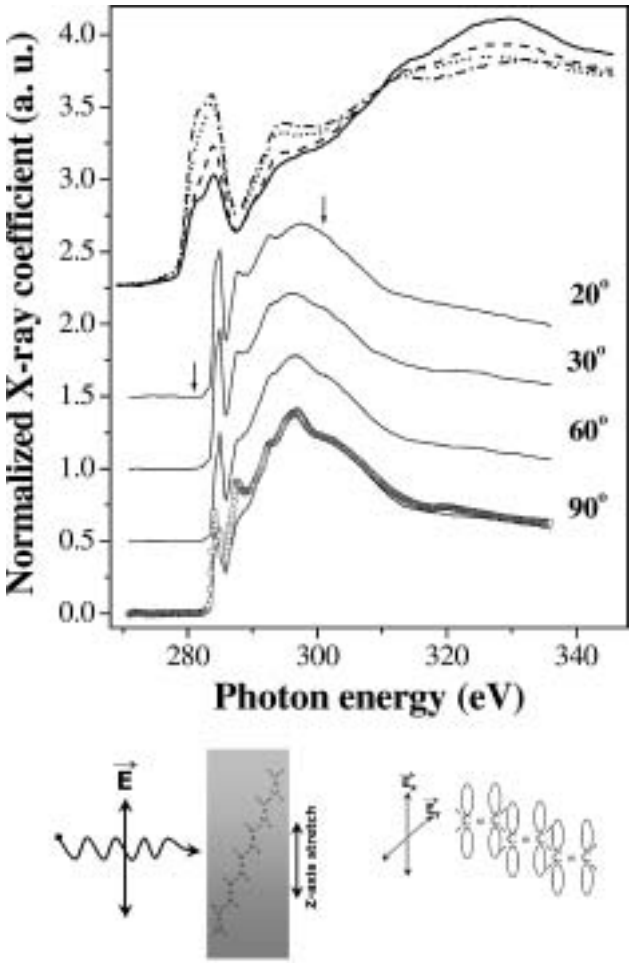

Fig. 1. Angular dependence of Carbon K-edge NEXAFS spectra for 2 times-stretched *trans*-form PA film. In the normal incidence angle, the electric field vector ***E*** of linear polarized X-ray is paralled to the hydrocarbon chain orientation. The open circles mean unstretched *trans*-PA film. The upper NEXAFS spectra from 281 to 301 eV have been magnified for clarity.

ring of 2.5 GeV with ring current of 120 ∼ 160 mA at Pohang Light Source (PLS). The PA film with thickness of about 10 μm was attached on Ta foil substrate. The NEXAFS were taken in a total electron yield mode by recording the sample current. The energy resolving power ($E/\Delta E$) in the entire measurement range was greater than 2000. The base pressure of the experimental chamber was in the 10^{-9} torr range. The experimental spectra were normalized by a reference signal from Au mesh with 90% transmission. The angular dependence of stretched PA films on linearly polarized incident X-rays has been obtained by rotating from normal to 20° with respect to the plane of the PA film.

Trans- and *cis*-form PA films with oriented chains have been intensively investigated with linearly polarized carbon K-edge NEXAFS. Figure 1 shows NEXAFS spectra of PA films for incident X-ray angles from normal to 20° with respect to the electric field vector E. The angular dependence of NEXAFS spectra for 2-times stretched PA film is presented in Figure 1, in comparison with those of pristine *cis*- and *trans*-PA films. Since the linearly polarized X-ray is very sensitive to C-H and C-C orientations within the hydrocarbon frame, the peak position and the intensity give important structural information about the chemical bonding between atoms.

The NEXAFS spectra show a typical absorption peak feature of unsaturated hydrocarbon with three kinds of resonance for $\pi^*_{C-C}, \sigma^*_{C-H}$, and σ^*_{C-C} levels. In the present PA films, the intense absorption peak (peak A) at ∼285 eV corresponds to electronic transition of carbon ls electron to unoccupied π^*_{C-C} molecular orbital (MO) level [15, 16]. The appearance of the π^* resonance indicates a distinct existence of a conjugation system, -[HC=CH−CH=CH]$_{n-}$, in the PA film. The broad higher energy peaks (peaks B and C) above 285 eV can be assigned to σ^*_{C-H} and σ^*_{C-C} MO levels, respectively. The intensity of peak A gradually increases with the incident X-ray angle, from normal to glancing ($\Theta \sim 20°$), meaning the systematic increase of interaction between the p-orbital for π bonding and the incident X-ray. The rotation to glancing leads to an increase of the peak intensity for σ^*_{C-H} resonance and a decrease for the σ^*_{C-C} resonance.

Such angular dependence of NEXAFS spectra can be described with the relationship between the PA chain orientation and the ***E*** vector of linearly polarized X-ray. For oriented molecules, the C−H or the C−C resonance generally exhibits a large angular dependence for electric field vector ***E*** parallel to the chain direction. When the C−C bond of saturated hydrocarbon is in the basal plane, the intensity of σ^*_{C-C} resonance is relatively large. However, the intensity of σ^*_{C-H} resonance is small since the bonding orientation is perpendicular to that of the C−C bond. For unsaturated hydrocarbon, the angular dependence is similar to that of the saturated hydrocarbon although both C−H and C−C bonds exist within the basal plane with sp^2 hybridization.

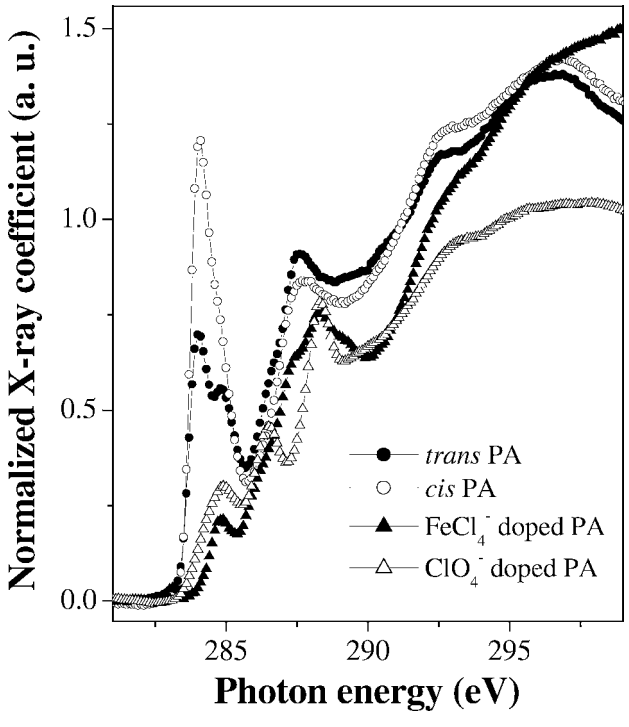

Fig. 2. Carbon K-edge NEXAFS spectra for *p*-doped PA films for normal incidence.

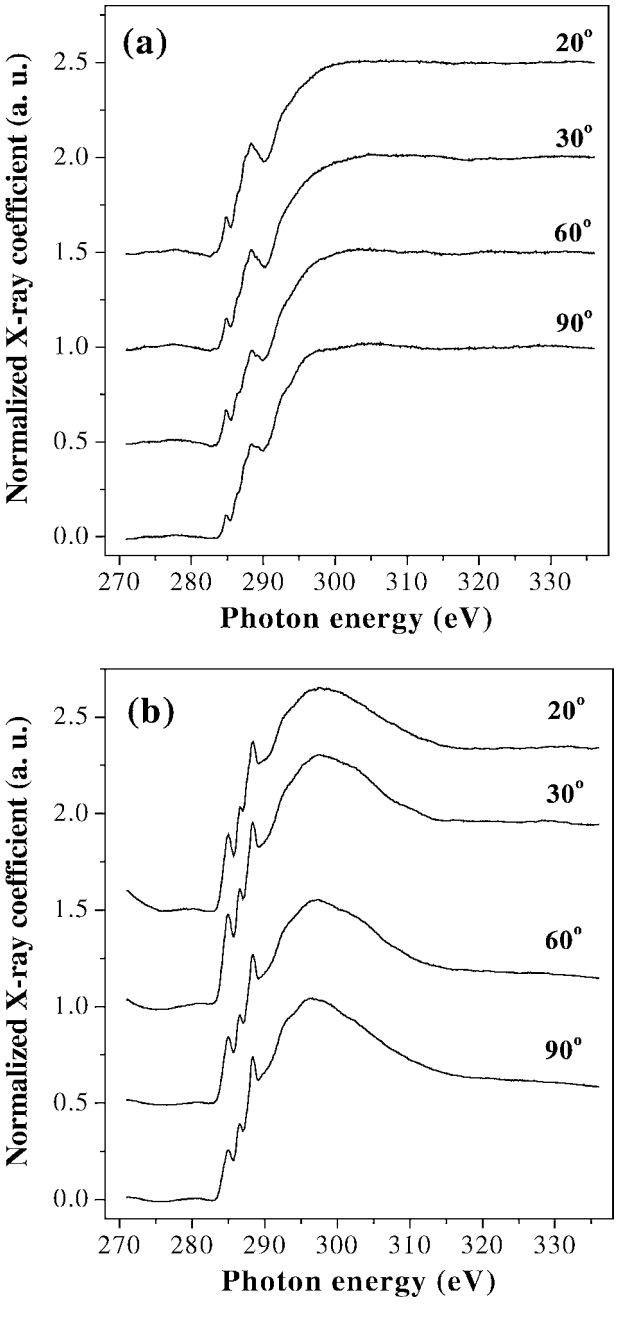

Fig. 3. Carbon K-edge NEXAFS spectra for (a) $FeCl_4^-$ and (d) ClO_4^--doped PA films with 2 times-stretch from the normal incidence angle to 20°.

In the present study, the PA chain orientation by stretching has been determined with the angular dependence of NEXAFS, based on earlier spectroscopic results of other organic materials [6, 7, 8]. The spectral change of PA film with respect to the incident X-ray angle directly shows a preferred orientation of the hydrocarbon chain, here $-$HC=CH$-$CH=CH$-$ acetylene chain. The σ^*_{C-C} resonance is dominant at glancing incidence of $\Theta = 20^\circ$, as shown in Figure 1. It means that the π conjugated orbitals are oriented nearly normal to the surface plane, which can be supported with the intensity variations of σ^*_{C-H} and σ^*_{C-C} resonance peaks.

Figure 2 shows NEXAFS spectra of p-doped PA films measured parallel to the hydrocarbon oriented direction. The results are compared to those of pristine *trans*- and *cis*-PA films. $FeCl_4^-$ or ClO_4^- doped PA films show different near-edge peak features from those of undoped PA film, especially in the energy region of $\sim$285 eV corresponding to the unoccupied π^*_{C-C} molecular level. Upon doping, the resonance peak intensity for sp^2 hybridization of unsaturated C=C bonding dramatically decreases and the peak position is shifted to the higher energy side, which indicates that the cleavage of conjugated π bonds by p-doping occurs in the *trans*-PA chain reducing the chain length of the alternating double bonds. The weak π* resonance means coexistenc of unsaturated and saturated C$-$C bonding in the p-doped PA films. The peak features for σ^*_{C-H} and σ^*_{C-C} have also been effectively changed in the doped PAs.

For the 2 times stretched p-doped PA films, however, no angular dependence of the peak feature has been observed from normal to glancing incidence angles, as shown in Figure 3. The peak intensities of the π* and σ* resonances are non-sensitive to the incident angle and the chain orientation, unlike in the case of both *trans*- and *cis*-PA films, which shows strong angular dependence of π^*_{C-C}, σ^*_{C-H}, and σ^*_{C-C} resonances.

The angle independent spectra for p-doped PA films are related to the disappearance of C=C bonding and to the increase of bonding disorder by local structural distortion, upon doping. The introduction of dopants into well-ordered hydrocarbon chain leads to local distortion around the doping site *i.e.*, creating solitons in the chain. The long range order of C$-$C, C$-$H, and C=C bonding breaks down, which causes a short range order around the doping site in the ordered PA films.

In summary, angular dependence with linearly polarized X-ray has been observed for *trans*-PA with preferred orientation from normal to glancing incidence. The strong angular dependence shows polymeric chain orientation of the stretched *trans*-PA. Upon $FeCl_4^-$ or ClO_4^- doping, the cleavage of conjugated π bonds by p-doping occurs in the *trans* polymeric chain. For p-doped PAs, NEXAFS spectra are independent of incident X-ray angle, in spite of the effective spectral change in doped PAs with respect to those of *trans*- and *cis*-PA films.

Abstract

The highly localized 4f electrons play an important role in forming of the electronic structure and properties of compounds. The 3d photoabsorption and resonant decay spectra of Cs halides represent an interesting case showing both the localized and spatially extended f wavefunction features. We present and discuss the Cs 3d X-ray absorption and resonant photoelectron emission spectra of the Cs halides. The Cs 3d absorption spectra exhibit a strong atom-like shape resonance behavior, solid-state effects play a minor role. The appearance of the spectral features, which are intrinsic to a localized state, in the decay spectra show that the Cs 3d photoelectron, temporally and spatially trapped in the Cs 3d shape resonance due to the potential barrier for εf electrons near threshold, has substantially localized nature.

1. Introduction

The highly localized 4f electrons play an important role in forming of the electronic structure and magnetic properties of lanthanide compounds. It is shown [1] that the localization of the 4f wave function may take place at 3d and 4d excitations also in pre-lanthanides where the 4f electrons are not present in the ground state. The collapse, *i.e.* sudden compression of the radial wave function of 4f electrons arises because of specific, double-well features of the effective potential for 4f electrons. In the 3d spectra the collapse of the 4f wave functions is expected to show up along the series Xe to Ba. Experimental results on the 3d photoabsorption of xenon-like ions I^-, Cs^+, Ba^{2+}, and La^{3+} in various halides [2, 3] show the collapse of the 4f wave functions in Ba halides. The 3d photoabsorption spectra of Cs halides represents an interesting intermediate case showing both the bound state and continuum features in the spectra.

To understand the nature of the photoabsorption at the 3d edge of Cs, we performed a careful study of the nonradiative decay processes at the 3d photoabsorption edge of the Cs halides by using resonant photoemission spectroscopy. The photoemission spectra have been recorded, over an energy domain of 150 eV covering up to the 4d levels, for selected exciting photon energies along the Cs 3d absorption curves. We use Hartree–Fock (HF) calculation in conjunction with the Watson sphere model to demonstrate potential barrier effects on the development of shape resonances in 3d photoabsorption spectrum.

2. Experiment

The experiments were performed on the beamline D1011 at the MAX-II storage ring. The electron spectra are excited by a photon beam from a modified SX-700 plane-grating monochromator with an energy resolution 0.2 eV at the caesium M_5 edge (around 730 eV) and analyzed by a hemispherical electron spectrometer Scienta SES-200. A 200 eV pass energy gave a kinetic energy resolution of about 0.2 eV. The thin films ∼100 Å of Cs halides were prepared in situ by thermal evaporation onto a polished stainless steel substrate in a preparation chamber at a pressure 10^{-7} Torr, and then transferred to the experimental chamber operated at a pressure 10^{-10} Torr. The Cs M_{45} absorption spectra were obtained by measuring X-ray-induced photoconduction current through the sample.

3. Results and discussion

Figure 1 shows the photoabsorption spectrum of Cs halides. The vertical bars mark the energy positions of the Cs $3d_{5/2}$ and $3d_{5/2}$ thresholds in Cs halides, which were found by measuring Cs 3d binding energies with respect to the top of the valence band and adding the band-gap energies [4]. The measured absorption

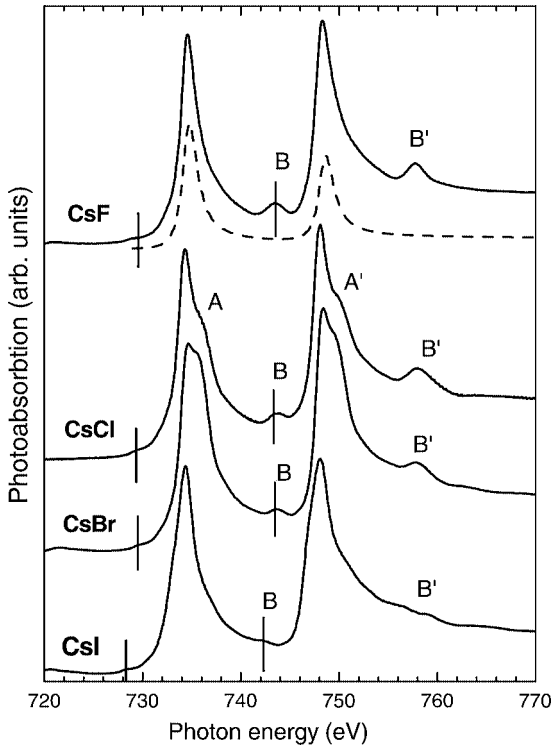

Fig. 1. Cs 3d X-ray absorption spectra of Cs halides (solid line). Vertical bars indicate the binding energies for Cs $3d_{5/2}$ and $3d_{3/2}$ levels relative to the conduction band. The calculated Cs^+ 3d subshell photoionization cross-sections (dotted). A value of −0.31 a.u. = −5.7 eV for the depth of the Watson sphere was used in calculating the cross-sections. A shift of 2.1 eV in the energy scale for the calculated curve was applied to align the first peak with the experimental one.

*e-mail: rein@fi.tartu.ee

spectra exhibit two strong peaks, asymmetric toward the high-energy side bands corresponding to the Cs $3d_{5/2}$ and $3d_{3/2}$ photoexcitations. These peaks are clearly above the ionization thresholds, thus the final states can be considered as the continuum states. In contrast to CsF and CsI where the main M_4 and M_5 peaks are similar to those found for the Cs atom [5], in CsCl and CsBr we see the high-energy shoulders (labeled as A and A' in Fig. 1) of the main line. These additional structures reflect the influence of the solid-state environment on the potential barrier for f electrons.

The experimental spectra show also two additional peaks (labeled as B and B′ in Fig. 1), which are very weak in CsI and are strongest in CsF. Since these peaks are absent from the atomic spectrum, the presence of these peaks should presumably be ascribed to the solid-state effects.

The absorption spectrum exhibits also a weak structure near the Cs $3d_{5/2}$ threshold. From the energy considerations it follows that this weak band may be due to transitions to the εp continuum of conduction band states.

The Hartree–Fock calculation of the 3d excitations shows that 4f orbital is collapsed in the free Cs^+ ion. But in crystals ions are completely screened by the surrounding ions. In the simplest approximation the electrostatic screening effects due to the solid environment can be described theoretically by the Watson sphere model [6]. In this model, the crystalline environment of an ion is approximated with a spherical shell of charge centered at the ion. The charge on the sphere is chosen to be equal in magnitude but opposite in sign to the charge of the ion.

For the present study, we modified the HF configuration average code of Cowan [7] by including Watson sphere model. Our calculations of the 3d excitations for the Cs^+ ion using the HF approximation in conjunction with the Watson sphere model show that the radial part of the 4f wave function crucially depends on the depth (V_c) of the potential well; if V_c becomes greater than -5 eV the mean 4f radius abruptly increases from 1.5 to 17 a.u. [8], i.e. 4f orbital becomes uncollapsed. Such strong changes we can see also for the 3d excited continuum states with f symmetry.

In Fig. 2 we display the results of the calculations of the photoionization cross section for the Cs^+ ion for different values of V_c . The curves show the development of the delayed onset of absorption for Cs^+, which is caused by the effective radial potential barrier effects for εf electrons. An electron excited above the 3d threshold into the εf channel will have to tunnel through the centrifugal barrier before it can escape from the atom. The increase of the depth (V_c) of the Watson potential well leads to the increase of the potential barrier for f electrons. At low kinetic energies of the εf photoelectron, the potential barrier prevents penetration of the εf wave into the inner region of the ion. Hence, the 3d-εf overlap is small as is the 3d → εf photoionization cross section. For higher kinetic energies, the εf probability strongly increases in the spatial region of the 3d electrons as also the 3d-εf overlap and the 3d → εf cross-section.

Another interesting feature to note in Fig. 2 is a gradual increase of width and asymmetry of the shape resonance with increasing height of the potential barrier. In the region of relatively small heights of the potential barrier, i.e. with $-V_c$ in the range of about 0.2–0.3 a.u., the intensity of the photoionization is concentrated in a narrow single peak that looks like a bound state. Note that in contrast to the strong potential barrier effects exhibited in the εf channel photoionization, the εp channel photoionization shows only very weak dependence on the choice of the parameters of the Watson sphere and is several orders of magnitude smaller than the εf channel cross-section.

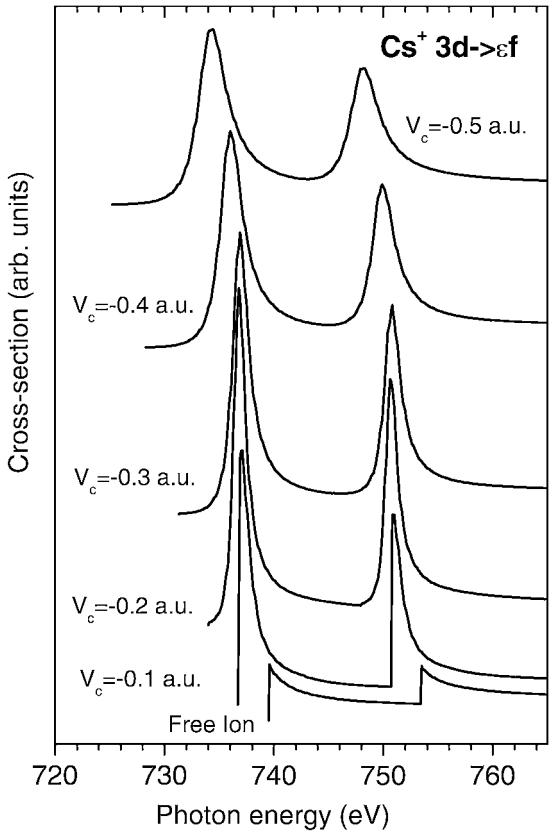

Fig. 2. Theoretical Cs^+ 3d photoionization cross sections calculated for different values of the depth of the Watson sphere V_c.

Unfortunately, the choice of the parameters of the Watson sphere (V_c) for a particular compound is substantially optional. Nevertheless, for the ionic crystals the physically justified parameters associated with the Watson sphere are the total charge Q, which equals the ionicity of the ion, and the $-V_c$, which is equal to the Madelung potential in the ion site, i.e. the potential ($-V_c$) at the ionic site coincides with the Coulombic crystal potential at that site. In Fig. 1, for CsF we show the comparison of the calculated photoabsorption cross-sections by using the Madelung potential value for Cs^+ ion ($V_c = -0.31$ a.u.) with the measured absorption spectrum.

The overall profile of the experimental spectrum is in good general agreement with the calculation, apart from an energy shift of ∼2.1 eV. However, the widths of the computed resonances are narrower than those observed experimentally, and relative peak intensities do not coincide exactly.

More detailed insights into the mechanisms of the Cs 3d absorption resonance can be gained from resonant decay spectra. The resonant photoemission studies are a very useful probe of the creation of localized states that are not accessible by other spectroscopic methods [9]. Since a shape resonance is considered as a temporary trapping of the photoelectron by the potential barrier and when the de-excitation time is comparable to the trapping time, the resonant decay spectra show spectral features, characteristic to the decay of the excited bound states. As an example we look into the details of the decay of the M_5 shape resonance in CsCl.

In Fig. 3 we present the photon energy dependence of the intensities of the peaks in resonant Auger spectra, obtained by the curve fitting analysis. The upper panel shows the intensities of 4d and 4p photoelectron lines, i.e. population of final 4d and 4p hole

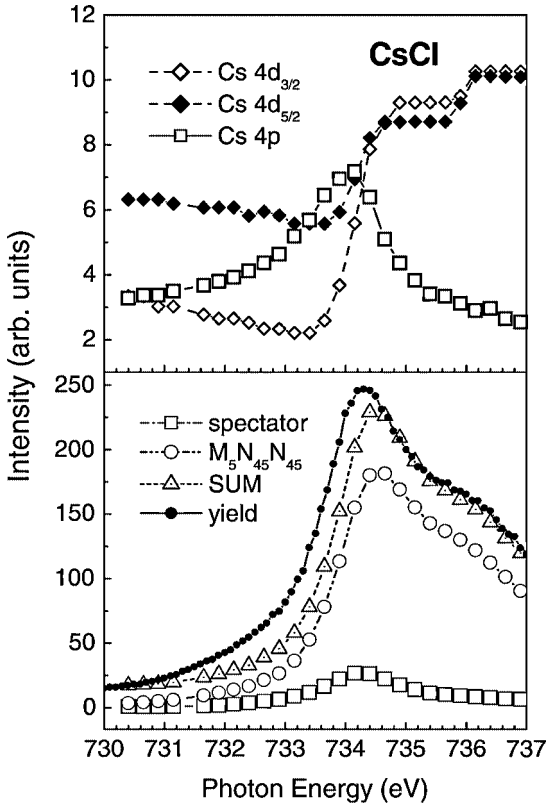

Fig. 3. The photon energy dependence of the different decay channels of the continuum Cs $3d_{5/2}$ resonance in CsCl, obtained from curve fits. The upper panel shows the cross-section of 4d and 4p participator channels while the lower one represents the spectral behavior of $M_5N_{45}N_{45}$ normal and 4f spectator Auger channels; a sum over the contributions of all these decay channels (labeled as SUM in Figure) and photoabsorption curve (labeled as yield).

states as a function of photon energy. These spectra thus represent the partial photoionization cross-section into a particular ionic state (Cs $4d^{-1}$ and $4p^{-1}$) and show enhancements in the region of the M_5 absorption resonance. As one can see in Fig. 3 the Cs $4d^{-1}$ partial photoionization cross-section show unexpectedly strong enhancement at the shoulder of the M_5 shape resonance. At the same time the enhancement of the Cs $4p^{-1}$ and $M_{45}N_{45}N_{45}$ 4f spectator intensities (in the lower panel of Fig. 3) is negligible. Moreover, as seen in Fig. 3 the spectral behavior of the Cs 4p partial photoionization cross-section is very different from that for the 4d spectral profiles. The similarity between the 4p cross-section and the 4f spectator photoemission signal (in the lower panel of Fig. 3) provides evidence that the observed spectral behavior of the 4p cross-section at Cs 3d absorption resonances originates from the $M_{45}N_{45}N_{45}$ 4f spectator transitions rather than from the participant decay transitions. However, because of strong configuration mixing of the $4d^84f + 4p^5$ final states, it is not exactly correct to separate the transitions to the single ($4p^5$) hole and double ($4d^84f$) hole states.

The different behavior of the 4d and 4p partial photoionization cross-sections can result from two different mechanisms. First, only the temporally and spatially trapped by the potential barrier εf electrons can gain additional intensity of the 4d partial photoionization cross-sections through the participator decay of the resonantly excited states, $3d^9\varepsilon f \rightarrow 4d^9$.

The second one may be considered as a result of the interaction of a low-energy εf photoelectron (de-excitation will take place after the electron has tunneled through the barrier) with a fast Auger electron *via* post-collision interaction, leading to the recapture of the photoelectron by the ionized core and, subsequently, to the transitions $3d^9\varepsilon f \rightarrow 4d^84f + 4p^5$, i.e. the enhancement of the 4f spectator as well as the 4p partial photoionization cross-sections.

Summarizing, we conclude that the appearance of the spectral features, which are intrinsic to a localized state, in the decay spectra show that the Cs 3d photoelectron, temporally and spatially trapped in the Cs 3d shape resonance due to the potential barrier for f electrons near threshold, has substantially localized nature. Our calculations of the 3d photoionization for the Cs^+ ion using the HF approximation in conjunction with the Watson sphere model show the importance of potential barrier effects in forming the shape resonances in the Cs 3d absorption.

Abstract

The local structures of semiconductor InSb compound have been studied by *in-situ* XAFS in the temperature range of 300 and 823 K. Reverse Mont Carlo calculation is used to simultaneously fit both In and Sb K-edge EXAFS functions $k\chi(k)$ of InSb compound. The fitting results indicate that the average bond length R_1 (2.80 Å) and the average coordination number N_1 (4.0) of the first In-Sb (or Sb-In) shell of InSb (723 K) are similar to those (2.79 Å, 4.0) of crystalline InSb (300 K) with a zinc-blende structure, in spite of InSb compound possessing a large thermal disorder degree at 723 K. At the temperature of 828 K ($T_{m(InSb)} = 798$ K), the R_1 and N_1 of the first In-Sb shell are 2.90 Å and 5.8, and the R_1 and N_1 of the first Sb-In shell are 2.90 Å and 5.5 for molten InSb, respectively. For molten InSb (828 K), the coordination numbers of the In-Sb (or Sb-In) first shell are mostly 5 and 6, and a few percent of In-In (or Sb-Sb) coordination appears in the first shell. It implies that the tetrahedron structures of the In-Sb (or Sb-In) covalent bonds of InSb compound have been destroyed in the liquid state.

1. Introduction

The studies of the structures and properties of molten matters have attracted wide interest recently, since some fundamental problems in liquid physics are not clear enough [1, 2], e.g., the mechanism of solid-liquid transition, the atomic and electronic structures of liquid semiconductors, metals and alloys. In particular, the III-V semiconductors with zinc-blende structure have exhibited some special properties upon the melting point, such as that the covalent bonds are destroyed, the density increases and a semiconductor-metal transition occurs. In the last two decades, Möller *et al.* [3], and Bellissent–Funel *et al.* [4] have succeeded in studying the structures of liquid metallic Sb and Ga with X-ray diffraction (XRD) and neutron diffraction (ND). However, normal XRD and ND techniques are not useful to study the structure of multi-component liquid matter, although the total partial correlation function can be obtained for GaAs [5] and GaSb [6]. In order to determine the partial correlation function of a multi-component system, a complicated experiment technique of anomalous X-ray scattering performed at different wavelengths or neutron scattering with isotopic substitution must be used [7].

Fortunately, X-ray absorption fine structure (XAFS) that is sensitive to the short-range order and atomic species surrounding the absorbing atom in a complicated matter, can obtain nice data with high ratio of signal to noise for molten matters, because of the applications of high brilliance synchrotron radiation light sources. Filipponi *et al.* [8] and Wang *et al.* [9] have investigated the local structures of liquid Rh, Pd and InSb with *in situ* XAFS. However, there are two difficulties in performing reliable XAFS data analysis for a large disorder system. One is that an unreasonable model-dependent pair distribution function used for the data analysis of a disorder system may lead to a large deviation. Another is that the multi-electron excitation can strongly affect the EXAFS oscillation signals of the molten matters. Hence, it is essential to propose a reasonable way for analyzing the XAFS data of condensed matters in the molten state.

In the present paper, *in situ* XAFS has been used to probe the local structures of pre-molten and liquid InSb compounds. The model-independent method of reverse Mont Carlo (RMC) calculation is used to simultaneously fit both In and Sb K-edge EAXFS functions $k\chi(k)$. It is possible to accurately and reliably determine the local structural changes of InSb compound from the solid state to the liquid state.

2. Experimental

An InSb sample used for XAFS measurement was prepared as the following procedures. Fine powder of InSb with sizes of about 10 μm prepared from single crystal was homogenously mixed with crystalline LiF powder. Then, the mixed powder was pressed into a tablet with diameter of 10 mm and thickness of 1 mm. The ratio of InSb to LiF powder was optimized by making the absorption jump $\Delta\mu x \approx 1$ at the In or Sb K-edge. The InSb tablet was sealed in a quartz sample holder that was composed of two thin quartz windows with thickness of 200 μm in a vacuum of 10^{-3} Pa. Our previous work has verified that InSb did not react with LiF at high temperature, even at temperatures above the melting point of InSb semiconductor [9].

The In and Sb K-edge XAFS spectra of InSb compound were measured in the XAFS station of BL01B1, SPring-8 of Japan Synchrotron Radiation Research Institute. The electron beam energy was 8.0 GeV and the maximum stored current was about 100 mA. X-rays covering a wide energy range ($4 \sim 113$ keV) is coming from the bending magnets. Si (311) double crystal was used as monochromator. A Rh-coted quartz mirror was used for the higher harmonics rejection. XAFS data were collected in transmission mode using ion chambers filled with mixed Kr/Ar gas at temperatures of 300, 723 and 828 K, respectively. The sample temperature was monitored by a Platinum-rhodium thermocouple placed between the sample and holder. XAFS data were analyzed by USTCXAFS [10] and UWXAFS3.0 codes [11].

3. Results and discussions

The normalized XAFS spectra and μ_0 background for the In and Sb K-edge of InSb measured at the temperatures 300, 723 and 828 K are shown as solid and dot lines in Fig. 1 (a) and

*Correspondent: Shiqiang Wei, E-mail: sqwei@ustc.edu.cn

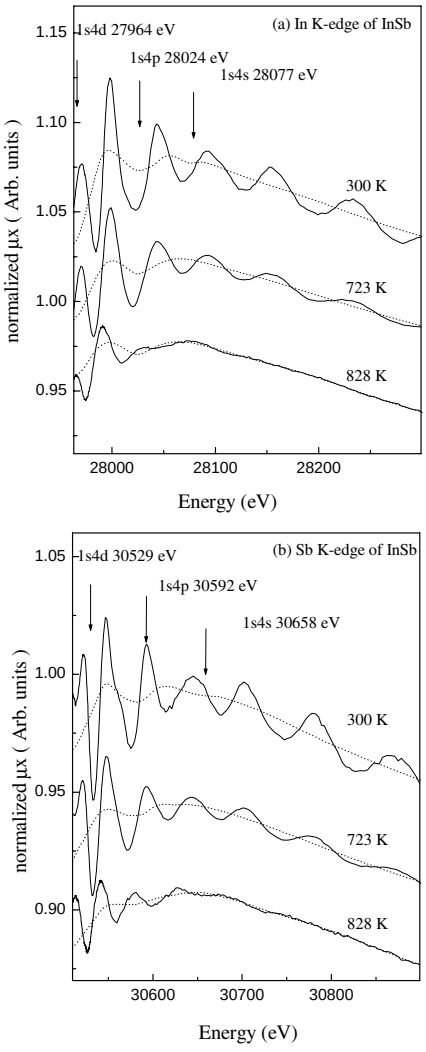

Fig. 1. Normalized XAFS spectra with μ_0 background removals for (a) In and (b) Sb K-edge of InSb fitted by arctangent functions.

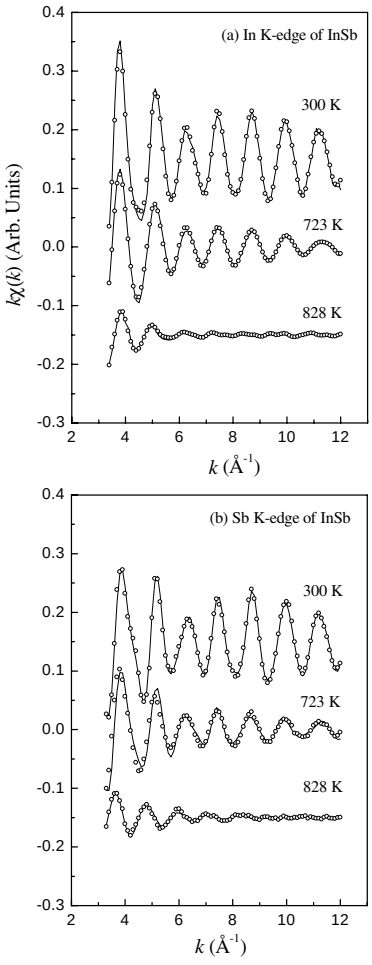

Fig. 2. RMC fitting results for (a) In and (b) Sb K-edge $k\chi(k)$ EXAFS functions of InSb at room temperature, pre-molten InSb (723 K) and molten InSb (828 K): experiment (solid line), fitting (open circle).

1 (b), respectively. The [1s4d], [1s4p] and [1s4s] double-electron excitations of In and Sb atoms in the InSb compound are noted by the arrows. Seen from both In and Sb K-edge XAFS spectra of InSb (300 K), the jump of [1s4d] excitation is much larger than that of the EXAFS oscillation peak. With going to [1s4p] and [1s4s] excitations, the jumps in the EXAFS oscillation curves of InSb (300 K) decrease greatly. For liquid InSb (828 K) ($T_m = 798$ K), the intensity of its EXAFS oscillations decreases significantly compared with that of crystalline InSb (300 K). One can observe unambiguously that the signals of double-electron excitation seriously affect the EXAFS oscillations of pre-molten and liquid InSb in the energy region of 20 $\sim$ 200 eV above the In and Sb K-edge. Here the μ_0 background, as shown in Fig. 1 (a) and (b), is fitted by an empirical model in which the jump is an arctangent function depending on amplitude, width and inflection point position [12].

Figure 2 (a) and (b) demonstrate the In and Sb K-edge EXAFS functions $k\chi(k)$ of the pre-molten and liquid InSb compounds (solid lines). It can be clearly seen that the positions of the oscillation peaks of InSb (723 K) are the same as those of InSb (300 K), whereas the intensity of oscillations strongly decreases with temperature from 300 K to 723 K. Compared with that of pre-molten InSb (723 K), the oscillation intensity of liquid InSb (828 K) further decreases, especially in the high k region. Moreover, the oscillation intensity of the In K-edge EXAFS functions in the high k-range drops faster than that of the Sb K-edge EXAFS functions in the liquid InSb (828 K). These results indicate that during the solid-liquid transition of InSb compound, the local structures around Sb and In atoms change markedly and the disorder degree around In atoms is slightly larger than that of Sb atoms for liquid InSb.

In order to quantitatively obtain local structural information of the pre-molten and liquid InSb, RMC calculation [13], a model-independent method, is used to simultaneously fit the In and Sb K-edge EXAFS functions $k\chi(k)$ of InSb compound. In the RMC simulation, the initial configuration having 512 In and Sb atoms in a cubic cell with length L of 24.8466 Å is used to fit the experimental $k\chi(k)$ spectra of molten InSb compound. The atomic number is determined by the chemical composition and mass density of InSb at the measurement temperature. The range for the EXAFS fitting is in R space of 0 $\sim$ 6 Å and k space of 2.5 $\sim$ 12.0 $Å^{-1}$. A new configuration is generated by random motion of one particle (In or Sb atom). A new partial correlation function $g'(r)$ is then calculated from this configuration. If the simulated $k\chi(k)$spectrum is in good agreement with the experiment data, the fitting is completed and $g(r)$ is obtained by calculating the average result of the last 200 configurations. The fitting curves are shown in Fig. 2 (a) and (b) (opened circles).

Figure 3 displays the $g(r)$ partial correlation functions of In-Sb and Sb-In shells of InSb compound measured at pre-molten and liquid states. In the temperature region from 300 to 723 K, the sharp peaks corresponding to the first and the second In-Sb (or

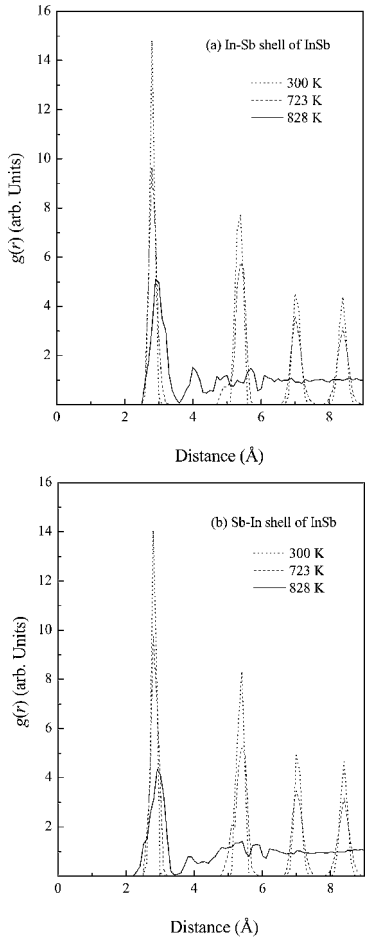

Fig. 3. Partial correlation functions of (a) In and (b) Sb atoms of InSb at 300, 723 and 828 K.

Sb-In) shells have the same positions at 2.8, 5.4 Å, respectively. For liquid InSb (828 K), only the main peak of the first nearest neighbor of In-Sb (or Sb-In) shell appears while the peaks of the higher shells are much lower. Moreover, the main peak shifts to 2.9 Å and its intensity strongly decreases and broadens for liquid InSb (828 K), as compared with that of the pre-molten InSb (723 K). The average coordination number N_1 calculated from the partial correlation functions of the first nearest neighbor around In (or Sb) atoms is 4.0 (or 4.0), 4.0 (or 4.0) and 5.8 (or 5.5) for the In-Sb (or Sb-In) shell at temperatures of 300, 723 and 828 K, respectively. Upon the melting point, the N_1 of In-Sb shell increases 1.8 and the N_1 of Sb-In shell increases 1.5 for the liquid InSb (828 K). It means that the coordination number in the In-Sb first shell is about 0.3 larger than that in the Sb-In first shell for the liquid InSb (828 K). This shows that there is a difference in the local structures around the In and Sb atoms in molten InSb (828 K).

It is well known that the In (or Sb) atoms in solid InSb crystal with zinc-blende structure are coordinated by four Sb (or In) atoms in the form of In-Sb covalent bond in the first nearest neighbor. Our fitting results show that R_1 and N_1 of the first In-Sb (or Sb-In) shell are 2.80 Å and 4.0 for pre-molten InSb (723 K), identical to those of InSb (300 K). This implies that the RMC calculation is reliable, since the RMC structural parameters of InSb compound in the pre-molten solid state is equal to those of crystalline InSb semiconductor. For liquid InSb (828 K), R_1 of In-Sb (or Sb-In) shell slightly elongates to 2.90 Å and the average coordination number N_1 of In-Sb (or Sb-In) shell largely increases to 5.8 (or 5.5). This means that the tetragonal covalent coordination of In (or Sb) atoms in the molten state is destroyed. Wang *et al.* [9] have reported that the coordination number N_1 of the In-Sb shell was 5.2 from the In K-edge XAFS results of liquid InSb. Wang's result is close to our results. With neutron diffraction, Bergman *et al.* [14] have studied the structure of liquid GaAs, and Mizuki *et al.* [6] have studied the structure of liquid GaSb. They both reported the coordination number of the first nearest neighbor to be $5.4 \sim 5.5$. These results are similar to ours, suggesting the similarity of the local structures in liquid GaAs, GaSb and InSb. Calculated from the final configuration of our fitting results, the coordination numbers of the In-Sb (or Sb-In) first shell are mostly 5 and 6 and about few percent In-In (or Sb-Sb) coordination is in the first shell around In (or Sb) atoms for molten InSb (828 K). Moreover, Wang *et al.* [9] considered that there is heterogeneous atomic coordination in the first shell of liquid GaSb, i.e., Ga is mainly surrounded by Sb atoms and partly coordinated by Ga atoms.

In conclusion, the XAFS results obtained from In and Sb K-edge XAFS spectra indicate that the melting destroys the tetragonal covalent network in crystalline InSb semiconductor. In the molten state, the average coordination number N_1 and the average bond length R_1 of the first nearest neighbor around In (or Sb) increases by $1.5 \sim 1.8$ and 0.1 Å for liquid InSb (828 K), and a few percent In-In (or Sb-Sb) coordination appears in the first shell of molten InSb (828 K). These results are key-factors in interpreting the transition of semiconductor-metal and the increase of density during the solid-liquid transformation of InSb semiconductor.

Acknowledgments

Abstract

We attempted to investigate whether the Ni valences change homogeneously in a grain of $LiNi_{0.8}Co_{0.2}O_2$ during charging/discharging Li-ion batteries. *In situ* XAFS measurements using X-ray microbeam with the size of about 1–2 μm were applied to measure position dependencies of Ni (Co) valences in a grain. In order to investigate the electronic changes caused by capacity fading, three types of coin cells for *in situ* XAFS measurements were prepared, the cell after one charge/discharge cycle, after 100 cycles at 60 °C and after aging at 60 °C for 21 days, respectively. Two-dimensional fluorescence maps of Ni and Co were obtained to determine measuring points in a grain (the center of a grain, the edge of a grain, etc.). Ni and Co K-edge XAFS spectra were collected in transmission mode for each point. As a result, no apparent differences depending on positions were observed for all types of the cells. It was concluded that the changes of Ni valences during charging/discharging batteries occur homogeneously in a grain, not depending on the degree of capacity fading.

1. Introduction

$LiNi_{0.8}Co_{0.2}O_2$ is one of the current candidates as a cathode material for advanced rechargeable batteries having high capacities. It is known that the stability of $LiNi_{0.8}Co_{0.2}O_2$ is superior to that of $LiNiO_2$ because it exhibits a single-phase region upon oxidation from 3.0 V to 4.1 V [1]. However, capacity fading occurs not only during charge/discharge cycling but also when batteries are stored at high temperatures. Thus, capacity fading is the most important problem facing practical use. From the standpoint of overcoming capacity fading, it is essential to understand the electronic and structural changes that accompany capacity fading. In our previous work, these changes have been studied by *in situ* XAFS measurements, where the relationship between these changes and the capacity fading were revealed [2].

In our practical uses of Li-ion batteries, $LiNi_{0.8}Co_{0.2}O_2$ is formed into grains with the size of about 10–20 μm. If the electronic changes have position dependencies in each grain, (for example, the Ni valence at the center of a grain is higher than that at the edge of a grain), our understanding of capacity fading has to be modified. So it is worth investigating whether the electronic and structural changes occur homogeneously in each grain. Furthermore, the information about homogeneity of Ni (Co) valences is of great significance in developing batteries with this cathode material. In this work, we studied the local valence changes in a grain by *in situ* XAFS using X-ray microbeam with the size of about 1–2 μm.

2. Experimental

Fig. 1 shows a drawing of the coin cell developed for *in situ* XAFS measurements in transmission mode. By using 0.4 mm Beryllium windows, the X-rays can penetrate through the cell. XAFS data can be obtained at various voltages without taking the cathode material out of the cell. In order to make each spectrum reflect the information from only one grain, the thickness of cathode was controlled to be less than 100 μm. To investigate the changes resulting from cycling and storing at high temperatures, three types of cells were prepared, the cell after one charge/discharge cycle, after 100 cycles at 60 °C and after aging at 60 °C for 21 days, respectively. The conditions of cells used in this study are listed in Table I.

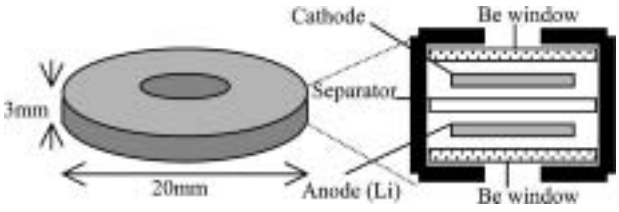

Fig. 1. Schematic drawing of an *in situ* coin cell.

Table I. *Conditions of in situ coin cells.*

Condition	Capacity (relative value)
After one charge/discharge cycle	100
After 100 charge/discharge cycles at 60 °C	66
After storing at 60 °C for 21 days	91

The experiments were carried out on BL16XU [3] at SPring-8. BL16XU has an X-ray optical system to generate X-ray microbeam using two elliptical mirrors with a Kirkpatric-Baez (KB) configuration [4]. Comparing with other methods for microbeam generation such as zone plates, KB mirror method is suitable for XAFS measurements because X-ray energy is tuneable with the focus point fixed. The KB mirrors can focus X-rays in a small area ranging from microns to submicrons in size at the sample position. The full width at half maximum of the microbeam used in this study was about 1–2 μm, estimated from knife-edge test results. Fig. 2 illustrates the experimental setup for this study. X-ray microbeams are irradiated to a sample mounted on a high-precision two-dimensional moving stage. Fluorescence and transmission maps can be obtained by scanning the sample with respect to the microbeams. A silicon semiconductor detector (SSD) and an ionization chamber are employed to collect fluorescent and transmitted X-rays, respectively.

The experimental procedure was as follows. A coin cell was mounted on the sample stage with its voltage kept at 3.0 V. Ni and Co distribution maps were obtained at 9.0 keV to determine points for XAFS measurements. At several points, Ni and Co K-edge

*e-mail: nonaka@mosk.thtlabs.co.jp

XAFS spectra were collected in transmission mode. After XAFS measurements for all points were finished, the cell was charged to a voltage of 4.2 V. XAFS measurements were performed at the same points as 3.0 V. The same procedure was repeated to obtain XAFS spectra for the cell after discharging.

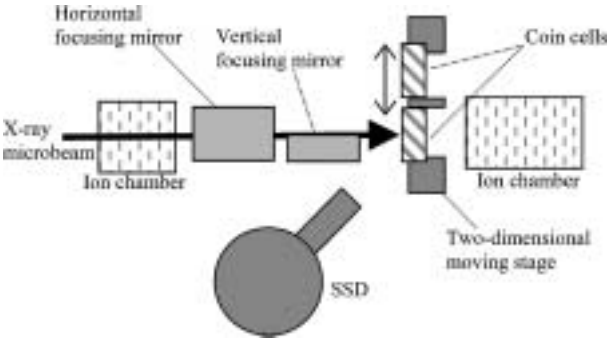

Fig. 2. Experimental setup for microscopic XAFS in transmission mode (top view).

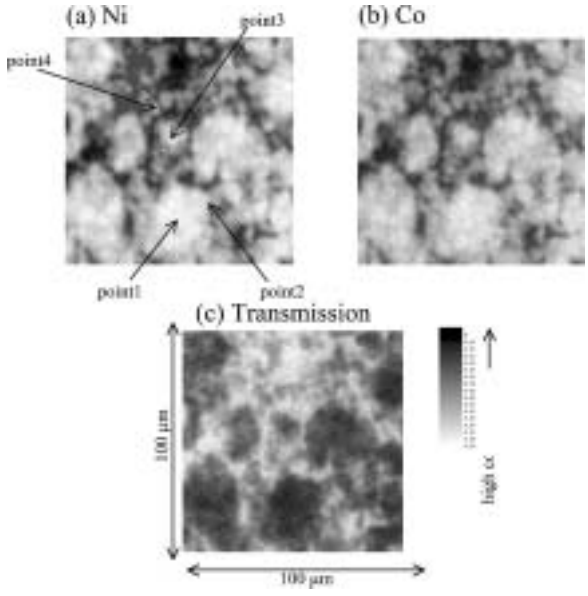

Fig. 3. (a) Ni fluorescence map, (b) Co fluorescence map, (c) transmission map for the cell after one charge/discharge cycle. All maps were obtained at initial state (before charging the cell).

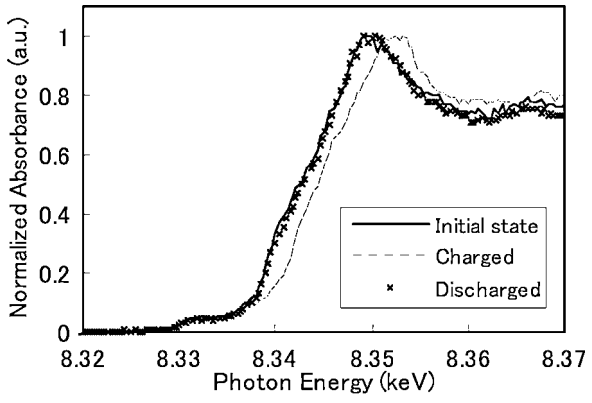

Fig. 4. Ni K-edge XANES spectra measured at point 2 (the edge of a grain) for the cell after one charge/discharge cycle.

3. Results and Discussion

3.1. *Cell after one charge/discharge cycling*

Ni (Co) fluorescence and transmission maps are shown in Fig. 3. Grains of cathode materials with the size of 10–20 μm can be clearly recognized in the fluorescence maps. The distribution of Co appears to be perfectly equal to that of Ni, indicating uniform mixing of Ni and Co. The transmission map is seen to be the "negative image" of Ni and Co fluorescence maps, which demonstrates that the thickness of the cathode is thin enough to prevent grains from piling up along the path of X-rays. Fig. 4 shows the change of Ni K-edge spectra upon charging/discharging at the edge of a grain (point 2). The absorption edge shifts to higher energy after

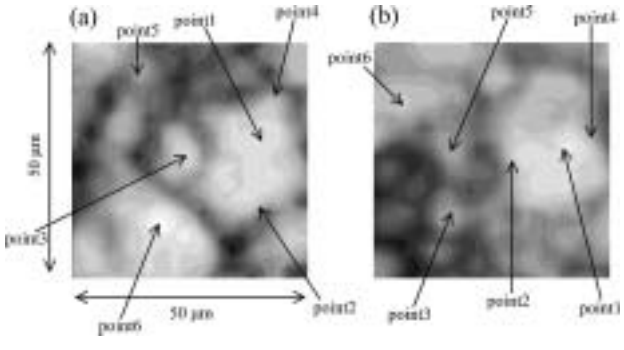

Fig. 7. Ni fluorescence maps for (a) cell after 100 cycles at 60 °C (b) cell after aging at 60 °C for 21 days.

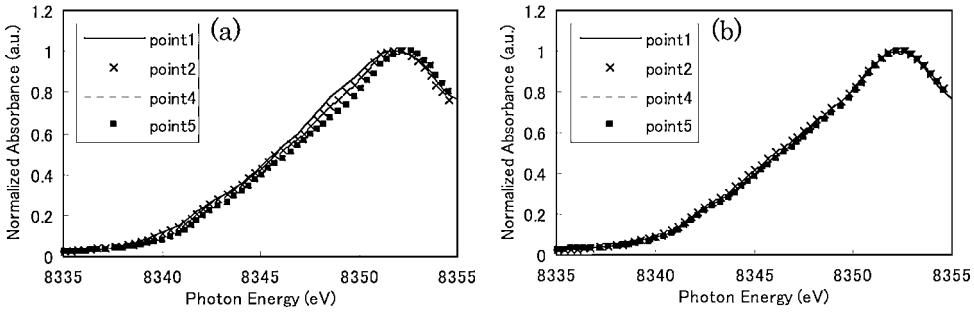

Fig. 8. Comparisons of Ni K-edge XANES spectra measured at several points for (a) cell after 100 cycles at 60°C (b) cell after aging at 60°C for 21 days (charged state (4.2V)).

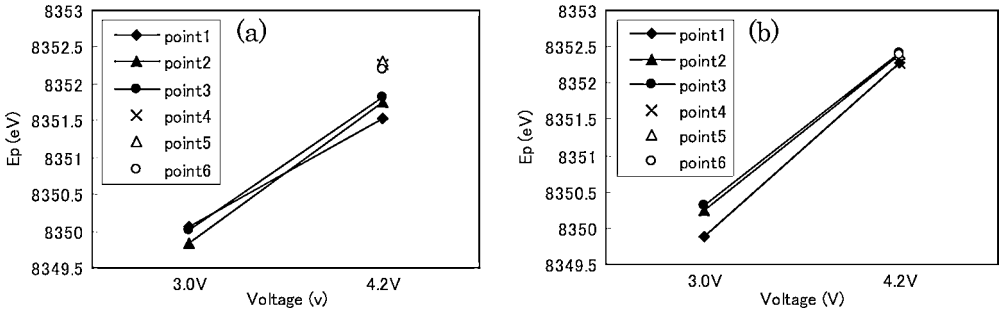

Fig. 9. Comparisons of Ni K-edge peak energies as a function of cell voltages for (a) cell after 100 cycles at 60°C (b) cell after aging at 60°C for 21 days. Ep: the energy at the maximum height of the edge jump.

charging the cell and returns to the same energy as the initial state reversibly after discharging. These chemical shifts corresponds to the change of Ni valence (from 3+ to 4+ upon charging, from 4+ to 3+ upon discharging) caused by the removal/insertion of lithium [5]. The position dependency of Ni K-edge spectra in its initial state is shown in Fig. 5. No apparent position dependency was found. Also in charged state, position dependency was not found. These results indicate that the changes of Ni valences occur homogeneously in a grain and have no dependency on grain size.

An example of Co K-edge spectra is shown in Fig. 6. As well as the result of Ni, we could not find any difference between each spectrum measured at different position.

3.2. *Cell after 100 cycles at 60°C, cell after aging at 60°C for 21 days*

Ni fluorescence maps are shown in Fig. 7 and the position dependencies of Ni K-edge XANES spectra obtained at charged state (4.2V) are shown in Fig. 8. The S/N ratios of these spectra are better than those of the cell after one charge/discharge cycling. It is supposed that the difference in S/N ratios is due to the difference in X-ray intensities. (The measurement described in 3.1 was done on another day from the day for the measurements described in 3.2.) XANES spectra shown in Fig. 8(a) seem to have position dependencies. In order to make this difference clear, a quantitative analysis was performed as follows. Graphical comparisons of the edge peak energies as a function of cell voltages are shown in Fig. 9. The edge peak energy E_p is defined here as the energy at the maximum height of the edge jump. In the cell after 100 cycles, the edge peak energies of point 4–6 are higher than those of point 1–3 (Fig. 9(a)). There is, however, possibility that these gaps of energies originate from the effect of X-ray irradiation. The measurements for point 4–6 were done once, on the other hand, the measurements for point 1–3 were done twice (at 3.0V and 4.2V). It is assumed that X-ray microbeams could cause local alterations of electrolytes and lead to lower oxidation states of Ni at points irradiated twice. The further experiments with increasing measuring points are needed to confirm this assumption. Except for the gaps described above, any apparent position dependency was found. At the present time, we concluded that the changes of Ni valences with charging a capacity faded cell occur homogeneously in a grain and have no dependency on grain size.

4. Conclusion

We attempted to investigate whether the Ni Valences change homogeneously in a grain of $LiNi_{0.8}Co_{0.2}O_2$ during charging/discharging Li-ion batteries. *In situ* XAFS measurements using X-ray microbeam with the size of about 1–2 μm were applied to measure position dependencies of Ni (Co) valences in a grain. As a result, no apparent differences depending on positions were observed for all types of the cells. It was concluded that the changes of Ni valences during charging/discharging batteries occur homogeneously in a grain, not depending on the degree of capacity fading.

The information obtained with this study is of great significance in developing batteries with this cathode material and also in understanding capacity fading. The experimental techniques described here can become strong tool in the analysis of Li-ion batteries.

Abstract

The speciation of niobium and tin in 29 silicate glasses was investigated by XAFS at the Nb and Sn K-edges using beamline 4-3 and 11-2 at SSRL (Stanford, USA). The metal content in the glasses varies between 100 ppm and 5 wt.% (to examine the effects of Nb_2O_5 and SnO_2 saturation in the melt composition prior quenching). The glasses show variation in composition from peralkaline to peraluminous, with either zero or ∼2 wt.% fluorine. In addition, hydrous glasses were quenched from water-saturated melts at 850 °C and 2 kbar under relatively reducing conditions. Three "haplogranitic" compositions (a model granite in the system Na_2O-K_2O-AlO_3-SiO_2) were investigated: peralkaline (labeled "ASI 0.6"), metaluminous ("ASI 1.0") and peraluminous ("ASI 1.2"). One series of haplogranitic glasses ("SQ") were synthesized at intermediate oxygen fugacity conditions (∼10^{-9} atm.). In addition, 15 model oxide and silicate compounds of tin and niobium were investigated.

The tin-bearing glasses show Sn K-edge XAFS spectra that resemble that displayed by eakerite, a Ca-Sn silicate in which Sn(IV)O_6 octahedra share corners with SiO_4 tetrahedra (⟨Sn-O-Si⟩: 150°). However, the most reduced glasses show significant contributions arising from weakly bound Sn(II)O_n complexes. The niobium-bearing glasses show Nb K-edge XAFS spectra that most closely resemble that displayed by vuonnemite, a Na-Ti-Nb silicophosphate. Niobium forms NbO_6 clusters, also bonded to Si/Al second neighbors. The coordination geometry of niobium in the glasses is strongly influenced by both Nb content and alkalinity; H_2O content does not strongly influence the speciation of niobium. Fluorine-bearing Nb-glasses show unusual XANES spectra, which might be related to a decrease in the coordination number of niobium from 6 to 4 (or 5). However, based on Nb K-edge XANES calculations (FEFF 8), fluorine does not appear to complex niobium.

1. Introduction

Tin and niobium are geochemically unusual, because they concentrate into late-stage magmas and hydrothermal fluids [5]. A growing body of evidence suggests that the behavior of such elements is highly dependent on the alkalinity and the presence of volatile elements (such as water, fluorine) of the parental melt/fluid. Recent experimental studies [1–4] involving these elements have focused on their solubility, diffusivity and mobilization in both hydrous and anhydrous melts and glasses. However, no speciation studies are available to ascertain these macroscopic properties. In this study, we utilize XAFS spectroscopy to elucidate the speciation and coordination geochemistry of tin and niobium in anhydrous, water-saturated and fluorine-bearing alkaline and haplogranitic melts in order to better understand their behavior in natural magmatic systems.

2. Experimental Methods

The tin-bearing glasses studied were quenched from water-saturated melts at 800 °C and 2 kbar. Three haplogranitic compositions were investigated: (1) peralkaline (labeled "ASI 0.6", where the 0.6 is the "alumina saturation index", i.e., the $Al_2O_3/(Na_2O + K_2O)$ molar ratio), (2) metaluminous ("ASI 1.0") and (3) peraluminous ("ASI 1.2"). One series of glasses ("SQ") were synthesized at the Bayerisches Geoinstitut, Bayreuth (Germany) at intermediate oxygen fugacity (f_{O_2}) conditions (∼ 10^{-12} atm. at 800 °C). Two other series ("AL" and "GB") were synthesized at the CRSCM (Orléans, France) at more oxidized and more reduced conditions, respectively. The amounts of Sn^{4+} were predicted based on cassiterite solubility measurements [2].

The niobium-bearing glasses (1000 ppm Nb to 5 wt.% Nb_2O_5) were quenched from melts at 850 °C and 2 kbar. Two haplogranitic compositions were investigated: (1) peralkaline (ASI 0.6) and (2) peraluminous (ASI 1.2). Niobium-bearing glasses of these compositions were either dry, wet (water saturated, ∼5 wt.% H_2O) or contained ∼2 wt.% F. Additional anhydrous sodium silicate glasses (NS2 and NS3) were synthesized at ENS (Lyon, France) at 1200 °C and 1 bar containing between 1000 ppm Nb and 3 wt.% Nb_2O_5.

X-ray absorption spectroscopy was performed at the Stanford Synchrotron Radiation Laboratory (SSRL) using spectrometers 4-1 and 11-2. Room temperature X-ray absorption fine structure (XAFS) spectra were collected at the Nb K absorption edge (∼19 keV) and the Sn K-edge (∼29 keV) using a Si(220) double crystal monochromator and a Stern-Held fluorescence detector (3 mm Zr filter and Ag Soller-slits) filled with Xe. Energy resolution is ∼ 4 eV. Nb and Sn foils were used for calibration purposes.

3. Results and Discussion

3.1. *Sn model compounds and glasses*

The tin-bearing crystals investigated included cassiterite (Bolivia and Malaysia), eakerite [$(Ca_2SnAl_2Si_6O_{18}(OH)_2 \cdot 2(H_2O)$] various perovskite-based polymorphs ($SnSrO_3$, $CaSnO_3$ and $CdSnO_3$), SnO , $SnCl_2$ and metallic Sn. No clear shift of the edge between Sn^{2+} and Sn^{4+} is observed due to low resolution at the Sn K-edge (∼6 eV). However, Sn^{2+}-O and Sn^{4+}-O distances are very different (due to ionic radii differences). Finally, Sn-O bonds are much more ionic, adding to the challenge of collecting noise-free EXAFS spectra in Sn^{2+}-rich samples. No evidence of SnO_2 saturation was observed at the Å-scale in any of the glasses studied, which validates previous macroscopic measurement on tin solubility in these glasses (see [1–4]).

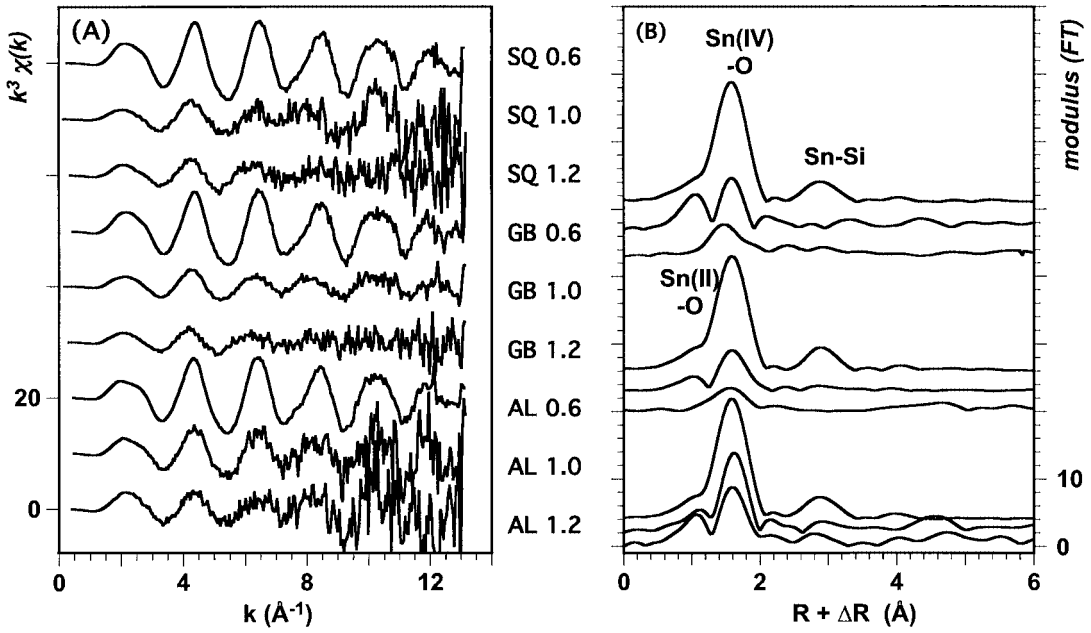

Fig. 1. Sn-bearing glasses. A. Sn K-edge normalized (k^3-weighted) EXAFS spectra for each series of glasses investigated. B. Fourier-transforms of normalized EXAFS spectra shown in (A), showing contributions arising from first oxygen neighbors and distant network formers such as Si in eakerite model compound.
