Large changes detected in the XANES spectra of the tin-bearing glasses are related to changes in the oxidation state of tin and its local environment. In general, tetravalent tin displays environments (Fig. 1) close to those measured in eakerite [6], suggesting that Sn bonds to the tetrahedral framework and is charge-compensated by network modifiers such as sodium. $Sn^{4+}O_6$ octahedra share corners with SiO_4 tetrahedra (⟨Sn-O-Si⟩: 150°). By contrast, Sn^{2+} forms more ionic complexes which are less connected to the glass structure. However, changes in melt composition (such as peralkalinity and water content) does not change drastically the tin speciation in these glasses.

3.2. *Nb model compounds and glasses*

Niobium model compounds include the silicates vuonnemite (from Canada and Russia), labuntsovite (Russia), the orthophosphate olmsteadite (USA) and the oxides pyrochlore (Canada) and columbite (Africa and Canada). Niobium in natural minerals is always found as Nb^{5+} in octahedral-coordination. Distances to nearest neighbors in niobium minerals span a range from 1.76 to 2.26 Å. There is no evidence for a change in oxidation state in the model compounds from Nb^{5+}.

Changes detected in the XANES spectra of the Nb-bearing glasses (Fig. 2) are dominantly the result of changes in niobium content and alkalinity. The presence or absence of H_2O in the melt does not appear to have an effect on the local structure of Nb, in agreement with [8]. Niobium occurs solely as Nb^{5+} and is present in 6-coordinated environments. The local coordination geometry of niobium in the silicate glasses is similar to that of $^{[6]}$Nb in the silicophosphate mineral vuonnemite [7]. In vuonnemite, the dominant contribution in the EXAFS spectra is due to Nb-O bonds. A weaker and more distant contribution arises from

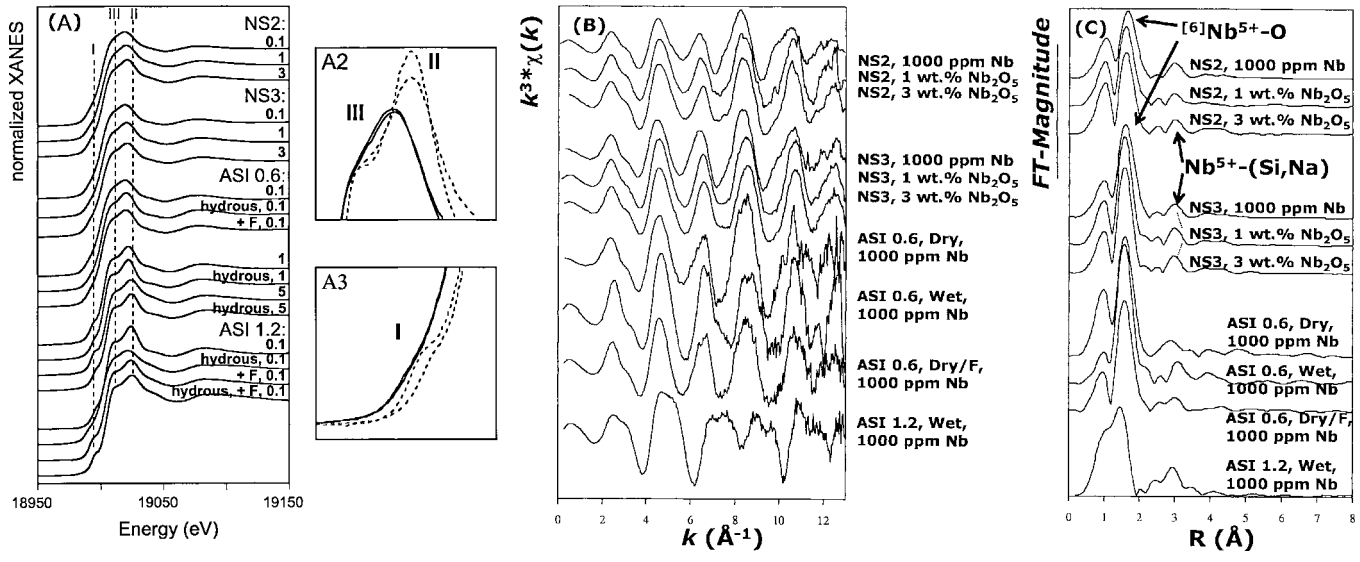

Fig. 2. Nb-bearing glasses. A. XANES spectra; A2: zoom on edge crests in 0.1 wt.% Nb glasses. The relative magnitude of the low energy shoulder increases with decreasing alkalinity; A3: zoom the on pre-edge (feature I). Feature I increases in height with decreasing alkalinity. B. Normalized (k^3-weighted) EXAFS spectra. C. Corresponding Fourier transforms.

next-nearest (Si, Na) neighbors. Development of a stronger pre-edge feature is observed in ASI 0.6 and 1.2 glasses with >1 wt.% Nb_2O_5 (Fig. 2) and is related to a Nb_2O_5 saturation of the melts. An even more intense and well-defined pre-edge is found in hydrated glasses containing 2 wt.% fluorine. Preliminary FEFF calculations on various model compounds indicates this pre-edge to be related to a decrease in niobium coordination from 6 to either 5 or 4 (but no direct complexation of Nb by F is found). The main edge crest features of the niobium K-edge XANES spectra for most glasses resemble those of model compounds such as vuonnemite (Fig. 2). A shift in the main edge crest to higher energies and an increase in the relative intensity of the first EXAFS oscillation is observed with increasing alkalinity and decreasing niobium content. The appearance of such a feature may be related to decreasing radial distortion around the $^{[6]}$Nb.

These preliminary results show that the behaviour of tin and niobium in these glasses: the melt structure exerts a much stronger influence on niobium (peralkalinity, presence of water and fluorine) than tin. Spectra from rare model compounds of tin and niobium (such as eakerite and vuonnemite), together with ab-initio FEFF 8 XANES calculations, help to provide a better understanding the local structure around these elements in glasses. The derived structural information not only has major implications to the understanding of the geochemistry of these elements in natural magmatic systems, but also on nuclear waste glasses in which niobium is a highly nucleating component.

Abstract

We have investigated solid electrolyte interfaces (SEI) of lithium ion batteries containing sulfur additive for electrolyte with S K-edge XANES spectra. Graphite anode and $LiCoO_2$ cathode were used as electrodes and ethylene sulfite (ES) was used as an additive for propylene carbonate electrolyte. Compared with XANES spectra of standard compounds, it is elucidated that the SEI layer on the graphite anode includes Li_2SO_3, $ROSO_2Li$, Li_2SO_4 and organic sulfur with C-S-C and/or C-S-S-C bonding. The XANES spectrum of the cathode shows that Li_2SO_4 and organic sulfur compounds with C-S-C and/or C-S-S-C are included in the SEI on the cathode. In the discharge state, the sulfur compounds in SEI layers on the anode dissolve into the electrolyte under high temperature around 120 °C although the dissolution of the sulfur species is not observed in the charge state. On the other hand, it is found that the rate of dissolution of the sulfur compounds in SEI layers on $LiCoO_2$ cathode is lower in the discharge state than in the charge state.

1. Introduction

In comparison to other rechargeable battery types, lithium ion rechargeable batteries have been more widely used in cellular phones or personal computers because they provide higher energy density and generate high voltage. They are also being exploited as batteries for electric vehicles. There have been many studies about materials used in lithium ion cells to improve the performances. In the development of electrolytes, the role of additives for electrolytes has been given more importance recently in an effort to prevent undesirable reactions on electrodes [1–6].

Propylene carbonate (PC) has a low melting point and high conductivity at low temperatures. It is attractive solvent for the use at low temperatures. However, PC is usually decomposed on electrodes and it is hardly utilized in commercial batteries. Ethylene sulfite (ES) is known as a good additive for PC based electrolytes [5]. It is considered to produce an effective passivation film, which is called a solid electrolyte interface (SEI), to suppress the decomposition of PC. Several studies on SEI layers including ES have been reported so far [7].

X-ray absorption near edge structure (XANES) is a useful tool for structural studies of many kinds of materials because it includes useful information about coordination geometry and electronic structures such as valency or symmetry of unoccupied orbitals of X-ray absorbing atom [8]. In particular, the fingerprints analysis of XANES is a convenient and reliable method for assignment of compounds if there are suitable reference compounds. There are many studies with Sulfur K-edge XANES spectrum to get direct information about sulfur compounds in many fields, for example, coal [9], asphaltenes [10] and soil humic substances [11]. The S K-edge XANES has been already utilized for the SEI analysis of lithium batteries, and has generated useful information about the SEI including sulfur compounds [12].

In this research, we have applied the S K-edge XANES to the SEI on electrodes in lithium ion cell to get more information about sulfur compounds and their thermal stability when ES is used as an additive to PC based electrolytes. The thermal stability of the SEI is an important factor in terms of the performance and the safety in lithium ion batteries. It is necessary to improve the thermal stability in commercial rechargeable batteries.

2. Experimental

The anode was prepared by coating a copper foil with a mixture of graphite (Mitsubishi Power Graphite (MPG), Mitsubishi Chemical Corporation) and poly vinylidene difluoride (PVdF). The cathode was prepared by coating an aluminum foil with a mixture of $LiCoO_2$ and acetylene black and PVdF. The electrolyte was a 1 M $LiPF_6$/PC solution containing 10% ES by weight (Sol-Rite™, Mitsubishi Chemical Corporation). The cell was galvanostatically charged and discharged at 0.16 mA/cm^2 within the potential range of 3.0–4.2 V. After one cycle, the cell was disassembled in an argon globe box. The samples for the XANES measurements were transferred by use of a sealed container with argon gas. The heating of the electrodes was carried out in the electrolyte at the rate of 1 °C per minute.

The S K-edge XANES measurements were performed at BL-9A in the Photon Factory of High Energy Accelerator Research Organization. The operation energy was 2.5 GeV and the stored current was between 300 and 450 mA. Si(111) double crystals were used as a monochromator and higher orders were reduced with a pair of Ni coated quartz mirrors. The photon energy was calibrated with the largest peak (2482.0 eV) in the S K-edge XANES spectrum of Na_2SO_4 powder. The incident X-rays were detected with an ion chamber filled with helium gas. Both conversion electron yield and fluorescence yield were detected simultaneously with the modified Lytle detector. All measurements were carried out in helium atmosphere. Therefore, we could measure samples with high vapor pressure, even in the liquid state. Powder samples and electrode samples were put on conductive tapes and drops of liquid samples were dried on conductive tapes for measurement. The XANES spectrum of the conductive tape showed that there are subtle sulfur compounds. Since the intensity of the XANES spectrum of the conductive tape was very weak, it did not substantially interfere with the spectra of reference samples. The X-ray beam was irradiated just on the electrodes in case of measuring the electrode samples. Therefore, the spectra of the electrode samples were not interfered with sulfur compounds on the conductive tape.

3. Results and Discussion

Figure 1 shows the S K-edge normalized electron yield XANES spectra of the graphite anode and the $LiCoO_2$ cathode before heating and heated up to 120 °C in 1 M $LiPF_6$/PC + ES10%

Li_2SO_4				2482.1
nC_7H_{15}-SO_3Na				2480.5
Ethylenesulfite (ES)		2476.3	2478.1	
Dimethylsulfide (H_3C-S-CH_3)		2473.3		
Di n-propyldisulfide (H_7C_3-S-S-C_3H_7)	2471.9	2473.4		

respectively compared with some reference compounds. The values of some peak energies are listed in Table I. There are four peaks in the anode samples before heating. The peaks at 2477.7 eV and 2479.7 eV are assigned to Li_2SO_3 because the values are attributed to the peaks energies of Li_2SO_3. The shoulder around 2482 eV in the spectrum of the anode shows that the anode also contains Li_2SO_4 whose peak energy is 2482.1 eV. We consider that the peaks at 2471.9 eV and 2473.5 eV on the anode are derived from organic sulfur having C-S-C and/or C-S-S-C bonding because the values of 2471.9 eV and 2473.5 eV are close to the values of peak energy in the spectrum of dimethylsulfide (H_3C-S-CH_3) which has a peak at 2473.3 eV and of din-propyldisulfide (H_7C_3-S-S-C_3H_7), which has two peaks at 2471.9 eV and 2473.4 eV. These two peaks have been assigned to $1s \rightarrow \sigma^*$(S-S) and σ^*(S-C) transitions, respectively in previous study [8]. It is reported that these compounds are produced by the reductive decomposition of ES [7].

Large two peaks at 2480.7 eV and 2481.9 eV, and small two peaks at 2473.2 eV and 2476.2 eV are observed in the spectrum of the anode heated up to 120 °C in the discharge state. Each peak is assigned to $ROSO_2Li$ (2480.5 eV), Li_2SO_4 (2482.1 eV), organic sulfur compounds (2473.3 eV) and ES (2476.3 eV), respectively.

Two peaks at 2472.0 eV and at 2482.0 eV are found in the spectrum of the cathode shown in Fig. 1. The peak at 2482.0 eV is attributed to Li_2SO_4. Most of Li_2SO_4 must be derived from impurities contained in $LiCoO_2$ in comparison with a cathode blank spectrum. The peak at 2472.0 eV has an unsymmetrical shape, which broadens to higher energy region. The unsymmetrical shape implies that the peak at 2472.0 eV may include another peak around 2473 eV. Therefore, we consider that the cathode also contains organic sulfur compounds with C-S-C and/or C-S-S-C bonding. In the spectrum of the cathode heated up to 120 °C in the discharge state, the intensity at 2472.0 eV decreases and the intensity at 2482 eV increases relatively compared with the spectrum before heating.

The background subtracted fluorescence yield spectra of the anodes heated up to 80 °C and 120 °C in the discharge state are shown in the upper part of Fig. 2(a) compared with the spectrum before heating. Since all spectra were measured under the same sensitivity and the same sample configuration, we consider the intensity of the background subtracted spectra shows the content of sulfur on the electrodes to some extent. The spectrum of the anode heated up to 80 °C is almost the same as that before heating. However, the shape and the intensity of the spectrum of the anode heated up to 120 °C are quite different from those of the other two spectra. The decrease in the intensity of the spectrum of the anode heated up to 120 °C shows that the sulfur compounds in SEI have dissolved into the electrolyte under high temperature around 120 °C. In particular, Li_2SO_3 is not found clearly in the spectrum. These results indicate that Li_2SO_3 dissolves into the electrolyte faster than $ROSO_2Li$, Li_2SO_4 and organic sulfur. We consider that both $ROSO_2Li$ and Li_2SO_4 exist in the SEI even before heating and are left in the SEI after heating although those peaks are not clearly detected in the spectrum before heating.

On the other hand, there is no large difference between the spectra of the anode samples in the charge state except that the intensity of the peaks in the 80 °C spectrum at 2477.7 eV and 2479.7 eV, which is attributed to Li_2SO_3, is a little stronger than those of other two spectra shown in the lower part of Fig. 2(a). This result is considered that both dissolution and production occur in the charge state. Lithium is intercalated into graphite anode in the charge state. The intercalated lithium has a capability of the SEI formation. As a result, the production of SEI by the intercalated lithium and dissolution by high temperature occur simultaneously in the charge state. Therefore, the large differences between the spectra of the anode samples are not found in the

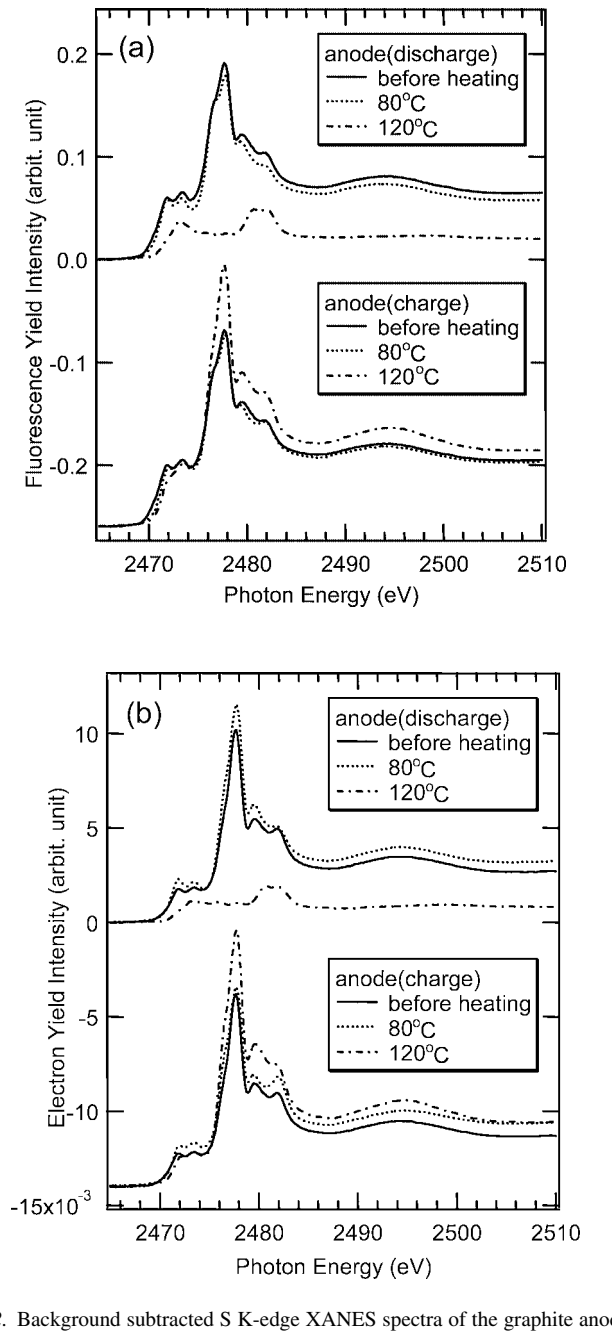

Fig. 2. Background subtracted S K-edge XANES spectra of the graphite anodes heated up to 80 °C and 120 °C (a) with fluorescence yield, and (b) with electron yield.

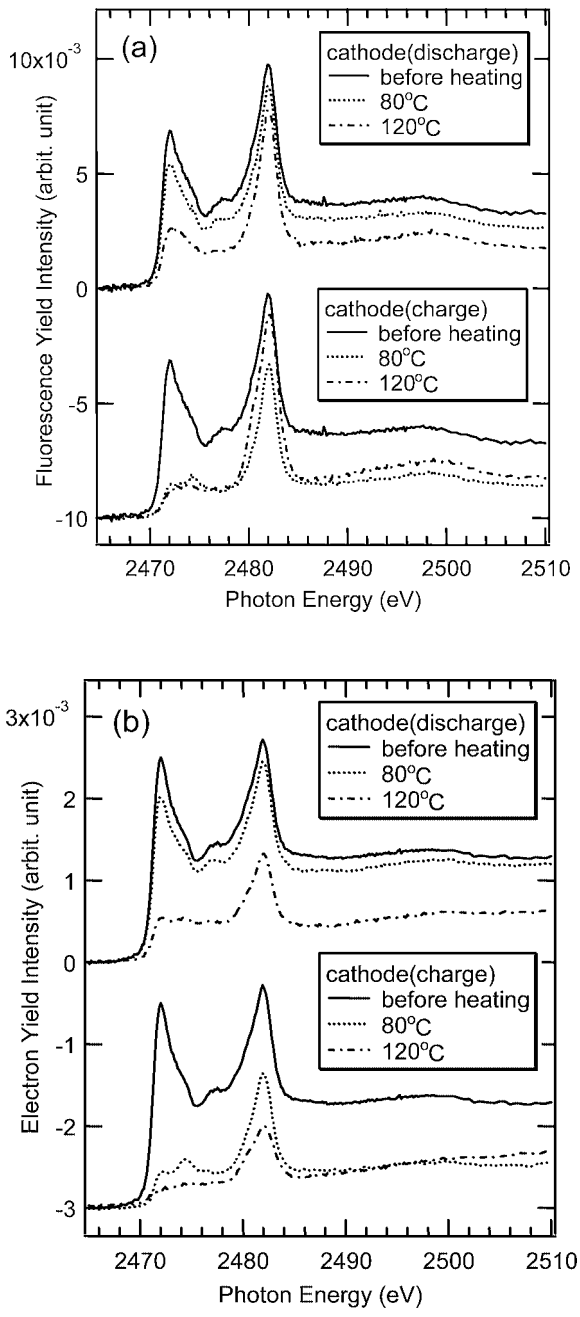

Fig. 3. Background subtracted S K-edge XANES spectra of the $LiCoO_2$ cathodes heated up to 80 °C and 120 °C (a) with fluorescence yield, and (b) with electron yield.

spectra in the charge state. Due to the same reason, the intensity of the peaks related to Li_2SO_3 (2477.7 eV, 2479.7 eV) increases in the spectrum of anode heated up to 80 °C. In this case, the rate of production is considered to be slightly higher than that of dissolution.

The spectra of anode samples with electron yield are shown in Fig. 2(b). The dependency on temperature is mostly the same as the result obtained from the spectra with fluorescence yield. The intensity derived from Li_2SO_3 in electron yield is slightly stronger than that measured in fluorescence yield. The concentration of Li_2SO_3 seems to be higher in surface than in bulk of SEI.

Figure 3(a) shows the background subtracted fluorescence yield spectra of the cathodes heated up to 80 °C and 120 °C in the discharge state (upper part) and in the charge state (lower part). The intensity around 2720 eV gradually decreases with temperature in the discharge state. The decrease in the intensity around 2720 eV in the charge state is larger than that in the discharge state in the case of 80 °C. These results imply that the dissolution rate of organic sulfur compounds in the charge state is larger than that in the discharge state at 80 °C. This trend in the cathode is opposite to that in the anode, explained as the following. As lithium atom is extracted from $LiCoO_2$ in the charge state, it changes into Li_xCoO_2, where x is less than 1.0. The Li_xCoO_2 in the charge state has a higher oxidation activity than the $LiCoO_2$ in the discharge state. Therefore, it is considered that the sulfur compounds contained in SEI dissolve faster in charge state than in discharge state under high temperature.

The electron yield spectra of the cathodes heated up to 80 °C and 120 °C are shown in Fig. 3(b). The dependency on temperature is almost the same as the result obtained from the fluorescence yield spectra. The large difference is found in the intensities derived from organic sulfur compounds. The intensity of the

peak at 2472.0 eV in electron yield is stronger than that in the fluorescence yield. This means organic sulfur compounds exist more on the surface of SEI on the cathode.

4. Conclusions

The S K-edge XANES has been applied to analyze the SEI containing sulfur in lithium ion batteries. It is found that the S K-edge XANES is very effective in studying the SEI. It is also found that the SEI on anode includes Li_2SO_3, $ROSO_2Li$, Li_2SO_4 and organic sulfur having C-S-C and/or C-S-S-C bonding. The XANES spectrum of cathode shows that Li_2SO_4 and organic sulfur compounds with C-S-C and/or C-S-S-C are included in the SEI on the cathode. Most of Li_2SO_4 must be derived from impurities contained in $LiCoO_2$ in comparison with the blank spectrum of $LiCoO_2$ only.

The authors have also investigated the thermal stability of the sulfur compounds in SEI layer. In the case of the graphite anode, the sulfur compounds in SEI layer in the discharge state dissolve under high temperature around 120 °C. Such dissolution is not found in the charge state. It is considered that the SEI layer on the anode is more stable under high temperature in the charge state than in the discharge state. It is also observed that Li_2SO_3 dissolves more easily than other sulfur compounds. On the other hand, it is found that the rate of dissolution of the sulfur compounds in SEI layer on the $LiCoO_2$ cathode is lower in the discharge state than in the charge state, which implies that the SEI on the $LiCoO_2$ cathode is more stable in the discharge state than in the charge state.

Abstract

Structural changes of pyromellitimido-oxydianiline (PMDA-ODA) polyimide (PI) films by UV irradiation were studied by means of XAFS and XPS. UV irradiation in air was found to cause oxidative cleavage of the imide ring of the PMDA part, whereas that in vacuum changed the conjugated structure involving nitrogen but did not likely open the imide ring. The results indicate that the combined analysis of XAFS and XPS is a powerful tool for polymer surfaces.

1. Introduction

Changes in properties of polymers by UV irradiation are of significant industrial and scientific interest. There have been many investigations on the structural changes of polymers by UV irradiation in relation to, for example, degradation of mechanical properties or improvements of adhesion properties. Because the structural changes start from the surface, surface analytical methods are very often used for the investigation. In this context, many scientists have used X-ray photoelectron spectroscopy (XPS) that gives chemical information on specific elements based on the binding energies of the core electrons. XPS can discriminate a specific element with different chemical states and can give reliable semi-quantitative analytical results. X-ray absorption fine structure (XAFS) has an advantage over XPS in the respect that XAFS is more sensitive than XPS for the changes in the local structure around a specific atom. Although recent progress of synchrotron radiation technology has made it relatively easy to measure the XAFS spectra of light elements such as C, N and O, there still remained a problem to measure the XAFS spectra of bulk insulators by surface-sensitive electron yield methods. Recently, however, we developed a system consisting of a partial electron yield detector, hemispherical analyzer and charge-neutralization flood gun that enables us to measure XAFS and XPS spectra of bulk insulators [1]. In the present paper, we report the photo-degradation behavior of pyromellitimido-oxydianiline (PMDA-ODA) polyimide (PI, Fig. 1) films using the above system.

PMDA-ODA PI films have excellent heat-resistance properties and are used in wide applications as thermal blankets. When PI films are used as the thermal blanket in the aerospace industry, photo-degradation of the films is of significant importance, because the films are subject to very strong UV irradiation for a long period. In a previous paper [2], we reported photo-degradation of PI films in air. The results suggested that the imide ring in the PMDA part was cleaved by an oxidative reaction. In the present study, we monitor the spectral changes of the PI films by UV irradiation in vacuum that is more similar to the conditions for aerospace applications. We compare the XPS and XAFS spectra of the PI films irradiated in air and in vacuum and discuss the difference in the degradation behavior of the PI films. Through the results and discussions, we show that the combined analysis of XPS and XAFS is a powerful tool for the analysis of polymer surfaces.

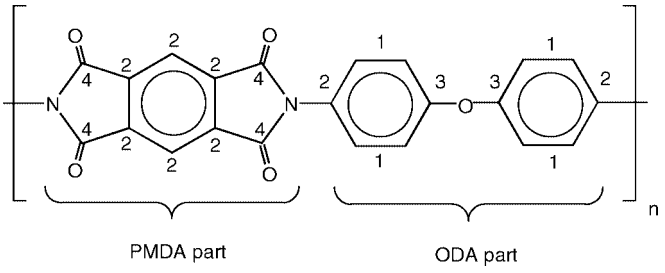

Fig. 1. Structural formula of PMDA-ODA polyimide films.

2. Experimental

The XAFS spectra were measured at a soft X-ray beam line BL-13C of the Photon Factory at the Institute of Materials Structure Science (KEK-PF). An ultra high vacuum (UHV) chamber with an electron yield detector and a hemispherical analyzer was equipped at the end of BL-13C. The experimental setup of the measurement system is shown in Fig. 2. The electron flood gun and low-energy Ar ion gun equipped in the UHV chamber performs charge-neutralization of sample surface and enables spectral measurements of insulators. The experimental method was already described in a previous paper [1]. The XPS spectra in the present paper were measured with Al Kα X-ray excitation ($h\nu = 1486.6\,\mathrm{eV}$).

*e-mail: tanaka-t@aist.go.jp

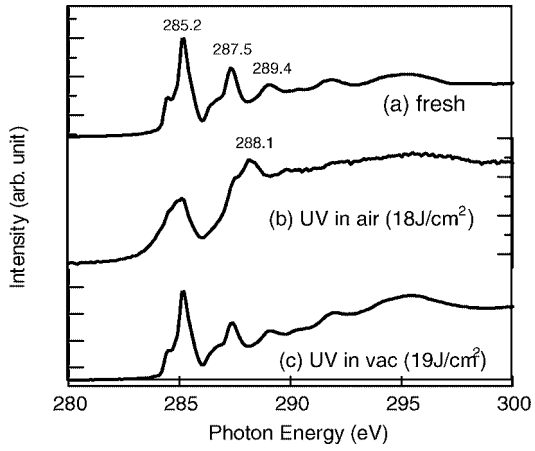

Fig. 3. C K-edge XAFS spectra of fresh and irradiated PI films; (a) fresh, (b) 18 (J/cm^2) under air, (c) 19 (J/cm^2) under vacuum.

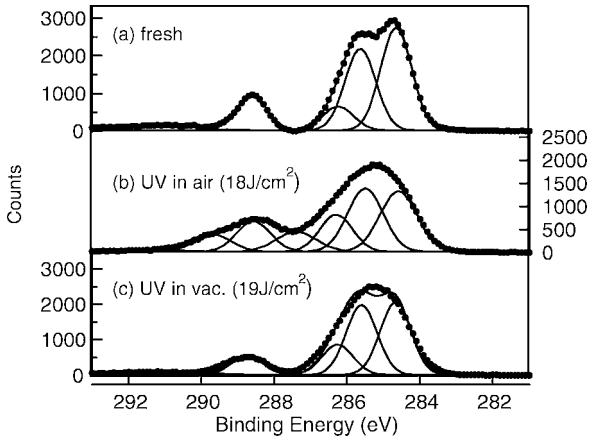

Fig. 4. C1s XPS spectra of fresh and irradiated PI films.

As a UV light source, a low-pressure mercury lamp with wavelengths of 184.9 nm and 253.7 nm was used. For UV irradiation in vacuum, a PI film with a diameter of 5 mm and a thickness of 20 μm was set in the UHV chamber and irradiated through a view-port made by synthetic fused silica. The background pressure of the irradiation chamber was $\sim 1 \cdot 10^{-8}$ torr. Before introduction to the UHV chamber, the topmost surface of the PI films was removed by scraping, because the surface of the films was contaminated with adventitious carbon.

3. Results and discussion

3.1. *C K-edge XAFS analysis*

Figure 3 shows the C K-edge XAFS spectra of fresh and UV irradiated PI films in air and in vacuum. According to a literature [3], the most sharp and intense doublet peak observed at about 285 eV and the peak at 289.4 eV in the spectrum of the fresh PI film were assigned to the π^* resonance (C=C) of PMDA and ODA aromatic rings. Similarly, the sharp peak at 287.5 eV was assigned to the π^* resonance (C=O) and the peaks observed at higher energies than 290 eV were assigned to σ^* resonance. UV irradiation in air significantly changed the spectrum; the intensities of the π^* peaks assigned to the aromatic rings decreased, whereas a new peak appeared at 288.1 eV. Compared with the past literatures, the peak at 288.1 eV is most likely assigned to π^* resonance (C=O) of carboxyl (-COO-) groups [4]. In contrast, UV irradiation in vacuum did not cause evident changes in the spectrum.

Figure 4 shows the C1s XPS spectrum of the fresh and irradiated PI films. The spectrum of the fresh PI film could be deconvoluted into four components that were assigned to two kinds of aromatic carbon (1, 2 in Fig. 1), C-O (3 in Fig. 1) and C=O (4 in Fig. 1) from the low energy side. Note that the relative intensity of each component is consistent with the atomic ratio in the PMDA-ODA structure. By UV irradiation in air, the intensities of the peaks assigned to aromatic carbon (1, 2) decreased, whereas new peaks appeared at 287.3 eV and 290.0 eV. On the basis of the literatures [5, 6], the peaks at 287.3 eV and 290.0 eV are respectively assigned to carbonyl and carboxyl groups. Thus, both XAFS and XPS spectra suggested that UV irradiation in air caused the cleavage of the imide ring of the PMDA part. Similar to XAFS, no significant change was observed in the spectrum of the PI film by UV irradiation in vacuum.

3.2. *O K-edge XAFS analysis*

Figure 5 shows the O K-edge XAFS spectra of fresh and UV irradiated PI films. The spectrum of the fresh PI film showed a sharp peak at 530.1 eV assigned to π^* resonance (C=O) and a broad peak at 539.7 eV assigned to σ^* resonance (C=O). Two small peaks observed at 532.3 eV and 534.7 eV were not exactly assigned but probably assigned to π^* resonance related to C=O, such as -N-C=O-. After UV irradiation in air, the intensities of the two small peaks decreased and the sharp peak at 530.1 eV was broadened. These results are likely attributed to the structural change of the imide ring. UV irradiation in vacuum did not cause detectable changes in the O K-edge XAFS spectrum.

Figure 6 shows the O1s XPS spectra before and after UV irradiation. All the spectra exhibited a peak with a shoulder at the higher energy side. No obvious changes in the spectral shapes were observed during UV irradiation. However, the relative peak area ratio of O1s relative to C1s increased by 17% after UV irradiation in air. This indicates surface oxidation of the PI film during UV irradiation in air.

3.3. *N K-edge XAFS analysis*

Figure 7 shows the N K-edge XAFS spectra of fresh and UV irradiated PI films. The two sharp peaks at 400.4 eV and 403.0 eV observed in the fresh PI film were likely assigned to

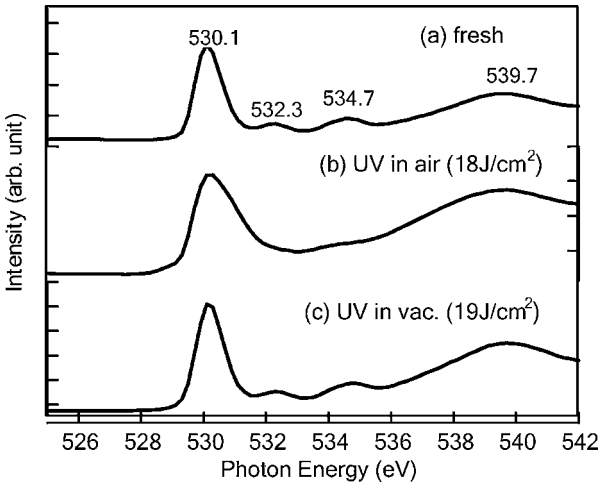

Fig. 5. O K-edge XAFS spectra of fresh and irradiated PI films.

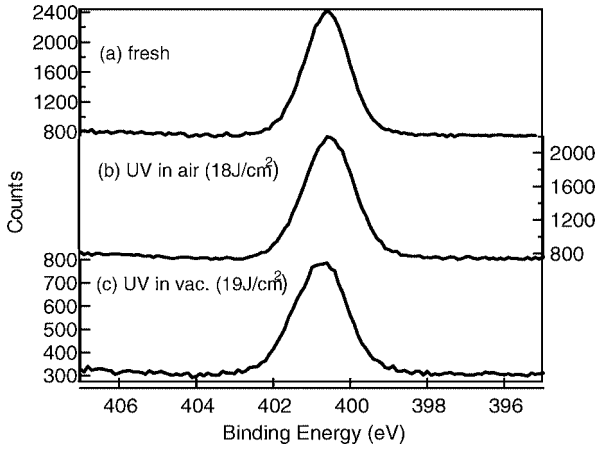

Fig. 8. N1s XPS spectra of fresh and UV irradiated PI films.

π^* resonance (-N-C=O). By UV irradiation in air, the intensities of the both peaks decreased in line with the changes in the C K-edge and O K-edge XAFS spectra. In contrast to the C K-edge and O K-edge XAFS spectra, an evident change was observed in the spectrum of the UV irradiated PI film in vacuum. The intensity of a small peak at 399.0 eV observed in the spectrum of the fresh PI film increased after UV irradiation in vacuum. According to past literatures [7–10], a feature observed below 400.0 eV was assigned to a pyridine-like ring or CN triple bond that leads to a more strongly conjugated system than imide rings.

Figure 8 shows the N1s XPS spectra before and after UV irradiation. All the spectra exhibited a symmetric peak and no meaningful difference was observed among them.

3.4. *Discussion and summary*

The XAFS and XPS results presented here may not be sufficient to conclude the structural changes of the PI films occurring by UV irradiation, however, below we discuss possible changes of the PMDA-ODA structure. UV irradiation in air most likely caused the cleavage of the imide ring of the PMDA part. The cleavage between -CO- and −N< likely formed -COO- with the addition of oxygen from air. As a next step, the active -COO- readily reacts with the aromatic ring of the neighbor polymer chain. This resulted in the decrease in the intensities of the features arising from the aromatic carbon with no substituted functional group in both XAFS and XPS spectra (Figs. 3 and 4). The above discussion is also consistent with the changes observed in the O K-edge XAFS spectra (Fig. 5) and the increased O1s/C1s ratio in XPS spectra. Note that the above discussion is slightly different from a recent paper by Okajima *et al*. [11] who claimed formation of an aldehyde group from an ester group by UV irradiation of a poly-butylentelephthalate (PBT) film. The change in the local structure around N by UV irradiation in air is not clear, but the change in the N K-edge XAFS spectrum suggested a change in the local structure around N from −N< to $-NH_2$ that has no π^* resonance. Thus, UV irradiation in air caused cleavage of the imide ring followed by bridging between the polymer chains via –COO- groups.

The structural change of the PI film by UV irradiation in vacuum was relatively smaller than those by UV irradiation in air. The spectral changes indicated no cleavage of the imide ring but suggested reformation of the imide ring that resulted in the changes in the conjugated structure. Note that the changes in the local structure around N and O could not be detected by XPS. The present results implicate that the combined analysis of XAFS and XPS is a powerful tool for the polymer surface, because the two techniques give supplementary information each other on the polymer components.

Abstract

A structural study of a niobium-peroxo-citrato complex in an aqueous solution, used as a precursor for the synthesis of ceramic oxides by an aqueous solution-gel route is performed by Nb K-edge EXAFS analysis. The results clearly indicate the formation of niobium-peroxo-citrato dimers via Nb-O-Nb links. Nb(V) ions are seven-coordinated including one Nb=O bond of a niobyl group and two Nb-O bonds from a side-on metal-peroxo group. The results are consistent with a previously proposed structural model based on Raman and UV spectroscopy studies.

1. Introduction

There has been a lot of interest in the preparation of electroceramic metal oxides containing niobium by solution techniques. From an economical and ecological point of view, aqueous routes are preferred. The aqueous solution-gel route involves the formation of a gel network by hydrolysis, condensation and complexation reactions in an aqueous solution of metal salts and chelating or bridging ligands [1–3]. Drying and a suitable heat treatment convert the amorphous gel into the desired ceramic oxide.

Aqueous solution chemistry of high valent metals such as Nb(V) is however very complicated because they are extremely sensitive towards hydrolysis, leading to precipitation and undesired phase segregation. Despite the additional fact that the only available water-soluble Nb compound – an oxalate – is not appropriate for gel formation and combination with other metal ions, we succeeded to transform it into a water-soluble Nb precursor, suitable for gel formation, by reaction with peroxide and complexation with citric acid.

In order to understand the mechanism of the solution-gel processes on the molecular level it is crucial to know the structure of the Nb complex formed in the precursor solution. Up to date only one model was proposed for a niobium-peroxo-citrato complex in aqueous solution by Narendar and Messing [4], based on Raman and UV spectroscopy studies of the solution and additional IR data on the condensed phase. However, to our knowledge, there are no XRD or other direct data on the structure of the Nb complex.

The objective of this work is to study the structure of the Nb-peroxo-citrato complex in the aqueous solution by Nb K-edge EXAFS. We analyse the local niobium environment and compare the structural results with the model proposed by Narendar and Messing.

2. Experimental

The aqueous niobium solution was synthesized according to the procedure of Nelis *et al*. [2] by first oxidizing niobium(V) ammonium oxalate with hydrogen peroxide in an aqueous solution of citric acid. The pH is then raised to 7.5 with ammonia which allows the citrate groups to co-ordinate the metal ions and to form a stable water-soluble Nb(V)-peroxo-citrato complex.

The Nb K-edge EXAFS spectrum of the solution was measured at the BM20 beamline of the ESRF synchrotron radiation facility. The station provided a Si(111) fixed-exit double-crystal monochromator with about 3 eV resolution at the Nb K-edge. Harmonics were effectively suppressed (below 8×10^{-4}) by a slight detuning of the monochromator crystals, keeping the intensity at 70% of the rocking curve with the beam stabilization feedback control. The beam was focused using two mirrors with silicon reflecting stripes on a silicon substrate. The first mirror is bent for horizontal collimation of the synchrotron radiation from the bending magnet on the monochromator, while the second mirror, placed after the monochromator, allows a vertical focusing of the monochromatic beam onto the sample. The beam size on the sample was 1 mm × 8 mm.

The solution was inserted in a polyethylene cuvette with a path length of 8.5 mm. The Nb concentration of 0.15 M was chosen to obtain an optimal absorption thickness of about 1 above the Nb K-edge. The intensity of the incident and transmitted beam was measured with Ar filled ionisation cells. The standard stepping progression within [−250 eV–1000 eV] region of the Nb K-edge was adopted for EXAFS spectra with an integration time of 2s/step. The exact energy calibration is established with simultaneous absorption measurements on an Nb metal foil.

3. Results

Nb EXAFS spectrum (Fig. 1) was analyzed by the University of Washington analysis programs using FEFF6 code for ab initio calculation of scattering paths [5, 6]. Nb neighbour shells are discerned in the k^3 weighted Fourier transforms of the EXAFS spectrum shown on Fig. 2 together with a best-fit EXAFS model. A very good fit is found in the R range from 1.3 Å to 4.0 Å with seven oxygen atoms in the first coordination shell, and one Nb atom and several carbon atoms in a second shell. The quality of the fit is shown also on Fig. 1. A complete list of best-fit parameters is presented in Table I.

To describe the first coordination shell we included in the model three different Nb-O distances that can be expected in similar metal-peroxo complexes [7–11]. Indeed, we found one oxygen at a short distance of 1.75 Å, corresponding to niobyl group (Nb=O)

which is consistent with bond lengths of metal-oxo groups, e.g. Mo=0 (1.66 Å) [8] and V=O (1.60 Å) [10]. The remaining six oxygens are found to be distributed into two groups: first three centered at the distance of 2.03 Å and the remaining three at a much longer distance of 2.59 Å. A metal-oxygen distance of about 2.0 Å is characteristic for side-on metal-peroxo bonds [12, 13], while the longer distance indicates the presence of carboxylate oxygens coordinated to Nb. Due to large correlations between fitting parameters it was not possible to obtain a more precise distribution of oxygen neighbours in the first shell. Even at this level of details we obtained relatively large uncertainties for number of neighbours and Debye-Waller factors.

Similarly, due to high correlations of the second shell parameters, we were not able to determine the exact number of carbon atoms, which were found at non-equal distances in that shell. However, the Nb neighbour parameters could be reliably determined since they were not affected by the correlations.

Table I. *Structural parameters of the nearest coordination shells around the Nb atom in aqueous solution of the Nb-peroxo-citrato complex: type of neighbour atom, number N, distance R, and Debye-Waller factor σ^2. Uncertainties of the last digit are given in the parentheses.*

C	2(1)	4.08(2)	0.004(2)

4. Discussion

The structural parameters obtained by Nb EXAFS can be compared with the proposed model for the niobium-peroxo-citrato complex in aqueous solution by Narendar and Messing [4]. Their model consists of a dimeric structure in which each Nb(V) ion is surrounded by seven oxygens, one from a niobyl group, two from a side-on peroxo group and four from citrate ligands.

In our case the presence of a single Nb neighbour at 3.30 Å clearly indicates the formation of dimers via Nb-O-Nb links. We also find seven-coordinated Nb with one short Nb=O bond of a niobyl group. Two of the three oxygens at about 2.0 Å may be ascribed to side-on metal-peroxo bonds, for which we have additional evidence from the UV spectrum of the solution, showing the characteristic ligand-metal charge-transfer band at 255–260 nm [14]. The remaining four oxygens most probably originate from carboxylate and α-hydroxy groups of citric acid ($C(OH)(COOH)(CH_2COOH)_2$). The hydroxy coordination is expected because the complex synthesized with a modified ligand without the α-OH group is not stable. The oxygens at a relatively long distance of about 2.6 Å may be ascribed to carboxylate groups for which a closer approach is hindered by increased strain within the citrate ligands. The carbon atoms in the second shell found at 3.0 Å, 3.8 Å and 4.1 Å originate from citrate functional groups.

Our results are consistent with the structural model of Narendar and Messing [4]. Other structural studies of metal-peroxo-carboxylato complexes in condensed phases based on IR spectroscopy, thermal analysis and X-ray diffraction [4, 7–15] also support our findings: most of them reveal a structure with a pentagonal bipyramid coordination of the metal which is then sp^3d^3 hybridized. Additionally, in many cases dimer units are formed in amorphous precipitates or in a crystalline form of similar peroxo-carboxylato complexes [4, 9–11]. However, we find some differences compared to the XRD data obtained on crystalline samples with the same dimeric structural units. In the solution we observed three long Nb-O distances instead of one reported for the crystalline samples of other metal complexes [9–11]. Therefore our results suggest that the dimers may have slightly different structure in solution than in a condensed phase.

Abstract

Granular solids composed of Co dispersed in a Cu matrix attracted the attention of magnetism community due to several interesting characteristics. One of their most striking properties is the giant magnetoresistance. In this work we used EXAFS to study the Debye-Waller factor, or disorder, of a $Co_{10}Cu_{90}$ sample as a function of the temperature. Using the correlated Einstein model, we were able to separate the thermal from the static contribution to the disorder. We concluded that the granular alloy has static disorder comparable to that of bulk well crystallized Co. In other words, for the $Co_{10}Cu_{90}$ sample around Co atoms, most of the disorder has thermal origin at room temperature. This is explained basically as the influence of the Cu matrix on the atoms at the interface of the well defined Co particles.

1. Introduction

Granular magnetic systems have been extensively studied in the last few years because they display a number of interesting physical properties which, besides the prospective technological use, settle a challenge to the physics community to be properly understood. Among these properties one can mention giant magnetoresistance, superparamagnetism, spin-glass-like behavior and the kinetics of growth of nanocrystalline grains. The system studied in the present work displays all the above mentioned properties, and therefore it is a unique setting to investigate the physical properties of granular solids.

In granular solids composed of cobalt particles embedded in a copper matrix, as is the case of the $Co_{10}Cu_{90}$ sample, it was observed that the relative disorder ($\Delta\sigma^2$) around Co atoms, taking bulk Co as reference, has a non-monotonous behavior and decreases for increasing annealing conditions (fig. 1) [1]. In EXAFS the disorder is represented by a Debye-Waller factor $\exp -\sigma^2 k^2$, where σ^2 represents the absolute mean square relative displacement (MSRD) and $\Delta\sigma^2$ is the relative value compared to a reference. The annealing enables an increase of the Co particles within the matrix and tends to better organize their interface with the matrix, leading to a smaller overall disorder. Nevertheless, the disorder can be of thermal or static origin and it is not yet understood which one contributes more. In order to disentangle both contributions, we used EXAFS spectroscopy to study the dynamical behavior of the Co-Cu sample, by comparison with the bulk Co and Cu metals.

2. Experiment

The studied Co-Cu sample was a melt-spun ribbon, 0.05 mm thick and 5 mm wide, of 10 at.% of Co embedded in a 90 at.% Cu matrix. The annealing was performed allowing a constant electric current of 4 A, flow through the sample length during one minute (Joule annealing [3]). Both bulk Co and Cu were also measured for comparison. The EXAFS measurements were performed at the D04B-XAS beamline at LNLS [2], Brazil, for sample and bulk metals from 10 K up to 600 K, in transmission mode. The data analysis followed the standard Fourier filtering procedure: initially a straight line (fitted in the pre-edge region) was subtracted from the raw spectra. The $\chi(k)$ signal was then extracted subtracting a seven segment spline. The Fourier transform was performed with k^2 weighting, from 2.5 up to 14.5 $Å^{-1}$. The back Fourier transform was done in an interval of 1 Å centered around the first neighbors peak. The EXAFS equation for the first neighbor shell was fitted using experimental amplitudes and phases, as will be described later in this paper. In these fits the coordination number was fixed at 12, the number of neighbors in the coordination shell for HCP and FCC structures. From the fitting procedure we obtained inter-atomic distances, relative Debye-Waller factors and energy shifts of the absorption edge. The following discussion will be based on Debye-Waller factors results solely.

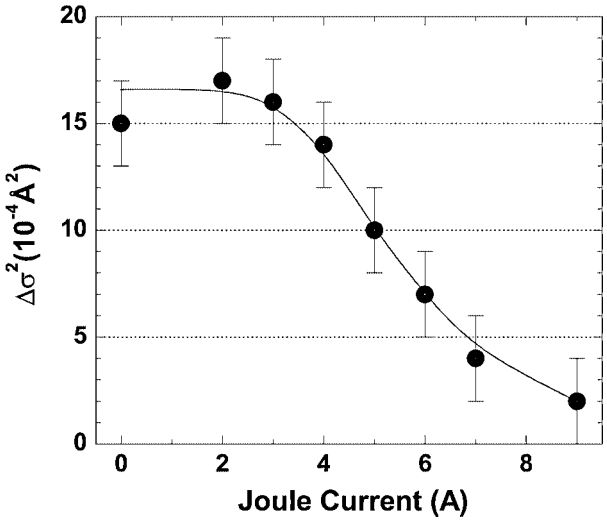

Fig. 1. Variation of the relative total disorder (static and thermal) around Co atoms with the annealing, for a series of $Co_{10}Cu_{90}$ samples. The reference bulk Co and all samples were measured at room temperature. The annealing was performed by Joule heating the samples during one minute with different currents. Details about these results can be found in reference [1].

3. Results and discussion

The $\chi(k)k^1$ signals for bulk Co and Co-Cu sample around Co K-edge, and Cu around Cu K edge are shown in figure 2 for some selected temperatures. It can be clearly seen the effect of the temperature in damping the EXAFS oscillations.

In the first approach to the analysis, the Co K-edge spectra of the Co-Cu sample, measured from 10 up to 600 K, were analyzed using the extracted experimental phases and amplitudes from the spectrum of the sample measured at the lowest temperature, i.e., from the Co-Cu spectrum at 10 K. So, the disorder found at different temperatures are relative to the sample at 10 K. These

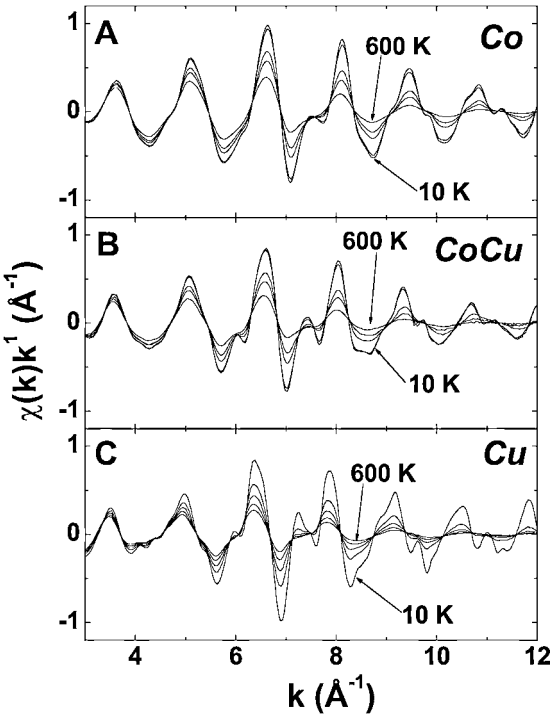

Fig. 2. Representative examples of EXAFS signal obtained for the bulk Co (a), $Co_{10}Cu_{90}$ sample (b), and bulk Cu (c). The measurement temperatures shown are 10, 100, 300, 400 and 600 K for Co and $Co_{10}Cu_{90}$. For Cu they are 10, 300, 400, 500 and 600 K. The arrows indicate only the minimum and maximum temperature.

data, carrying just the thermal contribution $\Delta\sigma^2_{TH}$ to the total disorder, were fitted using the correlated Einstein model [4, 5], according to the following equation:

$$\Delta\sigma^2_{TH}(\Theta_E, T) = \frac{\hbar^2}{2\mu k_B \Theta_E} \coth\left(\frac{\Theta_E}{2T}\right) - \sigma_0^2 \qquad (1)$$

where Θ_E is the Einstein temperature, T the absolute temperature and μ is the reduced mass of the pair of atoms involved in the bond. The σ_0^2 constant is introduced because our data give the disorder relative to the lowest temperature. In fact, the σ_0^2 represents the zero-point thermal fluctuation. So, the equation (1) has two adjustable parameters to vary in the fit, namely Θ_E and σ_0^2.

The same procedure was used for the bulk Co and Cu standards, using experimental phase and amplitudes from each metal measured at 10 K as reference. As result, we found the effective Einstein temperature Θ_E, and the absolute zero-point thermal fluctuation σ_0^2 for each sample (see Table I). In fig. 3, the experimental results and the absolute thermal disorder fitted to the correlated Einstein model are plotted against the temperature. The experimental points are shifted from zero by the zero-point thermal fluctuation value.

Table I. *Results of the fits shown in fig. 3.* Θ_E *and* Θ_D *are the Einstein and Debye temperatures obtained using the correlated Einstein model.*

	Co	$Co_{10}Cu_{90}$	Cu
$\sigma^2_{0K}(10^{-4}$ Å$^2)$	30 ± 1	32 ± 1	36 ± 2
Θ_E (K)	285 ± 3	269 ± 3	233 ± 3
Θ_D (K)	380 ± 4	359 ± 4	311 ± 4
f (N/m)	69 ± 1	61 ± 1	50 ± 1

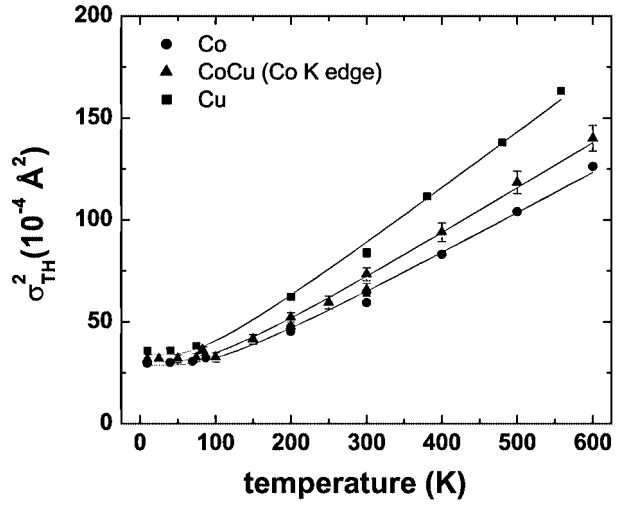

Fig. 3. Absolute thermal disorder variation as function of temperature for bulk Co and $Co_{10}Cu_{90}$ sample around Co K-edge and for bulk Cu around Cu K-edge. The continuous lines represent the fits to the correlated Einstein model.

The Einstein temperature can be considered as a measure of the effective bond-stretching force constant, given by $f = \mu k_B^2 \Theta_E^2/\hbar$[5]. The values corresponding to all samples (Table I) can be used to compare the strength of different bonds. The smaller Einstein temperature obtained for bulk Cu in comparison with bulk Co reflects the fact that Cu atoms present a greater thermal disorder at a given temperature. In other words, Cu-Cu bonds are weaker than Co-Co bonds, as shown by the effective force constants. For the $Co_{10}Cu_{90}$ sample, we observed an intermediate situation. That can be understood as the following: if individual Co atoms were dispersed in the Cu matrix, they would be bound to Cu atoms with weaker bonds compared to Co-Co bonds, and therefore would have a greater thermal disorder. Co atoms on the surface of the Co particles would have their lattice dynamics affected by the matrix, while atoms within the core of Co particles would tend to preserve the bulk Co properties. EXAFS gives the average over all Co atoms. Depending on the surface/volume ratio of the particles in the sample, the effective Einstein temperature Θ_E will tend to the bulk Cu (small particles) or Co (big particles) values. In the $Co_{10}Cu_{90}$ sample studied here, the Co atoms are forming particles with an average size close to 4 nm, whose surface/volume ratio corresponds to approximately 30% [1]. As expected, the thermal behaviour of the Co atoms in the $Co_{10}Cu_{90}$ sample is closer to that of the bulk Co sample. The Debye temperatures, estimated simply by $\Theta_D \approx 4\Theta_E/3$ [4], are listed in table I. The behavior of Θ_D follows that of Θ_E and compares very well to the values reported in the literature (315 and 385 K for Cu and Co respectively [6]).

Another approach to the data analysis was to fit the Co K-edge spectra of the Co-Cu sample using bulk Co, measured at the same temperature, as reference. Even if in the Co-Cu sample, Co atoms have Co and Cu as first neighbors, these atoms are very similar and can hardly be distinguished as scatters [1]. With this approach, the obtained Debye-Waller factor contains not only the disorder from thermal origin, but also the additional static disorder of Co-Cu sample relative to bulk Co. These experimental results are shown in fig. 4 for each temperature (squares). In addition, it is shown in the same figure (continuous line) the relative thermal disorder between the $Co_{10}Cu_{90}$ sample and the bulk Co, obtained by the difference between the respective fitted curves shown in fig. 3. One can observe that the experimental points lie above but fairly close to the expected relative thermal disorder of

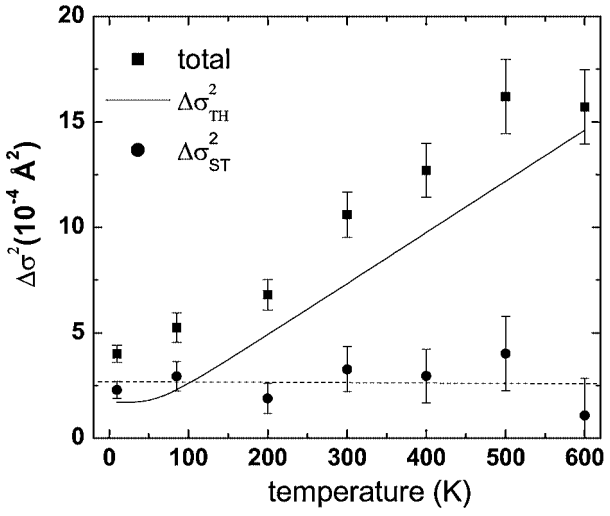

Fig. 4. Variation of the relative total disorder (squares) around Co atoms with temperature, in annealed $Co_{10}Cu_{90}$ sample. The bulk Co was used as reference and measured at each temperature together with the sample. The continuous line represents the expected relative thermal disorder. The circles represent the static contribution to the disorder ($\Delta\sigma^2_{ST}$).

$Co_{10}Cu_{90}$. The difference between the experimental points and the calculated curve arises due to a small amount of static disorder. This difference is also plotted in fig. 4 (circles), and the dashed horizontal line is a linear fit of these points, showing (as expected) a constant value for the static disorder ($\approx 3\times10^{-4}$ Å^2). One can note that the relative static disorder is very small compared with the thermal component.

4. Conclusions

In this work we investigated the behavior of the disorder in a Co-Cu granular alloy. The temperature dependence of the EXAFS Debye-Waller factor, compared with the same measurements on bulk Co and Cu, allowed us to conclude that most of the disorder in the granular alloy is of thermal origin, and that the static disorder is negligible and nearly the same as bulk Co.

Abstract

The structures of mechanically alloying $Fe_{60}Ni_{40}$ milled for 5, 10, 20 and 40 hours were investigated by XAFS and XRD. The XRD patterns indicate that the α-Fe phase almost disappears and only the fcc phase remains after milling for 10 hours. The XAFS results further show that the RSF shape of Fe atoms is similar to that of Ni atoms for the MA $Fe_{60}Ni_{40}$ (10 h) alloy. The Debye-Waller factors σ_1 of the Fe and Ni atoms in the MA $Fe_{60}Ni_{40}$ (10 h) increase from 0.071 and 0.091 Å to 0.102 and 0.105 Å, respectively. These results demonstrate that the local structure of most Fe atoms in the MA $Fe_{60}Ni_{40}$ (10 h) has changed from bcc structure to fcc one after milling for 10 hours. With the milling time going to 40 hours, the σ_1 of both Fe and Ni atoms increase to about 0.117 Å, the $R_1 = 2.48$ Å and $N_1 = 11.9$ around Fe atoms are equal to $R_1 = 2.48$ Å and $N_1 = 11.9$ around Ni atoms and the magnitude peaks of the higher shells disappear for MA $Fe_{60}Ni_{40}$ (40 h). These results imply that the changes of local structure around Fe atoms are identical with that around Ni atoms in MA $Fe_{60}Ni_{40}$ alloys. We consider that the MA $Fe_{60}Ni_{40}$ (40 h) alloy is a homogenous solid solution.

1. Introduction

Recently, a lot of studies have revealed that the mechanical alloying (MA) can strongly increase the solid solubility of the completely immiscible alloys with a positive heat (or small negative heat) of mixing. For example, the solid solubility of Fe-Ni, Fe-Cu and Cu-Ta alloys increase from 3–6% of the thermodynamics balance to about 30% of the supersaturated one [1–4]. The MA Fe-Ni alloy has been widely applied in the fields of magnetic read-write header, accurate instruments and the laser techniques due to its crystal lattice constant invariableness in a wide temperature range, good soft magnetism ability as well as its nice property in absorption of microwave [5–10].

Kaloshkin *et al*. [1, 5] have studied the structure of as-prepared and annealed $Fe_{100-x}Ni_x$ alloys using X-ray diffraction (XRD). Their results indicate that the $Fe_{100-x}Ni_x$ alloy is a single fcc phase for $x \geq 28$, a single bcc phase for $x \leq 22$ as well as coexisting phases with fcc and a bcc structures for x in the range of $22 < x < 28$. Baldokhin *et al.*'s results have shown that the single-phase (bcc) $Fe_{100-x}Ni_x$ $(10 < x < 20)$ alloys transfer to coexistence of fcc and bcc alloy phases after annealing at 923 K [6]. Kuhrt *et al*. [7, 8] reported the martensitic transformation of $Fe_{100-x}Ni_x$ alloys from their XRD, DSC and VSM results. They have found that the microstructure of the MA $Fe_{100-x}Ni_x$ alloy can influence considerably the kinetics of the martensitic transformation, and that its high density of grain boundaries and lattice defects can hinder the martensite growth of the MA $Fe_{100-x}Ni_x$ alloy. However, no a detailed investigation on the local structure of the MA $Fe_{100-x}Ni_x$ alloys has been done yet.

In the present paper, the long-range and short-rang structures of $Fe_{60}Ni_{40}$ alloys with various milling times have been studied by XRD and X-ray absorption fine structure (XAFS). The results are useful to understand the local structural change and the mechanism of forming supersaturating Fe-Ni solid solutions during the MA process.

2. Experimental

Crystalline iron and nickel powders with purity higher than 99.8% and with particle sizes less than 200 mesh were mixed to the desired composition $Fe_{60}Ni_{40}$. The mixture and tungsten carbide balls were sealed inside a cylindrical stainless-steel vial filled with argon gas. The weight ratio of the milling ball to the mixed powder is 40-1. The MA was performed in a planetary ball miller with a rotation speed of about 220 r/min. The various samples of $Fe_{60}Ni_{40}$ were obtained after $Fe_{60}Ni_{40}$ mixtures were milled for 5, 10, 20, 40 h, respectively. The standard Fe (or Ni) powder for XAFS measurement was prepared by milling the Fe (or Ni) powder in an agate mortar. The XRD patterns of the samples were measured on a D/max-rA rotating target diffractometer using Cu K_α radiation ($\lambda = 1.5418$ Å, 40 kV and 60 mA), with a 0.02 degree step (set time is 0.1 s), DS = SS = 1°, RS = 0.3 mm.

X-ray absorption spectra of $Fe_{60}Ni_{40}$ samples at Fe and Ni K-edge were measured at the U7C beamline of National Synchrotron Radiation Laboratory (NSRL) and the beamline of 4W1B of Beijing Synchrotron Radiation Facility (BSRF). The storage ring of NSRL was operated at 0.8 GeV with a maximum current of 160 mA, and the hard X-ray beam from a three-pole superconductor wiggler with a magnetic field intensity of 6 T was used. The storage ring of BSRF was run at 2.2 GeV with a maximum current of 100 mA. Fixed-exit Si(111) flat double crystals were used as monochromator. The XAFS spectra in NSRL were collected in transmission mode with ionization chambers filled with Ar/N_2 at room temperature, using a Keithley Model 6517 Electrometer to record the electron charge directly. XAFS data were analyzed by NSRLXAFS3.0 software package compiled by Zhong *et al*. and UWXAFS3.0 according to the standard procedures [11, 12].

3. Results and discussions

The XRD patterns of α-Fe, metallic Ni and the MA $Fe_{60}Ni_{40}$ alloys with different milling times are displayed in Fig. 1. For comparison, the intensity of the diffraction peaks of α-Fe and metallic Ni is decrease by a factor of 1/5 and 1/15, respectively. After the $Fe_{60}Ni_{40}$ mixture is milled for 5 hours, the XRD profile shows that the peaks corresponding to the crystalline face (110),

*Correspondent: Shilong Yin, e-mail: slyin@vip.sina.com

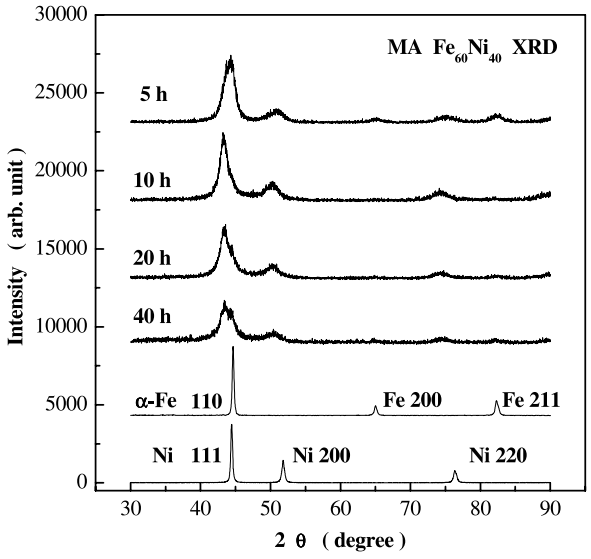

Fig. 1. XRD patterns of the MA $Fe_{60}Ni_{40}$ alloys.

(200) and (211) of bcc structural α-Fe and the crystalline face (111), (200) and (220) of fcc structural Ni are markedly clear in Fig. 1, but their intensities are much lower than those of the standard Fe and Ni references. Moreover, their diffraction peaks become broader. This indicates that the lattices of Fe and Ni powders become distorted. With the milling time going to 10 hours, the characteristic peaks of α-Fe phase almost disappear and only the peaks with fcc structure remain in the XRD pattern of the MA $Fe_{60}Ni_{40}$ (10 h), and the peak corresponding to the crystalline face (111) of the fcc structure shifts about 1.0 degree to the low angle direction. This implies that α-Fe and metallic Ni have formed the MA $Fe_{60}Ni_{40}$ alloy with fcc structure driven by the mechanical alloying, and that the lattice of the fcc structural Fe-Ni alloy has been expanded due to the diffusing of Fe atoms into the Ni lattice. The results (The MA $Fe_{60}Cu_{40}$ alloys) reported by Yavari *et al*. [4] and us [13] are in agreement with this work of the MA $Fe_{60}Ni_{40}$ alloys. Eckert *et al*. [14] have considered that the expansion of the lattice is induced by the elastic strain and magnetovolume effect. After milled for 40 hours, the peak associated with the crystalline face (111) for the MA $Fe_{60}Cu_{40}$ alloy becomes much weaker and broader, showing that the lattice distortion of the fcc Fe-Ni alloys increases further.

The EXAFS functions $k^3\chi(k)$ from both K-edge spectra of Fe and Ni atoms in the MA $Fe_{60}Ni_{40}$ alloys are shown in Figure 2. The radial structural functions (RSF) by Fourier transforming (FT) $k^3\chi(k)$ functions are shown in Figure 3. It can be observed that there are the following characteristics in the RSF functions of the α-Fe and metallic Ni powders. As shown in Fig. 3 (a), the RSF curve of bcc α-Fe powder has a strongest peak at 2.2 Å which corresponds to the first and second nearest Fe-Fe coordination shells, and the stronger peak at 4.48 Å associated with the fourth nearest coordination shell has an intensity of about 60% of that of the first peak. In the RSF curve of fcc metallic Ni powder as shown in Fig. 3 (b), the main peak located at about 2.15 Å is related to the first shell of Ni-Ni coordination, and two small peaks at about 4.0 and 4.6 Å correspond to the third and fourth nearest neighbor shells.

Seen from Fig. 3 and Table I, the main peak intensities of the $Fe_{60}Ni_{40}$ alloy decrease evidently for the sample milled for 5 hours, and the Debye-Waller factors of Fe and Ni atoms in the MA in $Fe_{60}Ni_{40}$ (5 h) increase to $\sigma_{\text{Fe-M}} = 0.086$ Å, and $\sigma_{\text{Ni-M}} = 0.095$ Å. The bond length R_1 and the coordination number N_1 of the first shell of the MA $Fe_{60}Ni_{40}$ (5 h) alloy ($R_{\text{Ni-M}} = 2.49$ Å, $N_{\text{Ni-M}} = 12.2$; $R_{\text{Fe-M}} = 2.49$ Å $N_{\text{Fe-M}} = 8.9$) are likely identical to those of metallic Ni ($R_1 = 2.55$ Å, $N_1 = 12$) and α-Fe ($R_1 = 2.48$ Å, $N_1 = 8.0$) powders. These results quantitatively manifest that the lattices of α-Fe and metallic Ni in the MA $Fe_{60}Ni_{40}$ (5 h) sample have been distorted in the beginning of the mechanical milling. Schultz has reported [14] that the structure change happens in the initial milling stage for the Fe-Zr and Ni-Zr binary systems, using XRD and DSC techniques. Their results are consistent with the conclusion of this work.

With the milling time increasing to 10 h, the main peak intensities in the RSF curves of Fe and Ni atoms of the MA $Fe_{60}Ni_{40}$ (10 h) decrease further, and the Debye-Waller factors of both $\sigma_{1\text{Fe-M}}$ and $\sigma_{1\text{Ni-M}}$ increase to about 0.102 Å. This implies that the disorders around Fe and Ni atoms in the MA $Fe_{60}Ni_{40}$ (10 h) alloy increase with the milling times. From the RSF curve of the Fe K-edge EXAFS spectrum of the MA $Fe_{60}Ni_{40}$ (10 h)

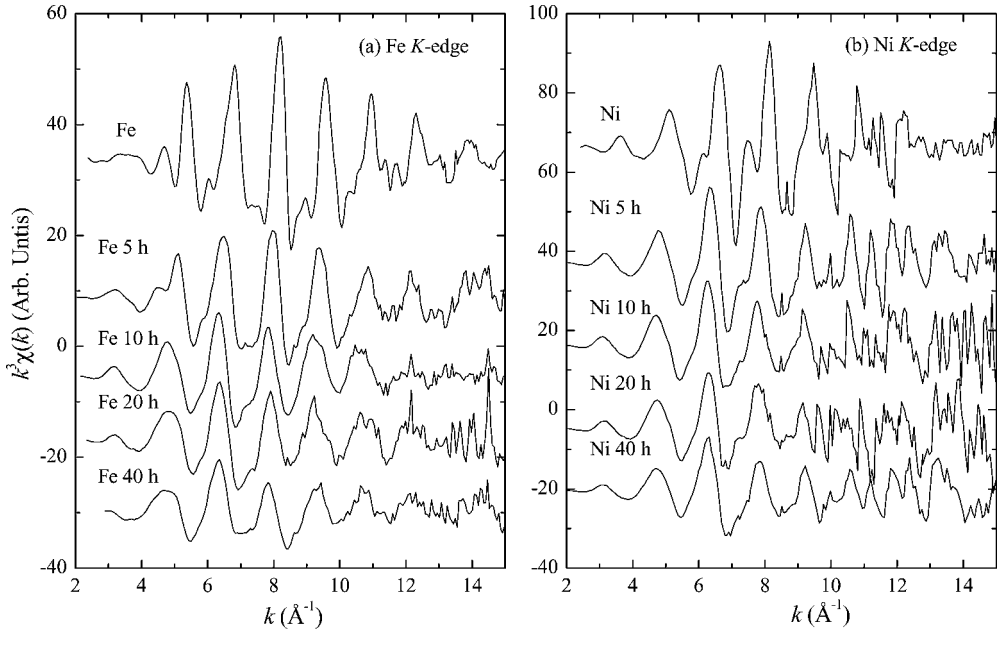

Fig. 2. $k^3\chi(k)$ curves of the MA $Fe_{60}Ni_{40}$ alloys: (a) Fe K-edge and (b) Ni K-edge.

milling time (hour)	Bond type	N	R/Å	σ/Å
(a) Fe K-edge				
5	Fe-M	8.9 ± 1.1	2.49 ± 0.01	0.086 ± 0.010
10	Fe-M	10.3 ± 1.2	2.49 ± 0.02	0.102 ± 0.012
20	Fe-M	11.2 ± 1.5	2.49 ± 0.02	0.102 ± 0.012
40	Fe-M	11.9 ± 1.5	2.48 ± 0.02	0.117 ± 0.011
Fe foil	Fe-Fe	8.0 ± 0.5	2.48 ± 0.01	0.071 ± 0.007
	Fe-Fe	6.0 ± 0.5	2.86 ± 0.01	0.084 ± 0.007
(b) Ni K-edge				
5	Ni-M	12.2 ± 1.0	2.49 ± 0.02	0.095 ± 0.020
10	Ni-M	12.3 ± 1.0	2.49 ± 0.02	0.105 ± 0.018
20	Ni-M	11.8 ± 1.5	2.49 ± 0.02	0.113 ± 0.022
40	Ni-M	11.9 ± 1.5	2.48 ± 0.02	0.117 ± 0.021
Ni powder	Ni-Ni	12.0 ± 0.6	2.49 ± 0.02	0.091 ± 0.005

alloy, the peak at 4.48 Å disappears and two new peaks appear at the positions of 4.0 and 4.6 Å. Meanwhile, the peak shape and intensity of the RSF curve from the Fe K-edge EXAFS spectrum is almost the same as that of the Ni K-edge EXAFS spectrum. This means that the local structure around Fe atoms has changed from bcc structure to fcc. However, $N_{1\text{Fe-M}}$ is about 10.3, which is larger than that of the bcc-phase α-Fe powder ($N = 8$) and smaller than that of fcc metallic Ni powder ($N = 12$). These results indicate that the local structures of most Fe atoms have transformed from bcc to fcc structure, and the main MA production is fcc structural Fe-Ni alloy, and part of bcc structural Fe-Ni alloy remains. When the milling time is increased to 40 hours, the magnitudes of the main peaks in the Fe and Ni RSF curves of MA $Fe_{60}Ni_{40}$ (40 h) obviously decrease, and are about half of those of α-Fe and metallic Ni powder. The Debye-Waller factor of $\sigma_{1\text{Fe-M}}$ and $\sigma_{1\text{Ni-M}}$ increases to about 0.117 Å for the MA $Fe_{60}Ni_{40}$ (40 h) alloy. Furthermore, $R_1 = 2.48$ Å and $N_1 = 11.9$ around Fe atoms are equal to $R_1 = 2.48$ Å and $N_1 = 11.9$ around Ni atoms for the MA $Fe_{60}Ni_{40}$ (40 h) alloy. It suggests that the MA $Fe_{60}Ni_{40}$ (40 h) alloy forms a homogenous solid solution after milling for 40 hours.

In summary, the XAFS and XRD results indicate that α-Fe and metallic Ni mixture start to form Fe-Ni alloy in the initial MA stage, and the local structures around Fe and Ni atoms in the fcc structural MA $Fe_{60}Ni_{40}$ alloys are greatly distorted with the milling time, finally, the middle range order has been almost destroyed for the MA $Fe_{60}Ni_{40}$ (40 h) alloy. A homogenous MA $Fe_{60}Ni_{40}$ alloy solid solution with large lattice distortion is produced after milling for 40 hours. These results are greatly different from those of MA $Fe_{60}Cu_{40}$ alloy reported in the literature [15, 16], in which there are both fcc Fe-rich and bcc Cu-rich regions in the $Fe_{60}Cu_{40}$ solid solution.

Abstract

We report a detailed analysis of O K-edges near edge X-ray absorption of maghemite, hematite and magnetite iron oxides. Measurements were performed on powder in Fluorescence Yield mode of detection.

Iron forms several stable oxides and its phase diagram is more complicated than that of other transition metal as Ni or Co. The differences in the local symmetry of the three iron oxides are related with the distinguishable NEXAFS spectra. In particular the spectra are characterized by a sharp doublet ascribable to transitions to the empty metal d-bands involving the t_{2g} and e_g states whose energy splitting and intensities depend on the structure and state of ionicity.

The NEXAFS spectra have been simulated and fitted by MXAN code. The aim of these simulations was the test of light *Z* element NEXAFS spectra calculation performed by phenomenological no-self-consistent potential in the near edge region, the most sensible to electronic properties details; a fit procedure of the potential parameters was performed in the extended NEXAFS photon energy range and subsequently used for near edge calculations. The MXAN simulations obtained in this way, reproduce the experimental data with good agreement and evidentiate the differences in the spectra of the three compounds. In particular maghemite, that has oxygen in two different sites, has been well simulated using potential details found for the other oxides hematite and magnetite.

1. Introduction

Iron forms several stable oxides and its phase diagram is more complicated than that of other transition metal as Ni or Co [1, 2, 3]. Iron oxides are used as catalyst materials and for their magnetic properties in the high-density magnetic recording media technology. For these reasons the investigation of iron oxides has gained increasing attention in the past years.

We report a detailed analysis of iron oxide near edge X-ray absorption fine structure (NEXAFS) performed at the O K-edge. NEXAFS spectra of maghemite, hematite and magnetite (in powder form) were performed by Fluorescence Yield detection mode. The differences in the local structure and symmetry around the central oxygen atom of the three iron oxides lead to distinguishable NEXAFS spectra. A detailed discussion on transition metal oxides trend in O K-edge spectra is reported in ref. [1]. The O K-edge spectra of iron oxides are characterized [1, 3] by a sharp doublet ascribable to transitions to the empty metal d-bands involving the t_{2g} and e_g states and showing different energy splitting and intensities as a function of the O-Fe structure and state of ionicity. The higher energy part is due to the 4sp contribution of Fe to the O 2p density of empty states.

This work is focussed on hematite, magnetite and maghemite oxides. In the three studied compound oxygen nearest neighbor shell is formed by 4 Fe anion in a pseudo tetrahedrical configuration. The oxidation state of Fe is a mixture of +2 and +3 for magnetite and exclusively +3 for maghemite and hematite. Hematite (α-Fe_2O_3) has a corundum structure, magnetite (Fe_3O_4) has a cubic inverse spinel, while maghemite presents a distorted spinel (γ-Fe_2O_3) structure with oxygen in two different sites both in a tetrahedral symmetry; it can be thought as derived by magnetite structure with all Fe^{3+} cations.

Total Yield spectra for magnetite and hematite, with an energy resolution of 500 meV, were previously reported by Wu *et al*. [3]; the spectra we present have better resolution of 200 meV. The results of this work measured in Fluorescence yield are similar, but show relative intensity ratios between the doublet peak and the higher energy feature group that are similar in the three compounds. Different intensity ratios of the 3d band relative to the 4 sp transition metal orbitals have been explained in terms of the diminished hybridisation of the metals 3d states with the O 2p states [1, 3].

Hematite is characterized by a structure at about 546 eV. This peak is much more pronounced with respect to literature data, taken at lower resolution.

The structure of the sample has been checked by O K-edge and Fe K-edge EXAFS [4].

The NEXAFS spectra have been simulated and fitted by MXAN code [5]. Our aim was the test of the calculation of light *Z* element (oxygen) near edge XAS spectra performed by phenomenological no-self-consistent potentials and analyse the simulated results in the near edge region, the most sensible to electronic properties details. These were obtained by a fit procedure of the potential parameters performed in the extended NEXAFS photon energy range (70 eV). Our simulations by phenomenological potential reproduce the experimental data with good agreement. The maghemite O K-edge spectrum has been calculated by multiple scattering for the first time. The procedure to obtain the phenomenological potential used here to get the simulated spectrum of the two different oxygen sites is detailed discussed in the following.

2. Experimental

Measurements at the O absorption K-edge were performed on the BEAR beamline of the ELETTRA synchrotron radiation facility in Trieste, Italy. The energy resolution was 200 meV for a typical photon flux on the sample of the order of 10^{10} ph/s [6]. All measurements were performed in the fluorescence yield mode using a photodiode (IRD AXUV100) operated in the current mode; the typical photodiode dark current was of the order of

*e-mail: pedio@tasc.infm.it

0.1 pA with an overall long term stability of the order of 0.01 pA. Use of fluorescence yield guarantees that spectra are relative to average bulk properties and unaffected by surface-specific structure. The samples were smeared on carbon tabs and then placed on a sample holder consisting of a steel plate mounted on a vertical rotary feedthrough. The samples were polarized at +1000 V in order to avoid electrons excited by the photon beam reaching the photodiode detector.

Fluorescence yield spectra of concentrated samples can be distorted due to self-absorption [7]. In order to minimize spectral distortions the angle between the impinging photon beam and the sample surface was fixed at 70°. Since some distortions can in any case be present the raw data was corrected according to a method developed by some of the co-authors which involves the scaling of the experimental spectrum to tabulated atomic cross-sections [8]. All the O K-edge data have been thus corrected for self-absorption. Absorption signals were normalized to the incident flux obtained by measuring the current drained by tungsten grid inserted in the beam path. The grid was flashed in order to remove contaminants, typically C and O.

3. Results and Discussion

Fig. 1 shows O K-edge NEXAFS spectra of hematite (α-Fe_2O_3), maghemite (γ-Fe_2O_3) and magnetite (Fe_3O_4) as measured by Fluorescence Yield of powder samples.

In the low photon energy region, within 5 eV above the edge, a sharp doublet is present in all the three spectra. The doublet was interpreted in the literature as due to transitions to the empty metal d-bands involving the t_{2g} and e_g states as projected on to the p O empty states and whose degeneracy is removed by the breaking of symmetry of the octahedral configuration in pure Fe while the higher energy is due to the 4sp iron contributions to the O 2p density of states.

O6				3.06 (×3)
⟨O-O⟩	2.876	2.968	2.958	2.956

The distances to the central oxygen atom in the three iron oxides are reported in Table I up to a radius of about 3 Å; note that the oxygen surrounding of hematite is sensibly different in symmetry and distances to the other two compounds.

In Fig. 1 the doublet is very well resolved for hematite and remains clearly detectable for the three compounds. The differences in the energy splitting and intensities are functions of the O-Fe structure: the energy splitting is larger in hematite (1.45 eV) and decreases to about 1.05 eV for the other two compounds, magnetite and maghemite; the peak at about 532 eV is related to the t_{2g} state with π character and the other at about 533 eV is due to the e_g states, with σ character [2]. The spectrum for maghemite is similar to that of magnetite but exhibits a significant shift towards lower energies of most features, including a −0.35 eV shift of the absorption edge itself.

The higher energy region is characterized by broader features that have been proved to be due in hematite and magnetite [3] to multiple scattering induced by atoms lying above 5 Å from the central oxygen atom. Moreover hematite is characterized by a structure at about 546 eV. This peak is much more pronounced with respect to literature data, taken at lower resolution. Total Yield NEXAFS spectra of hematite and magnetite have been reported in the literature at a resolution of 500 meV and analysed by multiple scattering formalism [3]. The spectra of the present work are measured in Fluorescence yield are similar, indicating the correctness of our procedure for correcting for self-absorption. Moreover the spectra presented here have the better resolution of 200 meV and show a similar weight of the 3d-band region intensity with respect to the 4sp region (for the implication of this result see the discussion of refs. [1] and [3]).

Here we use the well characterized systems hematite and magnetite O K-edge spectra (refs. [1] and [3]) to test the MXAN fitting procedure in order to analyse the reliability of the code in finding the no-self-consistent phenomenological potential parameters for near edge low Z element spectra. No multiple scattering simulation is present in the literature on maghemite.

Full multiple scattering simulations have been performed by MXAN code [5] that is based on the comparison between the experimental spectrum and several theoretical calculations generated by a fit procedure. The X-ray photoabsorption cross section is calculated using the general MS scheme within the muffin tin (MT) approximation. For the exchange and correlation part of the potential we used no-self-consistent phenomenological potentials: energy-independent Xα potential, the complex Hedin-Lundqvist (HL) and the real energy-dependent HL potential plus

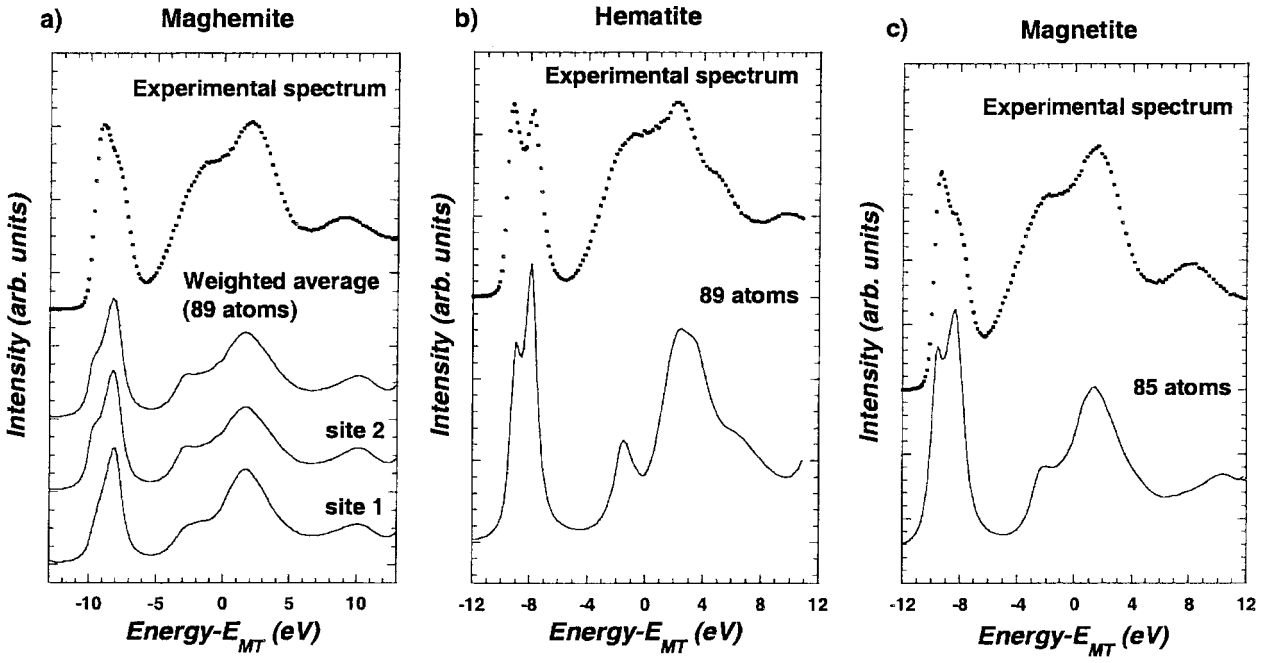

Fig. 2. Comparison of the NEXAFS simulations by MXAN and the experimental O K-edge spectra of (a) maghemite, (b) hematite and (c) magnetite. The number of atoms used in the input cluster of the simulation is indicated.

a damping factor [5]. In the fit procedure the coordinate structure was fixed while some potential parameters were fit, like the values of the interstitial potential, of the overlap between contiguous atoms, the Fermi energy. These are fit parameters which are changed at every step in order to minimize the square residual between the theoretical and the experimental spectra.

Figure 2 shows the O K-edge NEXAFS for the three oxides and the best fit obtained by MXAN. The calculation and fit procedure was the following: the extended NEXAFS part (up to about 600 eV) of the hematite and magnetite spectra were fitted by MXAN fixing the structure coordinates at 75 atoms for hematite, and 85 for magnetite, leaving as fitting parameters the interstitial potential and the overlap between contiguous atoms. This has been done both for HL and Xα potentials. We obtained similar parameter values for both hematite and magnetite, even though they have different nominal ionicity [9] (not surprising for the higher energy part of NEXAFS [10]). Note that in the muffin tin potentials calculated in this way (i.e., non self consistent) all the atoms are neutral.

The so obtained potential parameters were used to simulate the NEXAFS spectra for the three compounds: two distinct oxygen sites spectra of maghemite that were then weighted averaged and NEXAFS spectra for hematite and magnetite. In this way we obtained the simulation shown in fig. 2.

For hematite and magnetite we found good agreement with the experimental data, with some improvement in the higher part of the spectra with respect to the simulations performed in ref. [3]. The best simulations in both cases were obtained by using HL real potential with phenomenological dumping factor. The agreement with the experimental spectra of maghemite is good and a slightly better agreement was found for Xα real potential with respect to HL.

The broad peaks in the higher part of NEXAFS of hematite and magnetite are due to multiple scattering paths involving atoms above 5 Å away from the central oxygen atom. Their energy separation and relative intensities result to be different in the three compounds and can be related to the regularity of the octahedron formed by the metal surrounded by the oxygen atoms; actually the energy separation between the two features decreases from magnetite (3.37 eV), which presents all regular octahedron, to maghemite (3.0 eV), that has some distorted octahedron, to hematite (2.9 eV), which has all distorted octahedron.

Due to the better resolution in hematite the characterizing feature at about 546 eV can be clearly singled out; it is well reproduced by using input an cluster with a number of atoms higher than 75 i.e., is due to scattering paths involving the atoms within 5.5 Å from the absorber.

With the potentials obtained as described above we focussed our analysis on the doublets. It is worth noting that the simulations presented here are made in the single particle approximation. We were able to reproduce the doublets of the three compounds, even though we found differences in their relative intensities. Several tests have been performed and we found that this low energy part is extremely sensitive to the details of the potential.

Fig. 3 shows a shell by shell analysis of the doublet as performed by increasing the number of atoms in the input cluster. For hematite the doublet appears in simulation based on a cluster with more than 27 atoms. This cluster is formed by the central oxygen atom surrounded by 4 Fe, 12 O, 6 Fe and 4 O within 4 Å by the absorber. Whereas for magnetite and maghemite the splitting is present from a cluster of 17 atoms (4 Fe and 12 O around the absorber) in a radius of 3 Å from the central oxygen atom. In maghemite we do not found striking differences in site 1 and site 2 (Fig. 2a) results but in doublet splitting that is slightly higher in the case of site 1 (3.2 eV) with respect to site 2 (3.0 eV) and in some details of the higher energy peak group.

We found differences with ref. [3] in the at edge simulations relative intensities in doublets. We infer that these discrepancies are due to differences in potential details as found by fit procedure. The low energy part differences are ascribable to details in the potentials: actually playing *a priori* with the potential parameters in the calculations, it is possible to obtain an intensity ratio closer to the experimental value. It is worth noting that for ionic compounds it was found that the lower spectrum part is affected

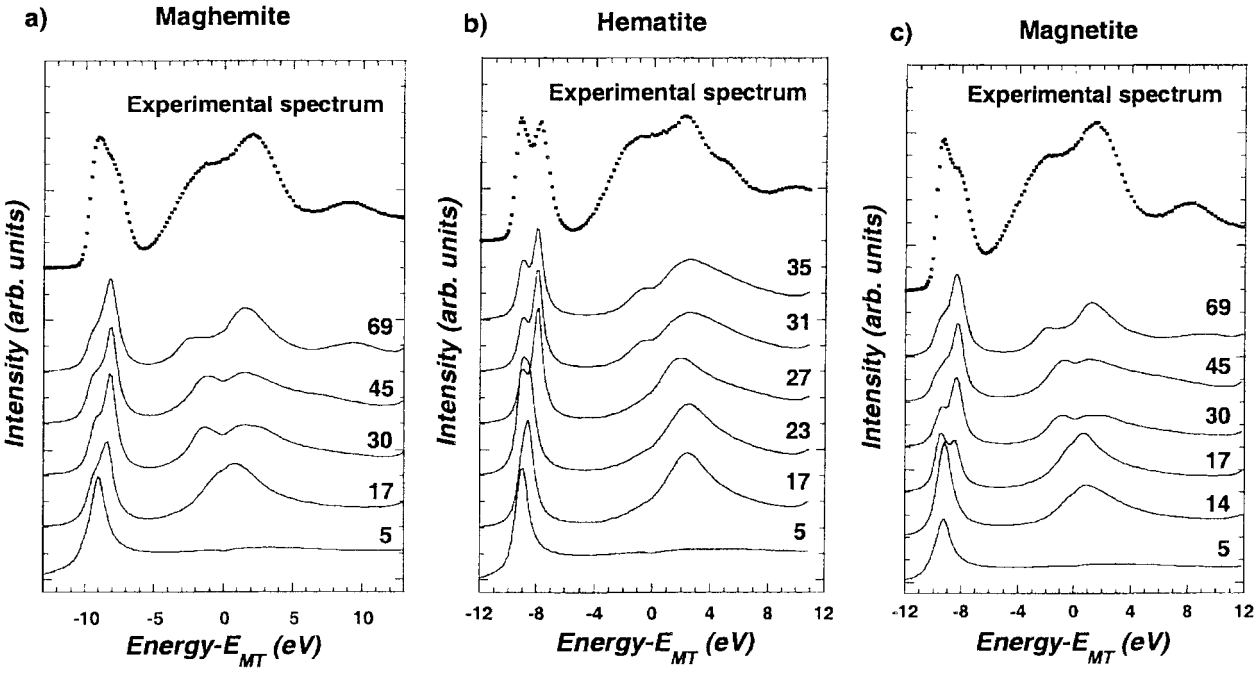

Fig. 3. Shell by shell NEXAFS simulation as a function of the number of atoms used in the input clusters for (a) maghemite, (b) hematite and (c) magnetite.

by potential details especially in case of O K-edge [9] and that the effect of self consistency allowing for charge transfer on the shape of the spectra are localized in the first region above the edge, namely at 25 eV. In order to improve the agreement with the experimental data we intend to perform further simulations by self consistent potentials by using the correct charge transfer between Fe and oxygen atoms in the systems, in the next future. In any case our results confirm that the muffin tin prescription for non self consistent potential is reasonable and the effects are quantitative at higher energies.

4. Conclusions

We measured the O K-edge NEXAFS spectra of hematite, magnetite and maghemite iron oxides in fluorescence detection mode with a resolution better than 200 meV. Spectra show a similar weight of the 3d-band region intensity with respect to the 4sp region.

We used the well characterized systems (refs. [1] and [3]) hematite and magnetite O K-edge spectra to test the MXAN fitting procedure in order to analyse the reliability of the code in finding the no-self-consistent phenomenological potential parameters for near edge low Z element spectra.

We report the Multiple Scattering analysis of iron oxides; we successfully simulated the three oxides. The fit procedure of the potential parameters has been performed in the extended part of the NEXAFS spectra of hematite and magnetite. The parameters found in this way for the no-self consistent potential have been used to calculate the near edge part of the three compounds spectra. Maghemite structure shows two different O sites and its NEXAFS O K-edge spectrum was well simulated, for the first time, by using potential parameters found by a fitting procedure of the hematite and magnetite oxides.

Simulations correctly reproduced the energy separation trend of the d-Fe state projection onto the O p states, forming the part of the spectra immediately above the O K-edge.

Abstract

We report on an EXAFS study of the local environment of manganese atoms in $LaMnO_3$ across the cell ordering transition temperature. During the EXAFS analysis the phase derivative method was used prior to conventional fits in order to prevent possible mistakes arising from the correlation between parameters in the fitting method. The combination of the two procedures assert the result that the local splitting in the Mn-O distance is maintained above the Jahn-Teller transition and support the order-disorder character predicted for this transition in $LaMnO_3$.

1. Introduction

The lanthanum manganite and its doped alloys have attracted much attention in the last decade, in large part due to the potential applications of the so-called Colossal Magnetoresistance. These compounds show very unusual physical properties, arising from intricate interrelations between spin, charge and local structure. Many of these phenomena still remain to be elucidated, even in the parent undoped compound $LaMnO_3$. At room temperature, $LaMnO_3$ is an A-antiferromagnetic insulator. The oxygen octrahedron surrounding the manganese is strongly distorted due to the tough Jahn-Teller (JT) character of the Mn^{3+} ion. Mn-O bonds with three different lengths coexist (1.91 Å, 1.97 Å, 2.15 Å) [1]. Cooperative ordering of the distorted octahedra results in the crystallization of $LaMnO_3$ in an orthorhombic variant of the cubic perovskite structure. Above $T_{JT} \simeq 700$–750 K, the lattice becomes metrically cubic [1, 3] and the resistivity decreases by about two orders of magnitude [2]. At the local scale this so called Jahn-Teller (JT) transition is not yet well understood. On the first hand, thermodynamical calculations have shown that the energy needed to remove the local Jahn-Teller should be far above the thermal energy at T_{JT}. The transition would happen as an order-disorder transition in the sequence of the distorted octahedra. Experimentally, the two pioneers works of Granado *et al*. [3] and Araya-Rodriguez *et al*. [4] supported the hypothesis of the upkeep of the local JT distortion, respectively from Raman results [3] and from the analysis of the overall disorder in the EXAFS data across T_{JT} [4]. On the other hand, the theory that the local Jahn-Teller distortion may vanish and the Mn-O distances collapse like the cell parameters was sustained by J. H. Song *et al*. [5], as result of the fitting procedure in the data reduction of their EXAFS spectra in thin $LaMnO_3$ films. More recently Sanchez *et al*. [6], using the same procedure of data reduction, have reached opposite conclusions in $LaMnO_3$ polycrystals. This disagreement may call into question the validity of the fitting method applied to high temperature data of this complex system and request definitive analysis methodology. In the present work we report on an EXAFS study of the manganese environment in a high quality $LaMnO_3$ manganite across T_{JT}. The Phase Derivative Method (PDM) [7] was combined to the fitting procedure to fully assert the results of the data analysis.

2. Experimental

The ceramic $LaMnO_3$ sample studied in this work was prepared by standard ceramic methods and shows a JT transition around 710 K [3]. Fine grained powder was pressed between two thin beryllium windows and placed in an electrical furnace for measurements from 300 K to 870 K. The EXAFS data were collected at the LNLS D04B-XAS1 beam line in the transmission mode up to 600 eV above the Mn K-edge (6550 eV). This extension in the data range ($k_{max} = 12.5$ Å^{-1}) establishes the value $\delta R_{min} = 0.13$ Å as the minimum difference between two close distances that can be resolved in the EXAFS analysis. The two distances at 1.91 Å and 1.97 Å are seen as one unique short distance Mn-O_s = 1.94 Å, easily resolved from the long distance Mn-O_l = 2.15 Å (δR = 0.21 Å).

The EXAFS oscillations were extracted following the standard procedure using the WinXAS program [9]. The signal corresponding to the oxygen coordination shell is then selected by Fourier filtering and analysed first using the Phase Derivative Method then using the fitting subroutine of the WinXAS code. In the fitting procedure the number of free parameters is limited to $n \approx 2\Delta k \Delta R/\pi$, where Δk is the useful range and ΔR is interval corresponding to the selected signal in the real space. Fitting procedures involving more than this limit of parameters may lead to systematic errors. On the other hand the number of parameters ideally requested for a joint fit of two subshells of the same backscatter is 8 (2 numbers of neighbours (N_1, N_2), 2 distances (R_1, R_2) and 2 Debye-Waller (DW) factors (σ_1^2, σ_2^2), the energy shift ΔE_0 and the amplitude-reduction factor (S_0^2)).

The PDM exploit the modulation in the EXAFS signal occuring when the contributions of two close shells separated by δR are combined. For two shells with the same backscatter atom, it can easily be shown [7, 8] that this modulation results in a minimum in the total amplitude, at $k = k_B$ given by $k_B = \pi/2\delta R$. The presence of this extremum – or beat – is widely used to identify the occurence of close shells. At the beat value also occurs an extremum in the total phase derivative [7]. Even when the EXAFS signal is strongly damped by thermal or static disorder, the determination of the position of the beat from the derivative (PDM method) is very accurate [8]. Due to and various sources of systematic errors $\delta R_B = \pi/2k_B$ does not give exactly the bond length separation [8]. However any modification in this separation will be detected by a shift in the beat position.

3. Results and Discussion

The k^2-weighted $\chi(k)$ spectrum and its Fourier transform (FT) are presented in fig. 1 for $LaMnO_3$ at 300 K. The first peak in the FT corresponds to the coordination shell and a back-FT is

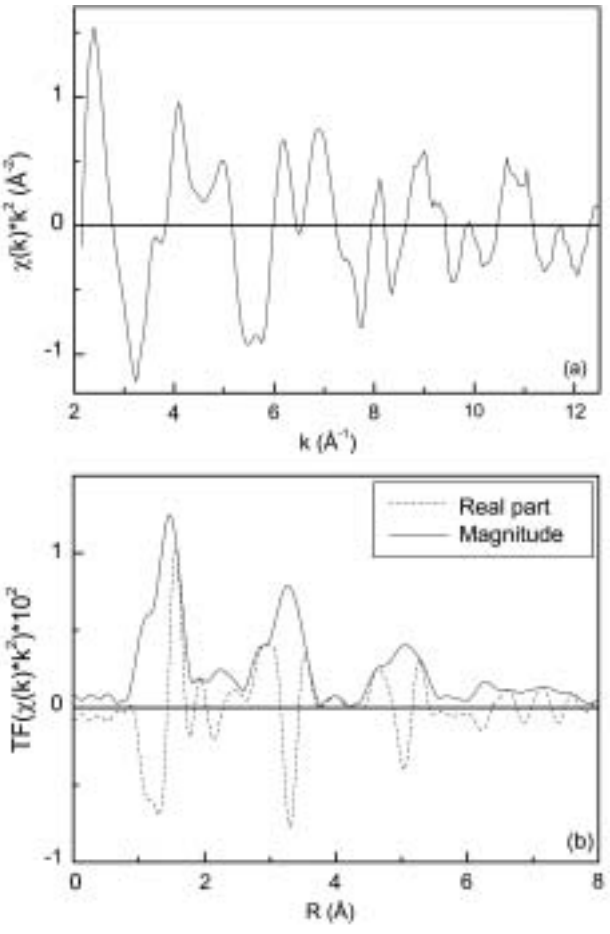

Fig. 1. (a) $LaMnO_3$ k^2-weighted EXAFS signal and (b) its Fourier transform.

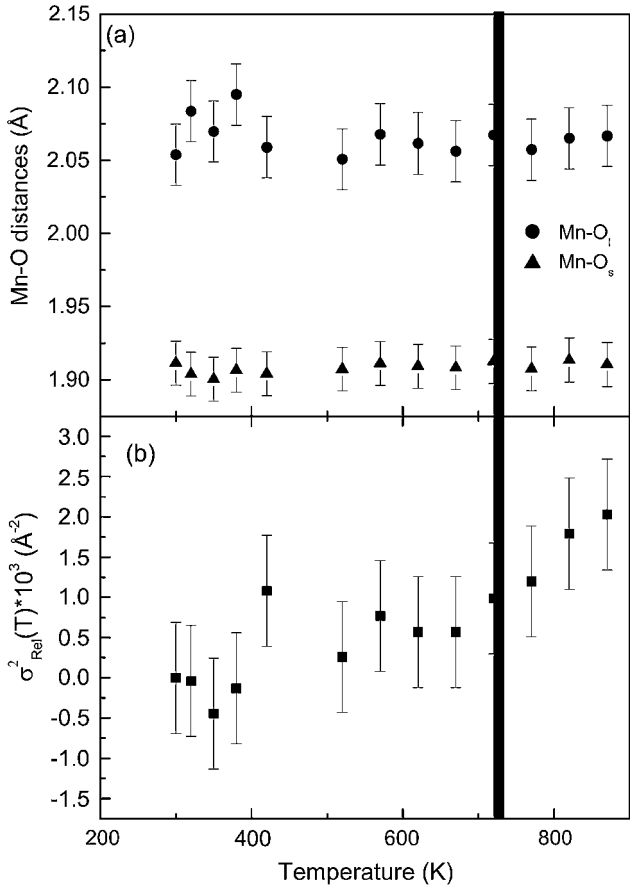

Fig. 3. Results of the fitting procedure: (a) distances Mn-O_s and Mn-O_l and (b) relative Debye-Waller factor: $\Delta\sigma^2(T) = \sigma^2(T) - \sigma^2(300\,\mathrm{K})$. The vertical line correspond to the Jahn-Teller temperature transition.

applied in real space over the interval $R_{min} = 0.9$ to $R_{max} = 2.1\,\text{Å}$ to separate this signal. When applying to PDM to the selected signal, we observe at $k_B(300\,\mathrm{K}) = 9.5\,\text{Å}^{-1}$ a beat corresponding to the separation δR between the short and long Mn-O distances.

The same procedure was repeated for all temperatures. $\delta k_B(T) = k_B(T) - k_B(300\,\mathrm{K})$ is plotted in fig. 2 as a function of temperature. Any reduction of the Jahn-Teller distortion around Mn^{3+}, would result in a decrease of δR and be detected as positive shift in the beat position ($\delta k_B \approx 0$). Actually, we observe a small minimum in the beat position at the JT temperature. This minimum could correspond to a maximum increase of 5% in the distances splitting, but is more likely associated to a small variation in the disorder. Within the errors bars, we can certify that the beat value does not increase above the transition temperature. The bond length splitting is kept unchanged across the JT transition.

When applying the conventional fitting method [9] with $\Delta k = k_{min} - k_{max} \approx 10\,\text{Å}^{-1}$ and $\Delta R = R_{min} - R_{max} \approx 1.2\,\text{Å}$, we found 7 independent points, maximum number of parameters ideally requested for this analysis. During the fitting procedure, the numbers of neighbours were fixed to $N_1 = 4$ and $N_2 = 2$ and the values of the DW factor σ^2 were taken identical in the two subshells: $\sigma_1^2 = \sigma_2^2 = \sigma^2$. The fit was performed in k space using theoretical scattering paths calculated using FEFF7 code. The conditions of the fit were kept the same for all temperatures. The distances and the DW factor obtained as result of the fit are plotted in fig. 3. There is no significant change in the behaviour of the σ^2 and the distances are almost constants over the whole temperature range. Like the PDM, the fitting procedure leads to the conclusion that the local Jahn-Teller splitting in the Mn-O bond length is kept constant across the transition temperature.

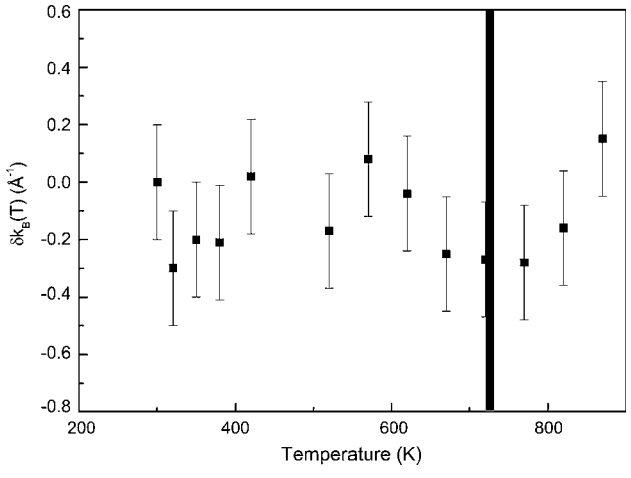

Fig. 2. PDM results: relative values of the beat position: $\delta k_B(T) = k_B(T) - k_B(300\,\mathrm{K})$. The vertical line correspond to the Jahn-Teller temperature transition.

4. Conclusions

The evolution of the local environment of manganese atoms in $LaMnO_3$ across Jahn-Teller transition was studied by EXAFS, using two independent methods of data reduction. We showed that the splitting in the Mn-O distances is kept unchanged across

the Jahn-Teller temperature and that there is no significant change in the Debye-Waller factor. Local distortion within the MnO_6 octahedra still exist above T_{JT}. Our results support the model of an order-disorder transition at T_{JT}, where the cooperative distortion vanishes, but the local distortion is maintained.

Abstract

In this work, geometric structures for ferromagnetic nanoscale zinc-blende MnAs dots grown on a sulfur-passivated GaAs(001) were investigated by using fluorescence EXAFS measurement. EXAFS measurements revealed that MnAs dots grown on GaAs(001) substrate did not form NiAs-type structure but zinc-blende structure. The Mn-As bond length in the MnAs dots is about 2.48 Å, which is close to that which was estimated from lattice constant of zinc-blende MnAs obtained by density-functional calculations. Existence of zinc-blende MnS (β-MnS) phase was also observed by EXAFS measurements.

1. Introduction

The thermal-equilibrium MnAs possess as NiAs-type structure. Very recently, it is predicted by density-functional calculations that the band structure of zinc-blende MnAs in the ferromagnetic state becomes half-metallic [1]. We have successfully fabricated zinc-blende MnAs dots grown on GaAs(001) by molecular-beam epitaxy (MBE) [2]. However, the geometrical structure of the MnAs dots is not yet clear, because it is difficult to evaluate the geometrical structure of the MnAs dots with average height of a few nm by conventional methods such as X-ray diffraction.

In the present work, geometric structures for ferromagnetic nanoscale zinc-blende MnAs dots grown by MBE were investigated by fluorescence extended X-ray absorption fine structure (XAFS) measurements using synchrotron radiation. The fluorescence XAFS measurement is a powerful technique for investigating local structures around a specific element and is suitable for evaluating the geometric and electronic structures around a specific element in the present study [3, 4].

2. Experimental

The nanoscale MnAs dots were grown on sulfur-passivated GaAs(001) substrates by MBE. Details of the growth procedure are described in ref. [2]. Deposition temperature was about 200 °C. The MnAs dots were capped by a 10 nm GaAs layer to prevent the oxidation.

The EXAFS measurements were performed at the beam line BL12C at the Photon Factory in Tsukuba with a Si(111) double crystal monochromator and a bent cylindrical mirror using the SR from the 2.5 GeV storage ring [5]. The EXAFS spectra were measured in the fluorescence-detection mode at a temperature of 70 K. The incident X-ray beam intensity was monitored with a nitrogen-filled ionization chamber, while the fluorescence X-ray signal was detected by an array of 19 elements Ge solid-state detector (SSD). The EXAFS spectra of the (Ga,Mn)As ([Mn] = 3%) film and NiAs-type MnAs film were also measured as references.

3. Results and discussion

Figure 1 displays the Fourier transformed Mn K-edge EXAFS spectra $k^2\chi(k)$ for MnAs dots, (Ga,Mn)As, and NiAs-type MnAs film. In the radial distance of 1.5–2.8 Å, we observed main peaks due to the first coordination shell around the Mn atoms were observed. The main peak in the MnAs dots was located at a shorter radial distance than those of the (Ga, Mn)As and NiAs-type MnAs film, suggesting that the local structure around Mn atoms in the MnAs dots is different from that in the (Ga, Mn)As and NiAs-type MnAs reference films.

In order to analyze the details of the measured spectra, curve-fitting of the EXAFS spectra was carried out with theoretically

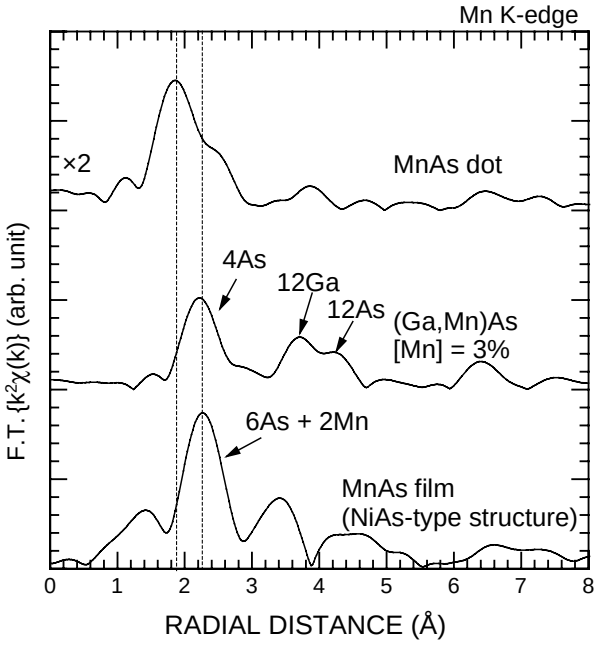

Fig. 1. Fourier transform of the Mn K-edge EXAFS oscillation function spectra $k^2\chi(k)$ of nanoscale zinc-blende MnAs dots, (Ga,Mn)As ([Mn] = 3%) film, and NiAs-type MnAs film. Dotted vertical lines at 1.9 Å and 2.3 Å indicate positions of the main peak for the MnAs dots and NiAs-type MnAs film, respectively.

*e-mail: ofuchi@numse.nagoya-u.ac.jp

calculated spectra using FEFF6 [6]. From the curve-fitting result, it is found that for the MnAs dots the Mn atoms are coordinated by As and S atoms. The Mn-As bond length is ≈ 2.48, which is close to that which was estimated from the lattice constant (≈ 5.6–5.7) of zinc-blende MnAs obtained by density-functional calculations [7]. The Mn-S bond length is 2.43 Å, which is close to that of zinc-blende MnS (β-MnS). The sum of coordination number of As and S atoms around Mn atoms is about 4, coinciding with that of zinc-blende MnAs and MnS. Thus, it is considered that zinc-blende MnAs and β-MnS coexist in the present film. It is considered that the formation of β-MnS phase is due to the sulfur which was passivated on GaAs substrate.

Abstract

Structural evolutions in a heat-treatment process have been studied using Si and P K-edge XAFS in SiO_2-P_2O_5 sol-gel layers on silicon substrates. The Si K-edge EXAFS results indicate that structural changes occur between 1173 K and 1273 K. In the case of heat-treated samples at 1273 K, the Si-O interatomic distance is 1.63–1.64 Å. On the other hand, the distances are 1.66 Å–1.68 Å below 1273 K. Furthermore, structural properties around Si and P in the sol-gel process have been studied. In the XAFS spectra, the ratio of P to Si shows 84% decrease after heat-treatment above 1073 K. For the Si-O and P-O distances, wet-gel has shorter interatomic distance than sol-gel raw solution, TEOS and TEP, respectively.

1. Introduction

The amount of energy supplied by the sun to the earth is more than five orders of magnitude larger than the world electric power consumption level that currently keeps modern civilization going [1]. Energy supply by solar systems has very important meanings for the future because of the direct conversion system of clean-solar energy into electric energy.

The sol-gel method is widely applied to produce functional coatings on substrates of metals, plastics, semiconductor materials and ceramics. It can also be used to fabricate coatings on desired shapes and areas homogeneously [2]. Recently, we have succeeded in the extraction of electromotive force from a solar cell that was made from the viewpoint of cost-reduction, using sol-gel procedure. In the process of manufacturing silicon solar cells, P_2O_5 glasses are generally used for n-type diffusion layers, but it is very difficult to handle them because of their delicate nature. Therefore, SiO_2-P_2O_5 glasses are adopted for the diffusion and protecting layer. In this study, the structural properties of Si and P in the SiO_2-P_2O_5 layer on silicon substrates are investigated by X-ray absorption fine structure (XAFS) measurements [3].

2. Experimental procedure

SiO_2-P_2O_5 coating layers have been deposited onto p-type single crystalline silicon substrates by the sol-gel method. Sol-gel starting solution was prepared by mixture solution of 0.5 mol% $Si(OC_2H_5)_4$ (tetraethyl orthosilicate, TEOS) (HIGH PURITY CHEMICALS), 0.5 mol% $PO(C_2H_5)_3$ (triethyl phosphate, TEP), (HIGH PURITY CHEMICALS), 4 mol% C_2H_5OH, and 4 mol% distilled water [2–5]. To avoid contamination, catalysts were not added to the mixture solution. After the removal of the SiO_2 layer on the silicon substrates using hydrofluoric acid, the substrates were dipped into the sol-gel solution and withdrawn at a rate of 4 cm s^{-1}. The substrates were dried at room temperature for 5 minutes and then given heat-treatment at 1073–1273 K for 30 min. In addition to these samples, other samples were prepared, which experienced different heat-treatment time from 30–120 min at 1273 K with the same technique. SiO_2-P_2O_5 wet-gels were also prepared by the generation of the mixture solution of TEOS, TEP, ethanol and distilled water in a sealed container at room temperature for 240 hours.

Si K-edge XAFS measurements were performed for SiO_2-P_2O_5 layer samples in total electron yield (TEY) mode at BL-4 XAFS spectrometer in Ritsumeikan University [6, 7]. Furthermore, the amount of out-diffusion of phosphorus in both hydrolysis reactions and heat-treatment processes were estimated from transmission XAFS measurements using the fundamental jump ratios of Si to P K-edge in mixture solutions of different composition of TEOS and TEP. The Si K-edge XAFS spectra for leucite ($K[AlSi_2O_6]$) were measured by both TEY and transmission mode as a standard sample to compare the spectra. EXAFS analysis was carried out by standard techniques.

3. Results and discussion

Fig. 1 shows normalized XANES spectra at the Si K-edge of the SiO_2-P_2O_5 layer. There is a weak pre-edge feature at about 1842 eV in the spectra for heat-treated samples below 1273 K. This feature decreases with increasing heat-treatment temperature and is not observed in spectra at 1273 K. The pre-edge feature is the peak by the Si-Si correlation. Furthermore, the position of the absorption edge in spectra at 1273 K was slightly changed. The XANES spectra at the Si K-edge of TEOS, wet-gel and leucite were also obtained. The spectral change was not observed in the several wet-gel samples. However, the position of the absorption edge was changed in the spectra of TEOS, wet-gel and leucite. Fig. 2 shows extracted EXAFS spectra at the P K-edge for $AlPO_4$, TEP and wet-gel. There is little change in the phase and the amplitude of EXAFS oscillations. Because the spectral change was not observed in the wet-gel samples, only one spectrum of wet-gel is shown in Fig. 1. The results of the EXAFS analysis relating to the first coordination shell around the

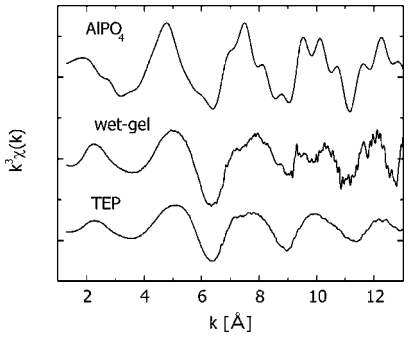

Fig. 1. Normalized XANES spectra at the Si K-edge in SiO_2-P_2O_5 layers. SiO_2-P_2O_5 coating layers have been deposited onto p-type single crystalline silicon substrates by the sol-gel method from the mixture solution of 0.5 mol% TEOS, 0.5 mol% TEP, 4 mol% C_2H_5OH and 4 mol% distilled water.

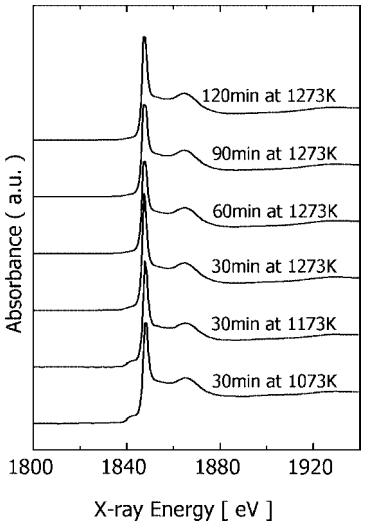

Fig. 2. Normalized EXAFS oscillation of the P K-edge in $AlPO_4$, wet-gel and TEP.

absorbing atom in SiO_2-P_2O_5 layers are summarized with TEOS, TEP, wet-gel and leucite in Table I.

The P-O coordination numbers in TEP and wet-gel are all 4.0, but the P-O distance for wet-gel is shorter than that for TEP. The decrease of the distance suggests that reticular structure was formed with P-O linkage by heat-treatment because of progress of the hydrolysis reaction.

The Si K-edge EXAFS results for SiO_2-P_2O_5 layers show that the coordination number is 3.7–3.8 and the Si-O interatomic distance is 1.63–1.68 Å. In sol-gel process, the alkyl group in the metallic alkoxide such as TEOS separates between metal ion and alkyl radical by external thermal energy. Metal-oxygen-metal bonding is usually formed, but imperfect reaction remains especially on the surface. In case of TEOS sol-gel process, -Si-$(O-)_3$ units with unpaired electrons were formed on the surface. It is observed as a decrease of the coordination number by TEY measurements because TEY method is sensitive to the surface structure. The Si-O interatomic distance decreases with increasing heat-treatment temperature from 1073 K to 1273 K and it was not changed by heat-treatment time at 1273 K. It is estimated by these results that the heat-treatment at 1273 K causes the separation of alkyl radical and causes re-bonding with oxygen in air and re-location of atoms.

The concentration ratios of P to Si in the mixture solution and wet-gel consisting of 0.5 mol% TEOS and 0.5 mol% TEP were 1.01 and 0.96, respectively. On the other hand, the ratios in the SiO_2-P_2O_5 layers were about 0.16. As a result, the heat-treatment above 1073 K causes phosphorus atoms to diffuse into the n-type Si substrate and to air. Thus, phosphorus atoms hardly exist in the glass layers after heat-treatment above 1073 K in air.

4. Conclusion

Structural evolutions have been studied, by XAFS techniques, in heat-treatment processes around Si in SiO_2-P_2O_5 sol-gel layers on silicon substrates. EXAFS results indicate that structural changes occur between 1127 K and 1273 K. The Si-O distance decreases from 1.68 to 1.64 Å with increasing heat-treatment temperature from 1073 to 1273 K and it was not changed by heat-treatment time at 1273 K. These results indicate that heat-treatment at 1273 K removed alkyl radical completely and causes re-bonding with oxygen atoms in the air.

Abstract

X-ray absorption technique was applied to analyze the local structures of fused and synthesized silica glasses before and after irradiation in a nuclear reactor. Si K-edge EXAFS revealed changes in the SiO_4 tetrahedron structure by the irradiation, i.e. a distorted tetrahedron in the silica glass returned to more regular one but the connection between neighboring tetrahedrons became looser. In addition, the detailed analysis of EXAFS spectra gave evidence for the formation of direct Si-Si bonding after prolonged irradiation, suggesting the appearance of Si precipitates in silica glass.

1. Introduction

Irradiation effects by high-energy particles such as neutron and ions on silica glasses are one of the main concerns for their application as optical windows, insulators and optical fibers in nuclear environments. The chemical states and density of defects in silica glasses should be closely related to their optical and physical properties such as transparency and hardness. Therefore, defects in silica glasses such as oxygen vacancy-related ones and Si precipitates caused by displacement damage have been widely studied by optical techniques and ESR measurements [1–6]. However, it is still difficult to observe the structures of the defects at an atomic scale in a SiO_2 glass, because the structural changes in its amorphous nature does not allow us to apply diffraction techniques. In the present work, we have investigated the change of the local structure of the SiO_2 glass before and after in-reactor (i.e., neutron and γ-ray) irradiation by Si K-edge X-ray absorption fine structure.

2. Experimental

Samples used in this work were a fused silica (SiO_2) glass (T-2030) and a synthesized silica glass (T-4040) of 13 mm diameter and 2 mm thickness produced by Toshiba Ceramics, Japan with different OH contents of ca. 1 ppm and 800 ppm, respectively.

The samples were irradiated in the nuclear reactor YAYOI at the University of Tokyo. YAYOI was operated with a power of 1.5 kW, where a neutron flux was about 6×10^{11} n/m^{2}s with an average neutron energy of 1.3 MeV and the γ-ray level was about 3.0 kGy/h [7]. The irradiation temperature was ambient and kept below 323 K because of the small output power of the reactor.

Si K-edge X-ray absorption spectra were recorded under vacuum ($<10^{-6}$ Pa) at room temperature at the BL-7A station of UVSOR, or at the BL-11B station of the Photon Factory, Institute of Materials Structure Science, High Energy Accelerator Research Organization (KEK-PF), using a two-crystal InSb(111) monochromator. Two different recording modes, i.e. a total

electron yield (TEY) mode and a fluorescent X-ray yield (FY) mode were employed with detectors consisting of an electron multiplier and a gas-flow proportional counter, respectively [8].

3. Results and Discussion

3.1. *The changes of SiO_4 tetrahedron structure and the connection of SiO_4 tetrahedrons in silica glasses by in-reactor irradiation*

Fig. 1 shows the *k*-weighted Si K-edge EXAFS spectra of the silica glasses before and after in-reactor irradiation together with that of a SiO_2 crystal (quartz) sample as a reference, and Fig. 2 compares their radial structure functions (RSFs) obtained from Fourier transforms of the EXAFS. We also performed curve-fitting analysis of the Fourier-filtered EXAFS by the least-squares method. In Fig. 2, the peaks in the region of 0.8–3.2 Å were isolated with a Hanning window, and inversely Fourier transformed. The curve-fitting analysis was carried out with Si-O and Si-Si shells. The amplitude and the phase shift of Si-O and Si-Si shells were extracted from EXAFS of the quartz crystal and a silicon crystal, respectively. The curve-fitting results are summarized in Table I.

The EXAFS oscillation of the quartz crystal (Fig. 1c) has distinct shoulders at around 3.6, 5.8, 6.6 and 8.5 Å^{-1}, which are characteristic of the long-range periodic nature in the quartz sample. In a SiO_2 crystal, a regular SiO_4 tetrahedron is connected to four neighbors to form an ordered structure. Correspondingly, the peak at ca. 1.2 Å attributed to the first neighboring oxygen atoms (Si-O) appeared very intense and sharp (Fig. 2(c)). The peak observed at ca. 2.6 Å in the RSF originates from the second neighboring Si atoms (Si-O-Si). The distance between two Si atoms situated at the center of neighboring SiO_4 tetrahedrons estimated from the curve-fitting is nearly equal to the tabulated value for SiO_2 crystal, and the coordination number was 4 as expected.

The EXAFS spectra and their RSFs of the silica glasses were clearly different from those of the quartz crystal. In their RSFs, the intensity of the 1.2 Å peak corresponding to Si-O is smaller than that for the crystal and the peaks at ca. 2.6 Å attributed to the neighboring Si atoms are also reduced. The absence of the intense peaks relating to the second nearest neighbors indicates

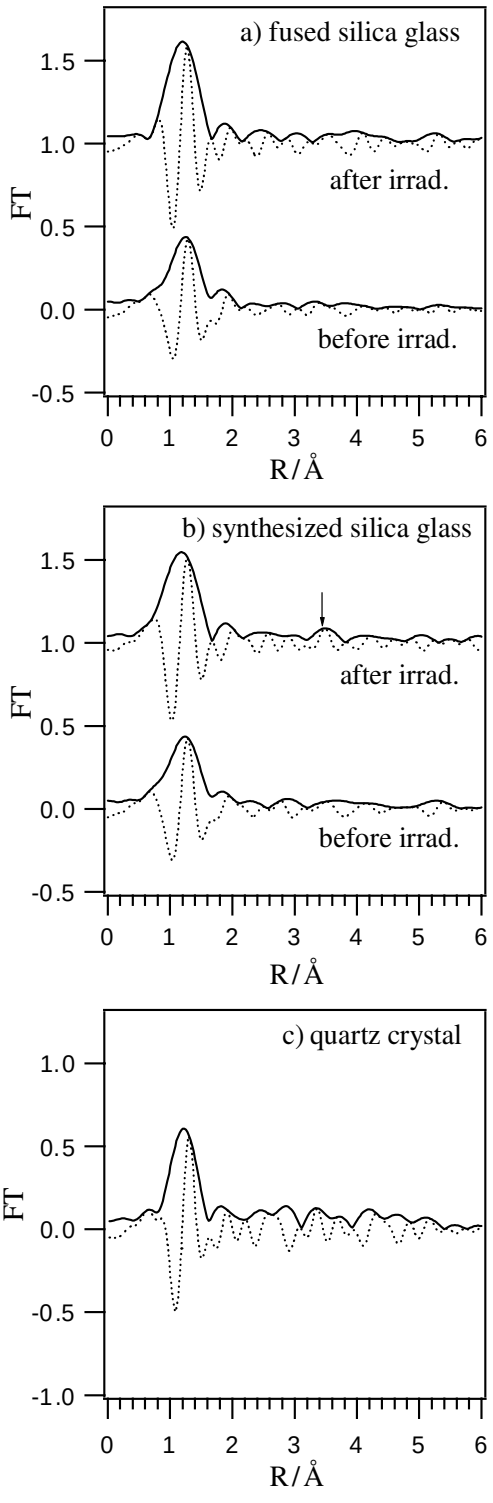

Fig. 2. Radial structure functions of *k*-weighted Si K-edge EXAFS spectra of (a) the fused silica glass before and after in-reactor irradiation, (b) the synthesized silica glass before and after in-reactor irradiation, and (c) a quartz crystal. The neutron fluence of the irradiated fused and synthesized silica glasses are 2.8×10^{19} n/m^2 and 2.7×10^{20} n/m^2, respectively.

weaker or less linkage of the neighboring tetrahedrons in the glasses compared to that of the crystal, reflecting the disordered network of SiO_4 tetrahedrons [9], i.e. in the silica glass there are some variance in the distance between Si atoms in the center of neighboring tetrahedrons. Accordingly the estimated coordination numbers of the unirradiated silica glasses from the curve-fitting analyses were ca. 1, much less than the 4 for quartz crystal (Table I). Simultaneously, the symmetry of the SiO_4 tetrahedron

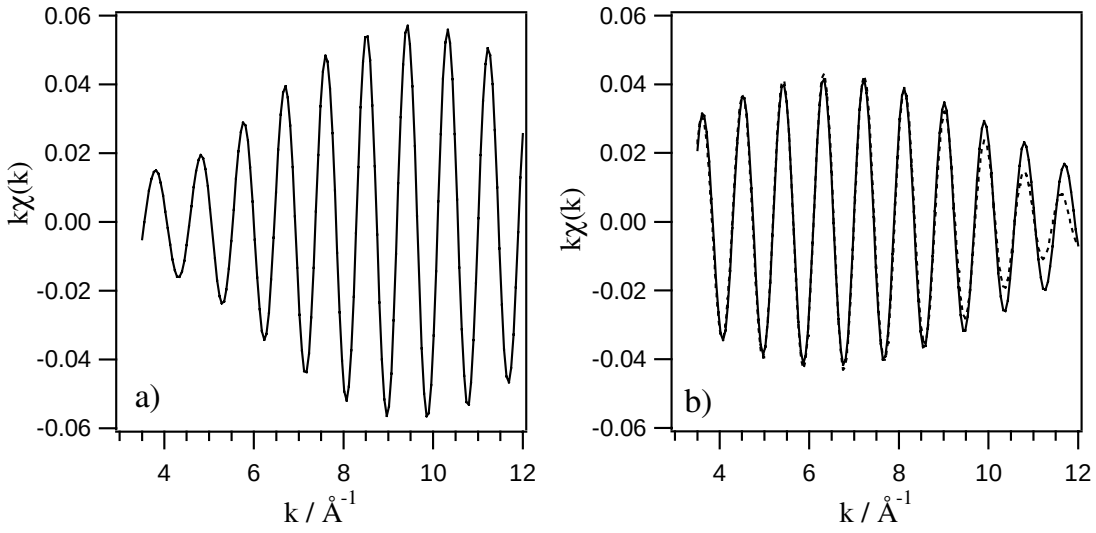

Fig. 3. Inversely Fourier transformed spectra of RSFs of a quartz crystal (a) and the synthesized silica glass after the irradiation of 2.7×10^{20} n/m^2 (b, solid line) and the curve-fitting by Si-Si shell (b, dashed line).

in the silica glass should be slightly distorted from a regular SiO_4 tetrahedron, resulting in the reduction of the peak intensity at 1.2 Å in RSFs.

The EXAFS spectra of the silica glasses irradiated with low neutron fluence (less than ca. 1×10^{19} n/m^2) were fundamentally the same as those of their unirradiated ones (not shown here). A structural change was recognized in the EXAFS spectra of the silica glasses irradiated with more than 2×10^{19} n/m^2 as shown in Fig. 1. The EXAFS oscillations in the range of $k = 6.5$–7.5 Å^{-1} were larger for the irradiated silica glasses than for the unirradiated one. In the RSFs, it should be noted that the peak intensity at 1.2 Å due to the Si-O bond increased to a level similar to that of the quartz crystal. Moreover, the coordination numbers of the first neighboring oxygen atoms increased from ca. 3.7 to ca. 4.2 after in-reactor irradiation (see Table I). At the same time the coordination number of the second neighboring Si atoms decreased, i.e., the Fourier-filtered EXAFS spectra of the irradiated silica glasses were not fitted well using a Si-Si shell. However, the curve-fitting using a Si-O shell instead of a Si-Si shell was successful. The distance 2.92 Å thus evaluated corresponds to the path length of multiple scattering for Si-O-O in the regular SiO_4 tetrahedron. These results suggest some decoupling of neighboring distorted SiO_4 tetrahedrons in a silica glass via the atomic displacement by neutron irradiation. Accordingly, the decoupled distorted SiO_4 tetrahedrons could relax and return to regular or isolated SiO_4 tetrahedron and the O-Si-O angles would be more uniform after irradiation, as observed in the growth of the peak assigned to Si-O in RSFs. This does not mean recovery of long range order (or recrystallization). The irradiation certainly gave more disorder in long range as the appearance of Si precipitates discussed below, or each tetrahedron became more isolated.

3.2. *The appearance of Si precipitates in silica glasses by in-reactor irradiation*

It is also noteworthy that a small but distinct peak around at 3.5 Å appeared in the RSF of synthesized silica glass after the irradiation by 2.7×10^{20} n/m^2. Then, for the irradiated synthesized silica glass, inverse Fourier transforms were also performed for the RSF peaks in the region of 3.2–3.8 Å. The results were compared with that for a quartz crystal (Fig. 3). The envelope of the spectrum for the irradiated synthesized silica glass is clearly different from that of the quartz crystal. The maximum of the envelope appeared at around 6 Å^{-1} in the irradiated synthesized silica glass while that of the quartz crystal was around 9 Å^{-1}. Our separate FEFF analysis [10] for a quartz crystal indicated that RSF peaks in the 3.2–3.8 Å region are caused by a single scattering of the third neighboring oxygen atom (Si-O) and/or multiple scatterings by the first and the third neighboring oxygen atoms (Si-O-O). Actually, the inversely Fourier transformed spectrum of the quartz crystal (Fig. 3(a)) could not be fitted well by the Si-Si shell, supporting the FEFF analysis.

The inversely Fourier transformed spectrum of the irradiated synthesized silica glass could be fitted by Si-Si shell as shown in Fig. 3(b). This indicates the formation of direct Si-Si bonding in the heavily irradiated silica glass. The interatomic distance of the Si-Si pair was estimated as ca. 3.86 Å by the curve-fitting analysis, which is very close to 3.84 Å of the second neighboring distance in a Si crystal. This is another evidence for the appearance of Si precipitates in the irradiated silica glass. Formation of Si precipitates of less than 1 nm in size in SiC by electron irradiation has been reported, and attributed to the preferential displacement of C-atoms [11]. Although the detailed mechanism of the formation of Si precipitates in the irradiated silica glasses is still unclear, and needs more work. Nevertheless, the present work clearly demonstrates that XAFS is a powerful technique to detect the change of local structure even in amorphous materials like silica glasses as well as the nucleation in atomic scale.

Abstract

The pyramid-like Ge islands deposited on Si(001) substrate using molecular beam epitaxy at 300 °C reveal quantum dots (QDs) properties. Measurements of X-ray absorption fine structure at the germanium K edge (GeK XAFS measurements) have been performed using total electron yield and fluorescent detection mode. The influence of effective thickness of the germanium film, Ge nanocluster sizes and Si deposition temperature on the QDs microstructure parameters is revealed. Some information concerning the energy structure of the free states of the quantum dot was extract from X-ray absorption near edge structure (XANES) spectra for the first time.

1. Introduction

Here we report the use of EXAFS (Extended X-ray Absorption Fine Structure) [1, 2] and XANES (X-ray Absorption Near Edge Structure) spectroscopy to study the spatial and electronic structure of Ge/Si heterostructures.

Development of techniques allowing to determine spatial and electronic structure parameters on the surface or interfaces of materials will provide the controllable fabrication of structures containing nanoclusters with discrete electronic spectra. The fabrication of such systems will allow success in the traditional trend toward miniaturization and in element engineering for quantum computers [3, 4]. In semiconductor nanostructures with spontaneously ordered inclusions of a narrower band gap material within a broader bandgap matrix the limiting case of the dimensional quantization is realized. Zero-dimensional quantization exist within a certain interval of microinclusion sizes with the formation of so-called quantum dots (QDs) characterized by discrete electronic spectra.

In a heteroepitaxial system with a mismatch between the lattice constants, the initial growth may occur by layers. Formation of thicker layers leads to a tendency toward elastic strain relaxation and elastic energy decrease by disturbing the two-dimensional growth and forming isolated islands, so-called Stranski-Krastanov growth. In a series of comparatively recent studies it was shown by different experimental methods (capacitance spectroscopy [5], hopping transport [6], admittance spectroscopy [7], optical spectroscopy [8]) that at a certain thickness of the epitaxial Ge film on Si(001) in the electronic spectra of the heterostructures there appear features associated with the zero-dimensional density of the states. These features are due to the dimensional quantization of the hole spectrum in the Ge islands appearing during disturbed two-dimensional growth.

The spectrum of states in the self-organizing nanoclusters may be largely influenced by the elastic deformation at the boundaries arising from a mismatch of the lattice parameters of the nanocluster and substrate. In the Ge/Si system the lattice mismatch amounts to 4.2%. This will cause changes in the local structure: local distortions of the symmetry, changes in the valence angles and interatomic distances. Such structural changes may change the energy spectrum by a magnitude of the order of 0.1 eV [9], which is comparable with the dimensional quantization energy in a QD.

The local structural changes in the thin layers and nanoclusters are not detectable by traditional X-ray structural analysis or electron diffraction, because such systems have no long-range ordering. EXAFS (extended X-ray absorption fine structure) spectroscopy [1, 2] provides a unique possibility for solving such problems [10]. These methods allow determination of parameters of the local environment of atoms and electronic parameters of nanoclusters. Thus in [11], using XANES (X-ray absorption near-edge structure) spectroscopy, a broadening of the forbidden gap with decreasing size of the CVD grown germanium nanoclusters in silicon was found. In [12, 13], using EXAFS spectroscopy, the local environment of Ge adatoms on Si(001), the structure of thin Ge layers on Si(001) and a superlattice with strained $(Ge_4/Si_4)_5$ layers were studied. It is revealed in [14–16] using GeK XAFS measurements that Ge QDs are characterized by interatomic Ge-Ge distances of 2.41 Å which is 0.04 Å less than in bulk Ge.

The growth of self-organizing Ge islands and later of the blocking Si layer is evidently accompanied by the temperature-dependent surface diffusion of Si and Ge atoms, affecting the composition of the wetting layer and the composition and width of the intermediate layer at the Si-Ge interface. These characteristics of the transitional layers should have a substantial influence on the features in the QD energy spectrum. Therefore, energy spectrum calculation for QD, interpretation peculiarities of their experimental energy spectra as well as design of elements with given electronic properties must take into account variations of the QD local structure.

2. Experimental

In this work, a surface-sensitive EXAFS measurement based on total electron yield and fluorescent detection was used to study peculiarities of Ge/Si structures.

The effective thickness varied from two to ten monolayers for the studied Ge films. Two-dimensional pseudomorphous Ge films have been grown up to a critical thickness of four monolayers on Si(001). As a result of continuing deposition, pyramid-like Ge islands were grown in Stranski-Krastanov mode.

Germanium K edge (GeK) EXAFS and XANES spectra in Ge/Si (100) heterostructures were measured using synchrotron radiation (SR) of the VEPP-3 storage ring at the Budker Institute of Nuclear Physics in Novosibirsk. The X-ray energy was defined by a double crystal monochromator with a channel-cut Si(111)

*E-mail: simon@che.nsk.su

single crystal. The obtained data were processed using the EXCURV92 software package [17]. In the data processing, the phase and amplitude characteristics were calculated in the X_α-DW approximation, using the procedures of the package [17]. For the analysis of the Ge local environment the Fourier-filtered data were fitted using the k and k^2-weighting procedure in the photoelectron wave vector interval from 2.5 Å^{-1} to 13 Å^{-1}. The error in determining interatomic distances with the fitting procedure was ±0.01 Å. The amplitude-damping factor $S_0{}^2$ was determined by data fitting for massive Ge and was equal to 0.8.

3. Results and discussion

Simplest models afford ground for inclusion of one averaged variant of the environment for Ge atoms with distances R_1(Ge-Ge), R_2(Ge-Si) and the coordination numbers of Ge with respect to germanium atoms (n_1(Ge)) and to silicon atoms (n_2(Si)). Such models are most likely correct for 4-monolayer Ge films in Si [16]. The better model should include at least two types of Ge atoms for the samples with QDs: 1) Ge atoms in the 2-monolayer thick transition layer on both sides of the boundary, 2) the atoms inside the quantum dots. The thickness of the transition layer was estimated using the conclusion from [16] that the pseudomorphous 4-monolayer Ge films are embedded in the Si matrix and the two transition layers on both sides of the boundary contain about 50% of Si atoms. This assumption turned out to be true, since with the use of the quantum dots of the same transition layer parameters (of the interatomic distances R_1(Ge-Ge), R_2(Ge-Si) and the coordination numbers n_1(Ge) in germanium and n_2(Si) in silicon) as in the 4-monolayer films, the Ge atoms within the quantum dots have practically no silicon atoms in the first sphere of their environment for the samples with effective thickness equal to 8–10 ML [16]. This samples were prepared at temperatures: 300 °C (film growth) and 500 °C (deposition temperature of the blocking Si layer).

Fig. 1 illustrates the monotonic growth of a fraction of Ge atoms inside pure germanium islands with only Ge atoms in their environment as the effective thickness of the germanium film increases from 4 to 10 monolayers, i.e. the monotonic size evolution of germanium nanoclusters as a function of film thickness in this series. It was of interest to study analogous systems prepared using slightly different temperatures for the film growth and the deposition of the blocking silicon layer. First, structures were prepared using the same temperature for the film growth (300 °C) but a lower (300 °C) deposition temperature of the blocking Si layer.

Table I. *Comparison of parameters obtained by the fitting procedure for pseudomorphous Ge films and structures with pyramid-like Ge islands on Si(001) with blocking Si layer deposited at 500 °C and 300 °C. R_1(Ge-Ge)-, R_2(Ge-Si) – interatomic distances; n_1(Ge)-, n_2(Si) – coordination numbers of Ge with respect to germanium atoms and to silicon atoms; T – blocking Si layer deposition temperature.*

T °C	sample	R_1	R_2	n_1	n_2
500 °C	Film	2.41 Å	2.37 Å	1.7	2.3
300 °C	Film	2.42 Å	2.37 Å	2.7	1.3
500 °C	QD	2.40 Å	2.36 Å	2.6	1.4
500 °C	QD	2.41 Å	2.37 Å	1.7	2.3
		2.41 Å	2.37 Å	3.7	0.3
300 °C	QD	2.42 Å	2.37 Å	2.7	1.3
		2.42 Å	2.38 Å	4.0	0.0

Table I displays influence of blocking Si layer deposition temperature on local structure parameters (n_1(Ge), n_2(Si)). As is seen from Table I with the change in the temperature conditions there is no appreciable change in interatomic distances but the partial coordination numbers of germanium with respect to Ge-n_1(Ge) and Si-n_2(Si), are seriously altered. I.e. such decrease in the temperature leads to a substantial decrease of the diffusion between the phases Ge/Si and the formation of sharper phase boundaries.

As is seen from Fig. 2 the amplitude characteristics of the EXAFS spectra for such films do not differ from those of bulk Ge

Fig. 1. Fig. 3. Scheme of hole states and X-ray absorption electron transitions in the Ge quantum dots with boron dopant.

and there is only a small phase shift. This effect may be explained by the scattering potentials of the environment for the absorbing atoms being similar not only in the first sphere of its environment. On the other hand, the phase shift at large energies for nanoclasters relative to bulk germanium is apparently due to a decrease in the Ge-Ge interatomic distances.

Thus, the strong influence on the microstructural parameters of Ge/Si heterosystems by elastic deformation at the boundaries due to mismatch of lattice parameters of nanocluster and substrate was detected by direct measurement showing that EXAFS spectroscopy is a very perceptive tool to study materials containing nanostructures.

In addition, the interatomic distances R_1(Ge-Ge) and R_2(Ge-Si) obtained from the EXAFS data are in agreement with the interatomic distances derived from the spatial distribution of elastic deformation calculated within the valence force field (VFF) model. The calculation was performed by the procedure based on the use of the Green function of the "atomistic" elastic problem, which was further developed in [18].

In conclusion, a few words about the first attempt to extract from X-ray absorption spectra some information concerning the energy structure of the free states of the quantum dot itself. XANES spectra of two samples were compared. One sample was synthesized using the conventional conditions. The other sample was doped with boron (B) by a special procedure so that Ge in nanoclusters had a substantial deficit of electron charge.

A detailed comparative analysis of the obtained spectra show the presence of an absorption maximum in the spectrum of the doped sample at a distance of -1.8 eV from the point of inflection of the main GeK absorption edge (the position of the GeK absorption edge). Such maximum is absent in the sample with no dopant. The maximum has an intensity of the order of 0.2% of the absorption jump in the main GeK absorption edge. It was established that the maximum is due to the appearance of free levels in the quantum dot at a depth of the order of 1.1 eV from the bottom of the Ge conduction band or 0.4 eV from the top of the Ge valence band (Fig. 3) in accordance with previous experimental and calculation results [19].

Abstract

Pr K-edge XAFS spectrum as a function of temperature in $Pr_{0.5}Sr_{0.5}MnO_3$ has been recorded on BL01B1 beam line at Spring-8, in order to study the effect of lattice distortions as the sample passes from a paramagnetic insulator phase at room temperature to ferromagnetic metal phase below 265 K and to an antiferromagnetic insulator phase at low temperatures. It is found that when the ferromagnetic to antiferromagnetic transition takes place, the MnO_6 octahedra rotate in the ab-plane and tilt away from the vertical along the c-axis. The tilting of the MnO_6 octahedra is responsible for the A-type antiferromagnetic phase.

1. Introduction

$Pr_{0.5}Sr_{0.5}MnO_3$ has been of great interest because of its peculiar magnetic and transport properties. This compound undergoes magnetic as well as structural transitions from a paramagnetic insulator (PMI) phase to ferromagnetic metal (FMM) phase at ~265 K and to an antiferromagnetic insulator (AFI) phase at ~140 K [1, 2]. The structure also changes from body centered tetragonal to face centered orthorhombic phase [3]. The antiferromagnetic ordering is A-type rather than CE-type and hence does not exhibit charge ordering. An important role in this context is played by the steric effects, macroscopic cooperative distortions, usually called tilting or buckling and the local deformations of the MnO_6 octahedra caused by size effects. Extended X-ray absorption fine structure (EXAFS) spectroscopy is an ideal tool to explore such distortions and local deformations and has been used quite successfully in lanthanum based manganites [4–7]. However, EXAFS at the Mn K-edge in other rare-earth based compounds is severely affected by the L edges of the rare-earth ions. One possible solution to observe the local structural changes in such perovskite oxides is by recording EXAFS at the K-edge of the rare-earth ion. Such a study requires EXAFS beamlines operating in the 40 keV range like the BL01B1 beamline at SPring-8. The present study was therefore undertaken with an aim to study the local structural changes around the Pr ion in $Pr_{0.5}Sr_{0.5}MnO_3$ as it traverses from PMI to FMM to AFI phase and to understand these changes in context of orbital ordering in $Pr_{0.5}Sr_{0.5}MnO_3$.

2. Experimental

Polycrystalline $Pr_{0.5}Sr_{0.5}MnO_3$ sample was synthesized using the conventional solid-state reaction method, which involved firing of stoichiometric amounts of starting materials at about 900 °C in a furnace three to four times with intermediate thorough grindings. Just before final sintering the sample was pressed into pellet and heated at 1000 °C for 16 hours. Powder X-ray diffraction pattern showed a single phase tetragonal perovskites structure without any detectable impurities. Further characterization was done by a.c. susceptibility and resistivity measurements. The results obtained were similar to those reported earlier [1, 3, 8]. XAFS spectra at the Pr K-edge were recorded using the BL01B1 XAFS beamline at SPring-8. A Si (311) crystal plane served as the monochromator. The first mirror and the monochromator were fully tuned in order to get optimal resolution. The slit width of the monochromator exit was 0.3 mm vertical and 6 mm horizontal to ensure good signal to noise ratio. During the measurements the synchrotron was operated at an energy of 8 GeV and a current between 80 to 100 mA. The spectra were scanned in the range 41.6 to 43.3 keV for the Pr K-edge EXAFS. The photon energy was calibrated for each scan with the first inflection point of the Pr K-edge in Pr metal (42002 eV). Both the incident (I_o) and transmitted (I) synchrotron beam intensities were measured simultaneously using ionization chambers filled with a mixture of 15% Ar and 85% N_2 gases and 100% Ar gas respectively. The absorbers were made by pressing the samples into pellets of 10 mm diameter with boron nitride as binder. The thickness of the absorber was adjusted such that $\Delta\mu_o x$ was restricted to a value ≥ 1, where $\Delta\mu_o$ is edge step in the absorption coefficient and x is the sample thickness. Data analysis was done using the UWXAFS program [9].

3. Results and Discussion

EXAFS spectra at the Pr K-edge of the sample were recorded at room temperature, 180 K and 50 K so as to study the local structural changes in each of the three phases. The Fourier transforms (FT) of these spectra are presented in Fig. 1. The FT

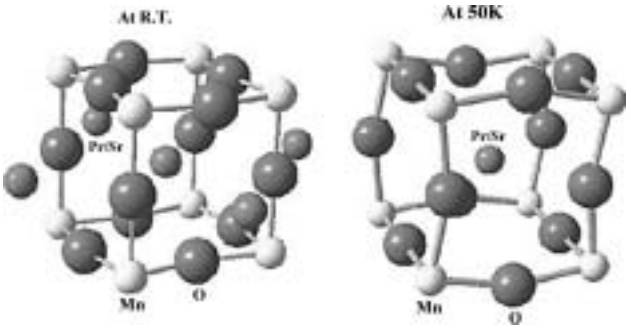

Fig. 3. Local structures around Pr ion at room temperature and 50 K in $Pr_{0.5}Sr_{0.5}MnO_3$.

spectra are not corrected for phase shift however; the values of bond lengths reported in the paper are the corrected values. The room temperature (R.T.) pattern shows two distinct correlations in the region 1.5 and 2 Å due to Pr-O bonds and a broad and most intense maximum at 2.8 Å comprising of a Pr-O and a Pr-Mn correlation. The FT spectrum at 180 K is similar to the one at R.T. One notable change however, is in the 1.5 to 2 Å range wherein there is a change in weight from first correlation to second. The 50 K spectrum has an additional subtle feature at about 2.3 Å, probably an indication of change of symmetry of the compound.

The EXAFS spectrum at R.T. was fitted using three Pr-O and a Pr-Mn correlations obtained from FEFF 6.01 [10] for I4/mcm symmetry. To reduce the number of fitting parameters the coordination numbers for all Pr-O correlations were constrained to be around 4.0 each and that of Pr-Mn correlation to be around 8.0. The final fitted parameters obtained are presented in Table I and the fitting in back transformed *k*-space is shown in Fig. 2. A good fit is obtained to the experimental data. For fitting low temperature data, the final parameters obtained for R.T. data served as starting guess parameters. In the first cycle only the debye-waller factors were varied followed by bond lengths to account for effect of lowering of temperature. A reasonably good fit was obtained for 180 K data. Although the metal – insulator transition in $Pr_{0.5}Sr_{0.5}MnO_3$ occurs only at about 140 K [11], neutron diffraction studies [3] have clearly shown that the structural transition starts around 180 K. This could be the reason for similarity between 180 K and 50 K F.T. spectra, especially in the 1.5 to 2.0 Å range. However, to fit the 50 K data the coordination number also had to be varied and resulted in physically unacceptable numbers. This data was therefore fitted with correlations obtained using FEFF for *Fmmm* symmetry with four Pr-O correlations two of which are four coordinated and two are two coordinated. For this fitting cycle also, the coordination numbers were constrained to be around the theoretically obtained values. The resulting fit was quite good and is shown in Fig. 2 and the fitted parameters are tabulated in Table I.

The local structure of Pr in $Pr_{0.5}Sr_{0.5}MnO_3$ is depicted in Fig. 3. This structure has been drawn using the bond lengths obtained from above analysis and structural information. It can be seen that the MnO_6 octahedra rotate in the ab-plane and tilt away from the vertical along the c-axis when the sample undergoes ferromagnetic metal to antiferromagnetic transition. This leads to two Pr-O bond lengths at 2.534 Å and 2.810 Å instead of one at 2.701 Å at R.T. in the plane of Pr atom. Furthermore due to rotation of MnO_6 octahedra, the 2.880 Å and 2.527 Å Pr-O bond lengths at R.T. change to 2.691 Å, 2.869 Å and 2.534 Å. This rotation and tilting of the MnO_6 octahedra result in ordering of Mn d_{x2-y2} orbitals along the *x*-axis that is responsible for A-type ordering in $Pr_{0.5}Sr_{0.5}MnO_3$.

4. Conclusions

(a) EXAFS at the Pr K-edge has been studied for the first time to explore structural changes in $Pr_{0.5}Sr_{0.5}MnO_3$ as the material undergoes a PMI to FMM to A-type AFI transition.

(b) In the AFI phase the EXAFS spectra can only be fitted using Pr-O and Pr-Mn correlations obtained from *Fmmm* type orthorhombic structure.

(c) This results in rotation in the a-b plane and tilting away from the vertical of MnO_6 octahedra that result in ordering of Mn d_{x2-y2} orbitals along the *x*-axis that is responsible for A-type ordering in $Pr_{0.5}Sr_{0.5}MnO_3$.

Abstract

Valence states and structural environments of polyvalent Fe and Ti ions in two different borosilicate glasses have been studied by X-ray Absorption Near Edge Structure (XANES) and Extended X-ray Absorption Fine Structure (EXAFS) techniques. The results indicate that different valence states of polyvalent metal ions usually exist simultaneously in glass matrix. Doping C favours the formation of reduced state of metal ion. Especially, Fe^{2+} ion can be reduced into neutral iron atom. Fe^{2+} ion generally occupies octahedrally coordinated site. Fe^{3+} ion tends to be in tetrahedral coordination with increasing total iron concentration. Adding oxidising agent can transfer the octahedral iron ions into tetrahedral Fe^{3+} ions. Ti^{4+} ions mainly occupy five-fold coordination sites in NBS1 and four-fold coordination sites in NBS2, depending on the existence of non-bridging oxygen ions in the glass matrix.

1. Introduction

Valence state and structural environment of iron and titanium ions have been widely studied using optical absorption [1], Mössbauer [2], electron spin resonance [3], square-wave voltammeter [4] and X-ray absorption techniques [5–8]. However, the coordination nature of iron and titanium ions by oxygen has been controversially discussed due to the difference in glass composition and in preparation condition. In Fe-bearing silicate glasses melting at ambient conditions, it is generally reported that Fe^{2+} occupy octahedral net-modifying sites. Fe^{3+} have two possibilities of occupying tetrahedral or octahedral sites depending on melting conditions of silicates. For instance, Hayashi *et al.* [9] proposed that Fe^{3+} ions tend to be in octahedral symmetry at large ratios of the number of Fe^{3+} ions to that of nonbridging oxygen ions, and to be in tetrahedral symmetry when the glass matrix is basic. Hannoyer *et al.* [8] suggested that Fe^{3+} is in both tetrahedral and octahedral coordination. The proportion of octahedral Fe^{3+} is found to decrease with increasing amounts of Fe^{3+} in soda-lime silicate glasses containing the same total iron. The relative number of octahedral Fe^{3+} increases with increasing total iron in oxidised soda-lime silicate glasses. Kukkadapu *et al.* [10] reported that the majority of ferric ions likely occupy the octahedral sites, $Fe^{3+}{}_{oct}$, that were isolated and were readily convert into ferrous ions, $Fe^{2+}{}_{oct}$, without changing its coordination. The limited tetrahedral sites for ferric ions are stable against reduction to ferrous ions even under strong reducing condition.

Sandstrom *et al.* [11] found that the oxidation state of titanium in SiO_2 was always Ti^{4+}. Nevertheless, change in Ti geometry occurred with concentration. For example, below 7 wt% TiO_2 all of the Ti was fourfold coordinated with a Ti-O bond length of 1.81 Å. At higher concentrations, some sixfold coordinated Ti occurred with a Ti-O bond length of 2.15 Å. Grunes's research [12] indicated that Ti^{4+} ions in oxides and silicate compounds are four-fold or six-fold coordinated. Dumas and Petiau [13] observed similar intermediate behavior of Ti environment in aluminosilicate glasses. However, Ti^{4+} is possibly five-fold coordinated just like in $Ba_2TiSi_2O_8$ and $Ba_2TiSi_2O_8$ crystals.

In this report, the valence state and coordination geometry of iron and titanium ions in sodium-borosilicate glasses have been studied by changing the redox condition, glass basicity and metal ion concentration. The XANES reflects the chemical bonding of the element and the local symmetry. Especially, the position of the absorption edge is shifted in dependence on the valence state. On the other hand, the EXAFS experiments enable to obtain structural information of local environment like the coordination species and coordination numbers (CN) surrounding the detected atom, interatomic distance, r, and mean-square relative displacement, σ^2, the so-called Debye-Waller factor (DWF) [14, 15].

2. Experimental procedures

NBS1 and NBS2 are sodium borosilicate glasses with compositions of $16Na_2O$-$74SiO_2$-$10B_2O_3$ and $4.3Na_2O$-$74SiO_2$-$20.7B_2O_3$-$1Al_2O_3$ (mole percentage), respectively. No non-bridging oxygen ions were found in NBS2. Fe_2O_3, $FeC_4H_4O_6$, TiO_2 and Ti_2O_3 powders were added into samples NBS1 and NBS2 and were melted at 1500 °C for NBS1 series and at 1600 °C for NBS2 series by an electric resistance furnace. In some cases, graphite or $NaNO_3$ powder was added as redox agent to change the valence states of Fe and Ti ions. Platinum crucible was used for the normal and oxidising melts and quartz crucible was used for the reducing melts [16].

X-ray absorption experiments at Fe and Ti K-edges were carried out at the beam line E4 of HASYLAB in Hamburg (Germany) in transmission mode, utilizing Si (111) double-crystal monochromator. Harmonic rejection was achieved by detuning the monochromator crystals between 40 and 50%. References and glasses were milled into powders by Mixer Mill MM 200 produced by Retsch Company, and then mixed with polyethylene and pressed into tablets with optimum thickness. Absorption edge energies were determined from the half-height of normalised absorption spectra.

The normalised spectra $\chi(k)$ were weighted by k^2 and Fourier transformed using a Hanning window function. Parameters were

fitted based on theoretical amplitude and phase function calculated by FEFF7 and FEFF8. The amplitude reducing factor, 0.7, was used to fit Fe K-edge EXAFS spectra of Fe-bearing borosilicate glasses. The k range used for the Fourier transformation was 2–10 Å^{-1} for the glass samples. In the real space, the fit range was 1–3 Å.

3. Experimental results and discussion

Fig. 1 shows the normalised Fe K-edge XANES spectra of Fe_2O_3 doped sodium-borosilicate glasses. Fe K-edge EXAFS spectra of samples Fe-1, Fe-2 and Fe-3 are given in Fig. 2. The corresponding FT spectra and fitting curves (dotted line) are given in Fig. 3. The fitted structural parameters are shown in Table I.

For transition-metal oxides it has been found experimentally that edge energy shift increases with increasing valence state of the metal ions in oxides or compounds [17] though it is difficult to give a quantitative relationship to explain the magnitude of edge shift because edge shift can be induced by many factors like effective nuclear charge, oxidation state, coordination number, type of chemical bonding, electronegativity, hybridisation, relaxation energy, screening and inner level shift. For example, the edge energies Fe-tartrate, Fe_3O_4 and Fe_2O_3 are 7120.4 eV, 7121.8 eV and 7123.6 eV, respectively. The absorption edge shifts 3.2 eV from bivalent iron ion to trivalent iron ion.

For NBS1 and NBS2 glasses doped by 0.5 mol% Fe_2O_3, the Fe-K edge energies are 7122.9 eV and 7122.4 eV, respectively, indicating the coexistence of Fe^{2+} and Fe^{3+}. Increasing the doped concentration of Fe_2O_3 from 0.5 mol% to 5 mol%, the edge energies move to 7123.7 eV for NBS1 and 7123.3 eV for NBS2, indicating that the majority of iron ions in NBS1 and NBS2 doped by 5.0 mol% Fe_2O_3 are in trivalent states. The lower edge energies in NBS2 series indicate that there are more Fe^{2+} ions in NBS2 series than in NBS1 series because NBS2 series have lower basicities and were melted at higher temperature. Higher melting temperature and lower basicity favour the formation of reduced states of iron ion. In addition, the energy and the intensity of Fe-K prepeak are larger in 5.0 mol% Fe_2O_3 doped NBS series than in the corresponding 0.5 mol% Fe_2O_3 doped NBS series, indicating

Table I. *The fitted structural parameters of first Fe-O coordination in some samples. The uncertainties for nearest neighbour distance and Debye-Waller Factor are 0.01 Å and 0.002 Å^2, respectively.*

Sample	R (Å)	DWF (Å^2)	CN	ΔE_0 (eV)	R-factor

that more Fe ions occupy tetrahedral sites with increasing the concentration of Fe_2O_3.

C-containing glasses have lower edge energies compared to the corresponding samples prepared in normal conditions, indicating that Fe^{2+} content increases due to the reduction of Fe^{3+} into Fe^{2+} by C. When C was doped into NBS1+1.0 Fe^{2+}-Tartrate, Fe^{2+} ion was reduced towards its neutral state by comparing near-edge features between the sample and Fe foil. Doping $NaNO_3$ into NBS1 does not change the position of absorption edge energy. However, it makes an increase in the prepeak height, indicating that more Fe^{3+} ions are in tetrahedral symmetries in the oxidised sample. EXAFS analysis also shows that the nearest neighbour distance and coordination number decrease for the oxidised sample. The increase in the relative number of tetrahedral Fe^{3+} ion may be attributed to the tranformation of octahedral Fe^{3+} ion into tetrahedral Fe^{3+} by adding oxidising agent.

Fig. 4 is the normalised Ti K-edge XANES spectra of Ti-containing compounds and borosilicate glasses.

Ti K-edge energies of Ti_2O_3 and anatase are 4975.8 eV and 4982.1 eV, respectively. When 0.5 mol% Ti_2O_3 was doped into glass NBS1, the edge energy shifted to 4980.2 eV, indicating that partial Ti^{3+} ion was oxidised into Ti^{4+} ion. Ti-K edge energies of samples Ti-2 and Ti-4 are 4981.8 eV and 4981.1 eV, respectively, indicating that the majority of titanium ion is four valence when anatase was doped into samples NBS1 and NBS2, and sample NBS2 contains more Ti^{3+} ions than NBS1 because higher melting temperature and lower glass basicity favour the formation of lower valent Ti ions. When C was doped into sample Ti-2, T-K edge energy decreases to 4981.0 eV, indicating that some of Ti^{4+} ions were reduced into Ti^{3+} ions.

Farges *et al.* [18] showed that the use of either position or normalised peak height alone is not sufficient to derive reliable coordination numbers for Ti when it is present in several coordinations. In our case, the evaluation of Ti coordination structures was further complicated due to the existence of trivalent Ti. The position and height of Ti-K edge prepeak are 4969.7 eV and 0.68 for $CsAlTiO_4$, 4970.4 eV and 0.61 for $Sr_2TiSi_2O_8$. For anatase there exist three prepeaks with decreasing heights due to the increase of symmetry. The position and height of the second prepeak are 4971.9 eV and 0.17, respectively. The prepeak position of sample Ti-2 is 4970.6 eV, larger than that of $Sr_2TiSi_2O_8$, indicating that Ti^{4+} ions in sample Ti-2 mainly occupy five-fold coordination sites. The shoulder observed in the main prepeak indicates the existence of some amounts of six-fold coordinated Ti^{4+} ions, which makes the prepeak height reduction to 0.31. The prepeak position of sample Ti-4 is 4970.2 eV, between that of $CsAlTiO_4$ and $Sr_2TiSi_2O_8$, indicating that Ti^{4+} ions mainly occupy four-fold coordination sites. The reduction in prepeak height can be attributed to the existence of some amounts of trivalent titanium ions. Similarly, Ti^{4+} ions in samples Ti-1 and Ti-3 mainly occupy five-fold coordination sites. The reduction in prepeak height compared to that of $CsAlTiO_4$ and $Sr_2TiSi_2O_8$ can be attributed to the existence of some amounts of trivalent titanium ions in the glasses. The conclusions concerning the coordination numbers could be confirmed by EXAFS calculations that yield Ti-O coordination numbers within the range of 4 to 5. Further experiments should be done to determine the concentration of Ti^{3+} ion in sodium borosilicate glasses and the effect of the concentration of Ti^{3+} ion on the position and height of Ti-K edge prepeak.

4. Conclusions

Valence state and structural geometry of polyvalent ions in glasses depends on doped cationic charge, glass composition and redox condition. Higher melting temperature and lower glass basicity favour the formation of lower valence ions. Doping C favours the formation of reduced state of metal ion. Especially, Fe^{2+} ion can be reduced into neutral iron atom. Fe^{2+} ion generally occupies octahedrally coordinated site. Fe^{3+} is in both tetrahedral and octahedral coordination in 0.5 mol% doped sodium borosilicate glasses, and tends to be in tetrahedral coordination with increasing the relative number of trivalent iron ions by doping $NaNO_3$ or increasing total iron concentration. Ti^{4+} ions in NBS1 with non-bridging oxygen ions mainly occupy five-fold coordination sites. In NBS2 without non-bridging oxygen, however, Ti^{4+} ions mainly occupy four-fold coordination sites.

Abstract

We examined the local environment of zirconium atoms in the $Pb(Zr_{0.53}Ti_{0.47})O_3$ (PZT) sol, prepared from lead acetate and transition metal n-propoxides in 2-methoxyethanol, and in the as-pyrolyzed amorphous film deposited on (0001) sapphire. The immediate neighborhood of Zr atoms changes markedly upon transition from the sol to the amorphous film. Clustering of Zr species in the process of film formation in the form of Zr oxide nanoparticles is indicated.

1. Introduction

Ferroelectric thin films have been widely studied for a range of applications such as memories, capacitors, sensors or micro-electromechanical devices [1, 2]. In comparison to solid-state synthesis, alkoxide based sol-gel processing of multicomponent materials is recognized to yield more homogeneous products at lower processing temperatures, due to the formation of heterometallic bonding already in solution. In chemical solution deposition (CSD) of thin films the main processing steps include the synthesis of a heterometallic precursor, typically in a nonaqueous medium, the deposition of the film, and the processes occurring upon thermal treatment: drying, consolidation and crystallization of the target ferroelectric phase [3]. Understanding the structural transitions in the process of film formation from the sol would allow a better tailoring of the properties of the final product.

In 2-methoxyethanol-based processing of $Pb(Zr_{0.53}Ti_{0.47})O_3$ (Zr-rich PZT) thin films an inorganic network arises in the reaction between transition metal alkoxides and lead acetate. Thermodynamically stable perovskite film on sapphire (0001) substrate crystallizes at 700 °C from the amorphous phase through the transitory pyrochlore-type phase [4] as generally observed for CSD PZT thin films [3]. It is known that the crystallization temperature of the perovskite phase is higher for Zr-rich PZT thin films than for Ti-rich thin films. Furthermore, the intermediate nanocrystalline pyrochlore-type (or fluorite) phase exists in a broader temperature range in Zr-rich PZT films [5, 6]. So far there are no reports on the structure of the amorphous phase of the PZT films, even though there are indications that it crucially influences the perovskite crystallization temperature in the film.

In this work Zr K-edge EXAFS of amorphous $Pb(Zr_{0.53}Ti_{0.47})O_3$ thin film pyrolyzed at 350 °C and its precursor prepared by the 2-methoxyethanol route is studied to provide insight into the structural changes in the process of the formation of amorphous Zr-rich PZT film from the sol.

2. Experimental

PZT sol, corresponding to the target composition of $PbZr_{0.53}Ti_{0.47}O_3$ with 10 mol% PbO excess, was prepared in a 100 ml batch by diluting zirconium and titanium n-propoxides in 2-methoxyethanol and by adding anhydrous lead acetate in the required quantity. The metal contents of all compounds were determined gravimetrically. The reaction mixture was heated to approximately 60 °C to get a clear solution. After 2 hours of refluxing and distillation of the ester formed during the reaction a stable 0.5 M sol was obtained. All manipulations were performed in dry nitrogen atmosphere. PZT thin film was deposited on sapphire substrate (0001) by spin-coating and pyrolyzed at 350 °C for 1 minute. The film thickness was about 200 nm. X-ray diffraction showed that the film was amorphous.

Zr K-edge EXAFS spectra of the PZT sol and thin film were recorded at the X1 station in HASYLAB at DESY (Hamburg, Germany). A Si(311) double-crystal monochromator was used with 3 eV resolution at 18 keV. Harmonics were effectively eliminated by detuning the monochromator crystal using a stabilization feedback control.

Absorption spectrum of the PZT sol was measured in a standard transmission mode. The sol, concentrated to approximately 1 M solution in order to increase the signal-to-noise ratio, was inserted in a liquid absorption cell with 0.5 mm lucite windows. Sample thickness of about 1 mm was chosen to obtain total absorption thickness of about 2 above the Zr K-edge. An empty absorption cell served as a reference spectrum measured under identical conditions. The intensities of the incident and transmitted beams were measured with Ar filled ionization cells. The standard stepping progression within the (−250 eV, 1000 eV) interval relative to the Zr K-edge was adopted with an integration time of 1 s/step.

Zr EXAFS spectrum of the PZT film was measured in a fluorescence detection technique using a 4-channel Ge fluorescence detector. The absorption spectra were obtained as the ratio of the fluorescence detector signal and the signal of the incident photon beam from the ionization cell filled with argon at ambient pressure. The same stepping progression was adopted as in the case of the sol with an integration time of 4 s/step. To improve the signal to noise ratio, eighteen consecutive runs were superimposed.

3. Results and discussion

Zirconium EXAFS spectra of PZT sol and thin film were analyzed by the University of Washington analysis programs using FEFF6 code for *ab initio* calculation of scattering paths [7, 8]. A comparison of both spectra (Fig. 1) shows that the signal-to-noise

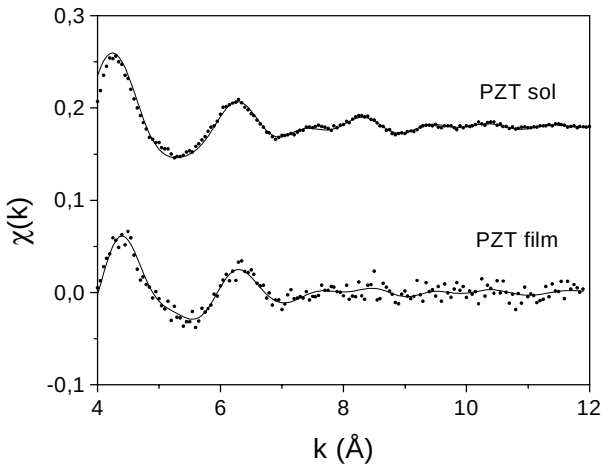

Fig. 1. Zr K-edge EXAFS spectra of PZT sol and amorphous thin film on (0001) sapphire: (dots) – experiment, (solid line) – EXAFS model.

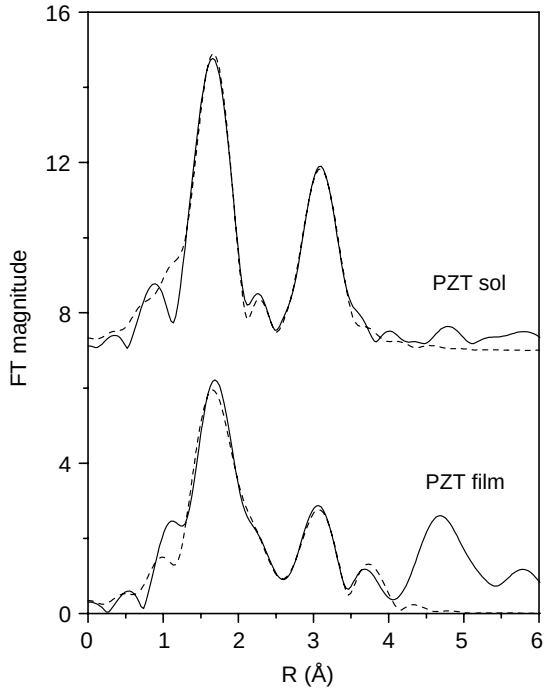

Fig. 2. The k^3 weighted Fourier transforms of zirconium EXAFS spectra of PZT sol and amorphous thin film on (0001) sapphire, calculated in the k range of 4–11 Å^{-1}: (Solid line)- experiment, (dashed line) – EXAFS model.

ratio of the fluorescence EXAFS spectrum measured on the film is about an order of magnitude lower, in spite of the much longer detection time. Nevertheless, a quantitative analysis reveals that the local neighborhood of Zr atoms in the film is different from that observed in the sol. The difference can be clearly seen in Fig. 2, where k^3-weighted Fourier transforms of the EXAFS spectra are shown.

Two shells of neighbors are discerned in the local neighborhood of Zr atoms in the sol. A fit of the EXAFS spectrum in the R range of 1.3 Å to 3.8 Å shows that the immediate neighborhood of Zr atoms is populated with about seven O atoms at two slightly different distances 2.11 Å and 2.23 Å, while the wide second shell of neighbors consists of zirconium atoms at 3.47 Å and carbon atoms at about 3.3 Å and 3.7 Å, in agreement with our previous study of PZT sols [4]. Carbon atoms belong to the functional groups of the starting compounds and the solvent. The number of Zr neighbors points to clustering of zirconium species.

Table I. *Parameters of the nearest coordination shells around zirconium atom in PZT sol and amorphous thin film: atomic species, average number N, distance R and Debye-Waller factor σ^2. Uncertainty of the last digit is given in parentheses.*

Zr	N	R (Å)	σ^2 (Å^2)
PZT sol			
O	3.8(5)	2.11(4)	0.002(1)
O	3.2(5)	2.23(4)	0.002(1)
C	3(1)	3.29(1)	0.003(1)
Zr	2(1)	3.47(2)	0.006(2)
C	5(2)	3.63(5)	0.003(1)
PZT film			
O	4.0(7)	2.14(4)	0.003(1)
O	2.8(7)	2.67(4)	0.002(1)
Zr	3(1)	3.43(2)	0.006(2)
O	6(1)	4.19(5)	0.007(3)

The local structure around Zr formed in the sol is not retained in the amorphous film. The fit of the EXAFS spectrum of the film (in the same R range of 1.3 Å to 3.8 Å) shows that the distribution of oxygen atoms around Zr is significantly altered: there are about four oxygens at 2.14 Å and about three at a much larger distance of 2.67 Å. In the second coordination shell Zr and O atoms are found, but no C atoms. The complete list of structure parameters is given in Table I. Relatively high uncertainties in the number of neighbors in individual shells are due to the high correlation of the shell parameters N and σ^2.

We attribute the difference between the amorphous film and the sol to the partial decomposition of organic functional groups upon heating to 350 °C [3]. Namely, the local structure around Zr atoms in the film is similar to the Zr neighborhood in the tetragonal ZrO_2 [9]. Most probably nano-clusters of zirconium oxide are forming within the film.

It is conceivable that the segregation of Zr species in the film – possibly as zirconia nanoparticles within the amorphous matrix-hinders the crystallization of the perovskite phase by the formation of the transient pyrochlore-type phase, so that the crystallization of the perovskite phase is shifted to higher temperature.

Abstract

Iron thin films of less than 100 nm have been grown on Si(100) wafers by DC magnetron sputtering at well-controlled substrate temperatures. Three different sets of samples have been prepared in order to study the influence of the preparation conditions on their magnetic properties: *i*) natural oxidized samples, *ii*) "*in-situ*" partially oxidized and *iii*) non-oxidized iron thin films. For the last two sets, a gold film prior to expose the air capped the samples. XRD and EXAFS experiments have been performed to obtain the size and the shape of the grains. They provide a columnar growth for samples prepared at room temperature and a diminution of the grain size along the normal to the surface when the preparation temperature decreases.

1. Introduction

Ultrafine particles of metals and alloys can be prepared by several techniques. In order to obtain thin film samples thermal evaporation [1], electron beam [2], or ion beam sputtering sources [3] have been used. An important improvement of these methods is to cool the substrate down to liquid nitrogen temperature. Nevertheless, no such a cooling technique has been extensively used to prepare thin films samples. Ultrafine particles are interesting because of spectacular changes in physical properties by decreasing the size of a material from the bulk to the atomic level. In particular, small grain size ferromagnetic materials exhibit different magnetic properties mainly as a result of the finite size effect. Enhanced magnetic anisotropy and coercivity have been observed in the materials with particle size close to the single domain size [4]; they are of interest for magnetic recording applications. Fe-based materials are the most promising candidates for high-density recording media [5] due to its high saturation magnetization and coercivity.

We have prepared iron thin films by sputtering at very low temperatures. After partial oxidation, they showed a very interesting magnetic behaviour: the coercive field evaluated at 5 K gave higher values for samples prepared at temperatures near 200 K, additionally, they had an exchange bias with a similar behaviour [6]. That behaviour has been correlated with the partial oxidation of the samples, as well as, with the grain size lowering [7].

The aim of the present work is to characterize iron thin films microstructures by X-ray absorption and diffraction techniques in order to give light to study their magnetic properties as a function of their characteristic lengths. It is known that both diffraction and absorption techniques provide data to estimate the characteristic size of the crystallographic grains. Generally, the results obtained by both techniques are comparable, but not in full agreement. It is also presented in this paper a method to explain the possible discrepancies by studying the grain shapes crystallographically.

2. Experimental

Iron thin films were grown on naturally oxidized Si(100) substrates using a DC-operated two-inches planar magnetron source. Base pressure was in the range of 10^{-7}mbar and Ar pressure for sputtering deposition was 5.0×10^{-3} mbar. The experimental set-up has a possibility of maintaining the substrate at constant temperature during deposition by use of a cold finger attached to a home-modified continuous flow Oxford CF-100 cryostat in the vacuum chamber. An Oxford ITC-502 temperature controller set the substrate temperature with a precision of 0.1 K; substrate temperature can be selected from 5 to 400 K. Additionally, in order to deposit a cap layer, the set-up has a possibility of changing sputtering targets maintaining the sample at the base pressure and at low temperatures.

Deposition rate was about 1 nm/min, the power (about 4 W) applied to the magnetron and deposition time were kept constant for the whole set of samples. Three sets of samples were prepared: the first one was exposed to the air, being passivated at room temperature and room pressure; the second set was capped with a gold film inside the preparation chamber in order to prevent oxidation; and the third set was intentionally oxidized inside the preparation chamber at room temperature under an oxygen partial pressure of 1×10^{-2} mbar for 1h, and subsequently a gold cap film was deposited in order to prevent further oxidation.

X-ray diffraction (XRD) was performed on the Bragg-Brentano geometry on a standard two-circle diffractometer (Siemens D-500) in order to determine the texture of the samples, as well as, the film grain size by evaluating the coherence length of the diffracted peaks.

X-ray absorption experiments have been carried out at LURE (DCI, XAS-13 beamline) with electron beam energy of 1.85 GeV and average current of 250 mA. Data of the Fe K-edge were obtained by using a fixed exit monochromator with two flat Si(311) crystals, with the total electron yield on a biased electrode in a He atmosphere sample chamber at liquid nitrogen temperature [8]. The experimental geometry was chosen in a way that the X-ray polarization vector was contained in the film and the incoming X-ray beam forms an angle of 70° with the normal to the surface. Details of the polarization experiments have been explained carefully elsewhere [9].

A standard EXAFS analysis was performed by using the VIPER program [10]. Oscillations were obtained after removing the background by a cubic spline fitting polynomial and EXAFS signal ($\chi(k)$) was obtained by normalizing the magnitude of the

#Correspondant author: e-mail: "cprieto@icmm.csic.es"

oscillations to the edge jump. The corresponding pseudo Radial Distribution Function around the three component atoms has been obtained by weighting by the wavenumber ($k\chi(k)$), multiplying by a Hanning window and Fourier transforming. For comparative study, the Fourier transform of EXAFS signal was performed within the same k-range. The here presented analysis is based on the fit of the oscillations obtained by back-Fourier transform of the first coordination sphere (between 1.5 and 2.8 Å). The amplitude and phase were calculated by the FEFF code version 6.01 reported by J. Rehr [11]. The S_0^2 amplitude loss factor was obtained by using the spectrum of a Fe foil as the reference.

3. Results and Discussion

Figure 1 shows the normalized XANES signal of the three sets of samples. The intensity of the main feature at 7130 eV clearly shows that gold-capping prevents the sample oxidation effectively (see Fig. 1(a)) and that the partial oxidation becomes more enhanced for the samples prepared at low temperatures (see Figs. 1(b) and (c)). X-ray diffraction study [6] indicates that the crystallographic grain size of a thin film decreases by preparing at low temperatures. It is reflected in the present XANES results, because oxidation of Fe grains should be more effective when the surface/volume ratio becomes bigger. This is the case for small grains.

$k\chi(k)$ EXAFS signals and their Fourier transforms of the three sets of samples are shown in Figs. 2 and 3, respectively. These data show that iron remains in the bcc structure for the whole set of conditions and temperature preparations, although a decrease of the EXAFS signal amplitude is observed for the samples prepared at low temperatures. It may be interpreted as a lost of the average coordination number due to the finite size effect.

Table I summarizes the parameters obtained by the EXAFS data analysis. The results indicate that remarkable variations are obtained neither in the Fe-Fe distance nor in the Debye-Waller factor, but a clear decrease in the coordination number (CN) is obtained.

From the CN, it is possible to calculate the characteristic size of the grains that forms the thin film. By using the model proposed by Borowski [12] for spherical clusters, we derived the dependence of the Fe-Fe CN as a function of the Fe grain size. Nevertheless, the large values obtained for the coercive field (about 2500 Oe) of oxidized samples [6] suggest the existence of grains with very elongated shape. Figure 4 presents calculated curves that relate the CN to the grain size with an elliptical form in order to compare

with the spherical form (calculations should be presented as a function of the averaged diameter). It is clear that for ellipse with higher eccentricity values the grain needs a bigger size to reach the maximum CN where the finite size effects are neglectable.

Moreover, in order to evaluate the dimensions of the grains along the perpendicular to the film, one can use the coherence length obtained from the width of X-ray diffraction (XRD) peaks. The studied samples have a (110)-bcc texture and it is possible to estimate the grain size from the FWHM of this diffraction peak by using the Scherrer formula. It should be noted that the measured characteristic length is along the direction of the transferred momentum ($\boldsymbol{Q}$) according to the XRD experiment. For textured films, a Bragg-Brentano geometry was used where the thin film was placed symmetrically respect to the beam incidence and the detector (at a specular position); this experimental arrangement maximizes signal for textures normal to the surface being the transferred $\boldsymbol{Q}$ perpendicular to the film.

As our films are not highly textured, "rocking curves" extend over $\pm 20^\circ$ from the normal. This fact allows performing measurements with transferred $\boldsymbol{Q}$ along directions different from the perpendicular. The analysis of these data [13] provides a general behaviour of iron thin films on silicon. Samples prepared at room temperature clearly exhibit a columnar growth and samples prepared below 200 K have grains of spherical shape.

The competition between this change of shape and its characteristic size should be taken into account in order to explain the reported magnetic coercivity behaviour [6, 7]. The film grains shape is independent of the oxidation process and the coercivity

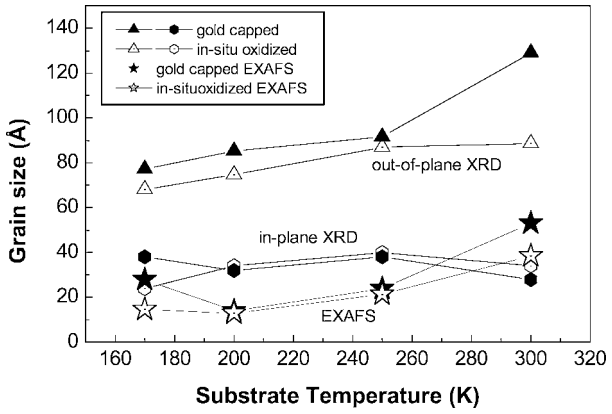

Fig. 5. "Out-of-plane" and "in-plane" characteristic sizes obtained from the coherence length in X-ray diffraction experiments. Partially oxidized gold capped and non oxidized gold capped samples are presented. Grain sizes obtained from the EXAFS data are given for comparison.

behaviour should be explained as follow. The film grains shape provides an increase of the coercivity when columns diminish in size respect to the obtained at room temperature and that increase drops for grains with nearly spherical form, as it occurs for samples prepared down 200 K.

Figure 5 shows the dependence of the characteristic "out-of-plane" and "in-plane" lengths obtained by XRD for *in-situ* oxidized and non-oxidized (gold capped) samples. We estimated the eccentricity and average size for each sample from the corresponding calculation curve as presented in Fig. 4. The sizes obtained by EXAFS are also shown in Fig. 5, compared with the characteristic lengths obtained by XRD.

The EXAFS results are in agreement with the "in-plane" XRD lengths, but not with the "out-of-plane" ones. This fact can be explained as follows. For the particle size determination of a thin film with randomly distributed elongated particles the XRD gives the larger dimension due to their sharper contribution to the diffraction peak, while the EXAFS is directly related to the shorter dimension because it controls the coordination number. This can be easily understood for an infinitely sharp needle (or wire) where the averaged CN only depends on the number of neighbouring atoms along the axis and is independent of the larger dimension size.

Additionally, there is another experimental parameter. The incoming X-ray polarization is parallel to the film plane, thus the polarization dependence makes that "in-plane" distances are highly weighted than the perpendicular ones in the EXAFS contribution [9]. This fact explains the reduction of the grain sizes obtained by EXAFS with respect to the "in-plane" dimensions obtained by XRD.

4. Conclusions

EXAFS spectroscopy and XRD have been used to study the microstructure of sputtered iron thin films prepared at low temperatures. The size and shape of the thin film grains were determined by two independent methods. They change with the substrate temperature at preparation.

The columnar growth of the films gives shorter characteristic sizes along "in-plane" than along "out-of-plane" directions. It has been proved that the smaller grain dimension is the characteristic length that governs the effect of the finite grain size in the EXAFS experiments. This effect should be taken into account in order to compare both EXAFS and XRD data.

A columnar growth explains results obtained for samples prepared near room temperature. At preparation, by decreasing the substrate temperature, a strong diminution of the column height is observed and, consequently, the grain shape changes for samples prepared at low temperature. This behaviour should be taken into account in order to explain the magnetic anomalies reported elsewhere [6].

Abstract

Ni and Si_3N_4 layers have been alternatively deposited by sputtering in order to study Ni clusters embedded in amorphous Si_3N_4. The nominal Ni layer thickness has been varied from 2 to 60 Å and the number of layers was planned to have a similar total amount of Ni. The decrease in the Ni-Ni coordination number observed by Extended X-ray Absorption Fine Structure spectroscopy has been used to study the microstructure of the Ni clustering. For small Ni layer thickness, the actual Ni layer becomes discontinuous and an average cluster diameter of Ni clusters can be determined. Ni metallic cluster in the Ni/Si_3N_4 system show a magnetization smaller than in bulk nickel, the decrease of magnetization of the cluster should be attributed to a dead skin at the surface of the Ni-clusters.

1. Introduction

Nano-scale structures have drawn a great deal of attention. By decreasing the material size from the bulk to the atomic level, many physical properties undergo spectacular changes. Small clusters have an average magnetic moment per atom larger than the bulk value [1]. In particular, materials with small grain size exhibit unique magnetic properties such as magnetization [1], superparamagnetic behaviour [2] or giant magnetoresistance [3].

Granular materials composed of magnetic clusters embedded in non-magnetic matrix can be prepared by typical thin film techniques such as sputtering [4] or ion implantation where clusters size can be controlled by the preparation parameters. We chose to study the $Ni\text{-}Si_3N_4$ system.

Materials with Ni clusters embedded in another ceramic matrix, AlN, have been prepared by ion implantation and their magnetic properties have been studied [5, 6]. The aim of the present work is to check the possibility to synthetize Ni clusters in another ceramic by sputtering and to perform the microstructural characterization to study their magnetic properties as a function of their characteristic length.

The effect of the matrix on the magnetization at saturation measured at low temperature will be discussed in view of the results presented in Ref. [6].

2. Experimental

$Ni\text{-}Si_3N_4$ multilayer films were grown at room temperature on Si(100) by using two planar 2″ magnetron source (Angstrom Science) operated by both Huttinger DC and RF-power supply, respectively. Circular targets were mechanically clamped to the water-cooled electrode. The vacuum system provides a residual pressure near 1×10^{-7} mbar. Using Ar as sputtering gas, a DC power of typically 20 W was used to deposit nickel by, and using N_2 as reactive sputtering gas, a RF power of 100 W was used to deposit silicon nitride from a pure silicon target. The compositional characterization of silicon nitride prepared in this way has been reported elsewhere [7, 8].

Within our preparation conditions, when the Ni layer average thickness ranges from 2 to 60 Å, their roughness makes that X-ray reflectivity spectra do not show a multilayer, but nevertheless, metallic nickel is present at the sample. Changing the Ni average thickness and the Ni concentration it is possible to control the cluster size and distance between clusters.

The Ni deposition rate was determined previously by X-ray reflectivity, but, due to the very short time to prepare each layer, some error cannot be avoided. Thus, we have determined the total amount of Ni by Rutherford Backscattering Spectroscopy (RBS) at the Centro Nacional de Aceleradores (Sevilla, Spain) by using the 3 MV Tandem ion beam accelerator.

X-ray absorption experiments have been carried out at LURE (DCI, XAS-13 beamline) with electron beam energy of 1.85 GeV and an average current of 250 mA. Ni K-edge data were obtained by using a fixed exit monochromator with two flat Si (311) crystals. Signal detection was made by collecting the total electron yield on a biased electrode placed in a He atmosphere sample chamber at liquid nitrogen temperature [9].

A standard EXAFS analysis was performed by using the VIPER program [10]. Oscillations were obtained after removing the background by a cubic spline fitting polynomial and EXAFS signal ($\chi(k)$) was obtained by normalizing the magnitude of the oscillations to the edge jump. The corresponding pseudo Radial Distribution Function around the Ni atoms has been obtained by weighting by the wavenumber ($k\chi(k)$), multiplying by a Hanning window and Fourier transforming. For comparative study, the Fourier transform of EXAFS signal was performed within the same k-range. The here presented analysis is based on the fit of the oscillations obtained by back-Fourier transform of the first coordination sphere (between 1.2 and 2.5 Å). The backscattering amplitude and phase were calculated by the FEFF code version 6.01 reported by J. Rehr [11]. The $S_0{}^2$ amplitude loss factor was obtained by using the spectrum of a Ni foil as the reference.

Magnetization hysteresis loops were measured at 4 K in a SQUID magnetometer (MPMS-5S from Quantum Design). Magnetic fields were applied up to 40 kOe in order to saturate the magnetization of the samples.

3. Results and Discussion

EXAFS signals of the studied set of samples are shown in Fig. 1(a). Samples with nominal Ni layer thickness more than 30 Å present a clear fcc-like EXAFS structure. However, the samples with nominal Ni thickness less than 30 Å, have no more fcc structure,

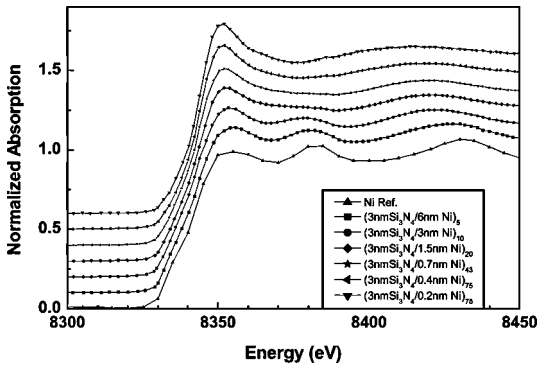

Fig. 2. Normalized XANES spectra corresponding to samples prepared with a Ni deposition rate of 3.5 nm/min.

taken into account in order to explain the distance that appears shorter than Ni-Ni, but we have found that the Ni-Si contribution is negligible. EXAFS analysis provides a decrease of the Ni-Ni coordination number that is associated with the finite size effect. Hence we could suggest that Ni clusters have been formed surrounded by the N atoms of the nitride.

Fig. 2 shows the normalized XANES signals. In agreement with EXAFS data, samples with nominal Ni layer thickness more than 30 Å present a clear fcc-like XANES structure and for the samples less than 30 Å, the increase of the feature at 8350 eV indicates that nickel atoms loose the fcc crystallographic structure and some of them are coordinated to the nitrogen of the silicon nitride. This suggests, a decrease of the Ni cluster size by lowering the nominal Ni layer thickness.

Next, we determined the average Ni layer thickness by measuring the total Ni atomic amount by RBS and normalizing by the number of layers. Results are given also in Table I, showing a good agreement between the nominal Ni layer thickness and the obtained data. However, for the thinner layers, there is a small increment of the actual Ni amount because there is an excess of the growing time coming from the time needed to position the substrate over the Ni source.

In Fig. 3, the EXAFS coordination numbers are plotted as a function of the Ni layer thickness determined by RBS. A monotonous increase is observed for the Ni-Ni coordination number that tends to the Ni coordination number (CN) in the bulk fcc phase. On the other hand, the Ni-N CN decreases to zero with the Ni layer thickness.

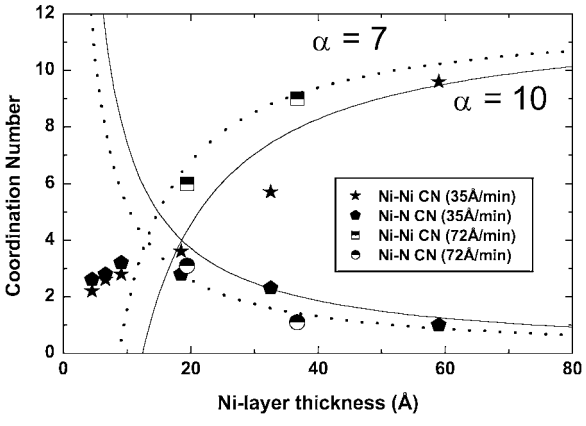

Fig. 3. Coordination number as a function of layer thickness. Points are EXAFS obtained results for Ni-Ni and Ni-N pairs. Lines are calculated as it is indicated in the text (solid line corresponds to $\alpha = 10$ and doted line to $\alpha = 7$).

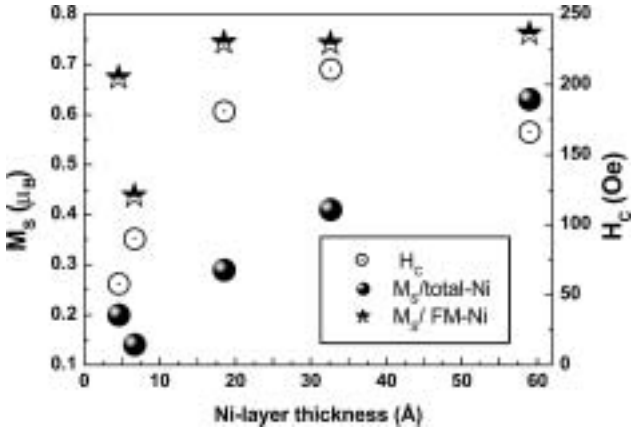

Fig. 4. Atomic saturation magnetization (M_S) and coercive field (H_C) vs. the Ni-layer thickness. Black circles are used to plot the magnetization normalized to the total amount of nickel and stars represent the atomic magnetization by considering only the Ni atoms in the ferromagnetic metallic phase.

It is possible to calculate the CN behaviour of a layer as a function of their thickness. By using a similar model as that proposed by Borowski [12] for spherical clusters, the following equation is derived for the Ni-Ni CN in a nickel layer: $CN_{(Ni\text{-}Ni)} = CN_{bulk}(1 - \alpha d/2t) = 12(1 - \alpha d/2t)$; where d is the distance between the nearest neighbour Ni atoms, t is the thickness of the layer and the bulk coordination number (CN_{bulk}) is 12 for the fcc phase; α is a parameter ($\alpha > 1$) in order to take into account the roughness of the layer that makes a bigger ratio for atoms situated at the surface of the layers. Additionally, the nickel atoms located at the surface of the layer and that can coordinate to the nitrogen atoms of Si_3N_4 can be estimated as: $CN_{(Ni\text{-}N)} = (1/4)CN_{bulk}(2\alpha d/t) = 3\alpha d/t$; where CN_{bulk} has been taken equal to 6 as typically for an octahedral coordination.

In Fig. 3 are represented the calculated curves relating the average CN to the layer thickness. In order to roughly fit the EXAFS-obtained CN for the higher layer thickness, the α factor has been taken as $\alpha = 10$ and $\alpha = 7$ for samples prepared at 3.5 nm/min and 7.2 nm/min deposition rate, respectively. This result shows that, within this range of deposition range, the Ni layer roughness decreases for higher deposition rate.

The set prepared with Ni deposition rate of 3.5 nm/min supplies very thin Ni layer samples. For thickness less than 15 Å, the obtained CN does not follow the calculated behaviour. This is because the roughness is bigger than the average thickness, which makes that Ni must not be considered yet as a continuous layer appearing in the sample as dispersed metallic clusters, this thickness can be considered as the percolation limit.

Finally, hysteresis loops have been measured at low temperature ($T = 4$ K) in order to obtain saturation magnetization (M_S) and coercive field (H_C). M_S has been determined by extrapolating the magnetization data for a magnetic field of 4 T. In order to obtain the atomic magnetization one can normalize by the total amount of Ni in the sample; results are given in Fig. 4 vs. the Ni-layer thickness. Compared with the bulk Ni ($0.63\mu_B$), samples present a significant decrease for thinner Ni-layers. Such a similar decrease of the magnetization has already been observed in Ref. [13] for Ni and Co clusters embedded in AlN whatever the preparation technique, sputtering or ion implantation. Moreover, coercive field also decreases for Ni-layer thickness less than 10 Å in coincidence with the percolation limit obtained from the EXAFS analysis, indicating that small size clusters have a super-paramagnetic character.

The large drop of magnetization for the thin Ni layers should be ascribed to a dead skin effect. The surface of the Ni layer is covered by a Ni-N wrap. In order to calculate the magnetization per metallic Ni atom, the amount of nickel forming Ni-N bonds should be excluded from the normalization. In order to estimate what is the relative amount of Ni atoms in the magnetic metallic phase, we have used the ratio between the obtained CN for Ni-Ni and Ni-N bonds. After performing this new normalization, the atomic M_S remains at roughly constant values (values are also plotted in Fig. 4). The reduction obtained for samples having very small coercive field can be attributed to an underestimation of the magnetic saturation due to the super-paramagnetic shape of the hysteresis loops.

4. Conclusions

EXAFS spectroscopy has been used to study the microstructure of sputtered Ni/Si_3N_4 multilayer system. For small Ni-layer thickness samples should be considered as Ni clusters embedded in amorphous Si_3N_4. It has been determined that the magnetization per Ni atom decreases with the Ni-layer thickness and that, is due to a magnetically dead skin where the Ni is coordinated to the nitrogen of the Si_3N_4 amorphous matrix. Additionally, the atomic magnetization of Ni atoms in the magnetic metallic phase seems to be independent of the nanometric characteristic size of the Ni.

Abstract

Sr_2FeMoO_6 double perovskits display low field MR at a relatively high temperature and unusual ferromagnetic properties. These compounds depicts metal to insulator transition increasing x above $x_c \sim 0.25$. A comparative analysis of the near edge regions (XANES) suggests that iron is Fe^{3+} in the metallic range. Checking the end compounds, we found that the doped samples can be viewn as inhomogeneous distributions of the end compounds. This could help to distinguish between the two scenarios proposed to explain the metal to insulator transition. Moreover, the local atomic structure of $Sr_2FeMo_xW_{1-x}O_6$ as a function of composition ($0 \leq x \leq 1$) has been investigated by Extended X-ray absorption spectroscopy (EXAFS) a the Fe, Mo, Sr K-edges and W L_{III}-edge.

1. Introduction

Recently, the double perovskits system, $Sr_2FeMo_xW_{1-x}O_6$, has attracted the interest of the solid state scientists because of its remarkable magnetoresistive properties. The ordered undoped end compound Sr_2FeMoO_6 ($x = 1$) has alternating occupancy of Fe^{2+} and Fe^{3+} ions at the B sites of the double perovskits A_2BO_6 structure, where A and B represent two cations. The interest in this compound derives from the rather high temperature of their ferrimagnetic transition (∼450 K). In this phase it is believed to be ordered with each B site sublattice of Fe^{3+} and Mo^{5+} arranged ferromagnetically, while the two sublattices are coupled to each other antiferromagnetically. It has been suggested [1] that high structural order in Fe^{3+} and Mo^{5+} occupancy leads to a half metallic ferromagetic state (HMFM), with only minority spin carriers present at the Fermi level.

This compound exhibits a large negative magnetoresistance (MR) at 5 K as well as at 300 K [1–3]. Such large magnetoresistance is believed to be driven by the complete spin polarization at the Fermi energy in the HMFM state. The other end compound, $x = 0$ (Sr_2FeWO_6), belong to the same double perovskite family but shows very different electrical transport and magnetic properties. It is insulating throughout the temperature range with antiferromagnetic ordering below 37 K [5, 6].

Since Sr_2FeMoO_6 and Sr_2FeWO_6 have contrasting transport properties, it is expected that an alloy system of these compounds, such as the $Sr_2FeMo_xW_{1-x}O_6$ series, would exhibit a metal insulator transition (MIT) as a function of x. Two models have been proposed to explain the MIT. In one scenario [5], Fe is believed to be in the 3+ state in the metallic range ($x_c \gtrsim 0.25$) and Mo and W in the 5+ state; one itinerant electron is provided by each Mo^{5+} ($4d^1$) and W^{5+} ($5d^1$) site. For $x < x_c$, Fe transforms into the 2+ state converting Mo and W into the 6+ state (W, $5d^0$). This gives rise to the insulating behavior since, for the $5d^0$ electronic configuration of the W^{6+} sites, the Fe^{2+} ions couple antiferromagnetically with each other via the Fe-O-W-O-Fe type super exchange interaction. In this scenario a valence transition is the driving force for the MIT.

In a more recent work [1], it has been proposed that Mo remains in the 5+ state in the entire composition range while W is in the 64+ state. This implies that there is no valence transition Mo and W ions at the critical concentration. The substitution of W^{6+} in place of Mo^{5+} requires the transformation of one Fe^{3+} to Fe^{2+} for charge neutrality. Thus the system is viewn as an inhomogeneous distribution of metallic Sr_2FeMoO_6 and insulating Sr_2FeWO_6 parts; in the scenario the MIT at the critical composition is driven by the percolation threshold of the system. Above x_c the system is in a macroscopically metallic ferromagnetic state of Sr_2FeMoO_6 with a distribution of small clusters of insulating antiferromagnetic Sr_2FeWO_6. At higher W doping, the insulating Sr_2FeWO_6 clusters grow in size, eventually engulfing the metallic Sr_2FeMoO_6 clusters for $x < 0.3$, giving rise to the observed MIT.

2. Results

X-ray absorption spectroscopy (XAS) experiments were performed at the GILDA (General Italian Line for Diffraction and Absorption) beam line [7] at the European Synchrotron Radiation Facility (ESRF) in Grenoble, France. X-ray beam energies were tuned using a double crystal, sagittal focusing monochromator mounting Si [311] crystals. High quality XAS spectra at the Fe (7112 eV), Mo (20000 eV) and SR (17998 eV) K edges and at the W L_{III} edge (10207 eV) have been collected in transmission mode: incident (I_o) and transmitted (I_t) beam intensities were recorded using ionization chambers and the absorption signal was defined as: $\mu(E) = \ln(I_o/I_1)$. Data were collected keeping the samples at low temperature (77 K) in order to reduce the effects of thermal disorder.

A qualitative analysis of the XANES region of the absorption spectra (figure 1) does not reveal appreciable differences in the W and Mo absorption edges over the entire concentration range indicating that the valence of the W and Mo ions does not change with the concentration. This is incompatible with the valence transition scenario proposed to explain the MIT and discussed above. Data refinement (to be compared with diffraction data [4]) in the EXAFS [8–10] region shows no changes even in the local structure near the Mo and W ions.

On the contrary the Fe edge absorption spectra show large effects in the XANES region while crossing the critical concentration value indicating a valence transition of Fe ions from 3+ above x_c to 2+ below x_c.

Moreover, we checked the possibility of fit the spectra to a weighted sum of the end compounds: $\mu_{FIT}(x) = \alpha \cdot \mu_{exp}(x = 1) +$

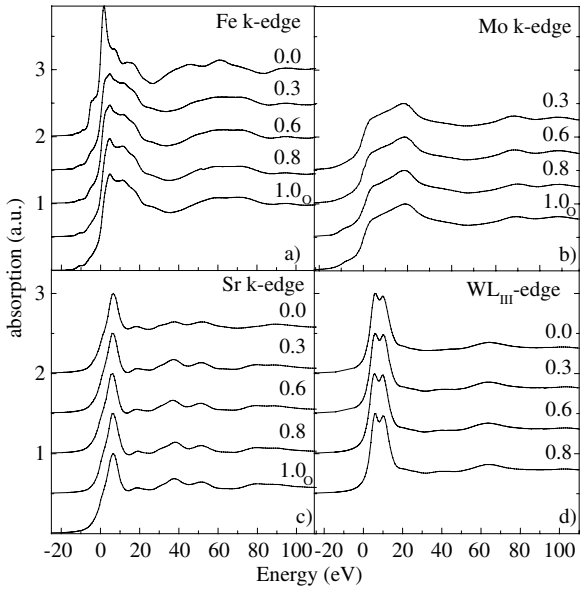

Fig. 1. The figure reports the raw absorption spectra for the Fe, Mo, W and Sr edges. As can be seen only the spectra of the Fe edge show appreciable variations as a function of the composition.

$(1-\alpha)\cdot\mu_{exp}(x=0)$ where α is a free parameter in the fitting procedure. We found an excellent agreement using this procedure. This result demonstrates without any doubt that the doped compounds are an inhomogeneous distribution of the end compounds. Moveover, this result is again incompatible with the valence transition scenario, because, in such scenario a shift in the edge position should be observed, and this will result in the failure of the fits.

Figure 2 reports the values of α and $1-\alpha$ obtained by fitting different concentrations samples. Keeping in mind the correspondence between the Mo^{5+} concentration x and the concentration of Fe^{3+} ions (together with that between W^{6+} and Fe^{2+} ions) from figure 2 we can deduce that the concentration of Fe^{3+} remains constant above x_c. This seems to be in contrast with the percolative transition scenario, because, in this case, the concentration of end compound necessary to best fit the doped compounds spectra should equal the nominal concentrations, i.e. the values of α and $1-\alpha$ should be on the straight lines reported in the figure.

3. Conclusions

Our work strongly excludes the valence transition scenario but even the other scenario proposed the percolation transition one,

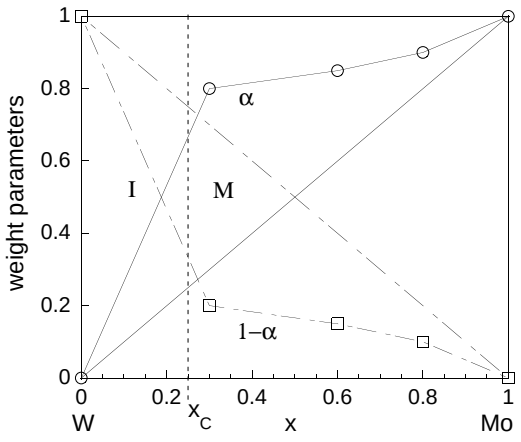

Fig. 2. Figure reports the values of the weight parameters α and $(1-\alpha)$. The straight lines shows the hypothetical behavior of the same parameters as expected by the percolative transition scenario.

does not seem to be totally compatible with our results. On the one hand, the goodness of the fits described above agrees with the idea that the doped compounds are an inhomogeneous distribution of the end compounds, as proposed by the percolative scenario. On the other hand, the values, resulting from the same fits, do not agree with the ones involved by the percolative scenario. To agree with this scenario something should balance the excess of Fe^{3+} (i.e. of α in the fits) in the metallic range above x_c introduced by the W^{6+} doping. So, more physics is required to accord our results with the percolative transition scenario. We suppose that the excess of 3+ valence Fe ions could arise from an unwanted oxygen deficiency present in our samples.

Abstract

We have investigated the local structure of Ag nano-clusters deposited as thin films on silicon substrate by using a total conversion electron yield XAFS (X-ray absorption fine structure) method at Ag K-edge. High quality spectra were obtained from samples with thicknesses of 1–10 nm. We have found that these clusters have an *fcc* structure and that the interatomic distance does not depend on the thickness. The coordination number, N, however, changes with the thickness of the film. The N value for the first nearest shell as a function of the film thickness is compared with the theoretically expected value by taking account of the surface effect. For thinner films, the observed N values are smaller than the expected values. We have observed a correlation between the N value and the electromagnetic field intensity at the surface evaluated from IR measurement. The morphology of Ag nano-cluster particles must affect the local electric field intensity at the surface.

1. Introduction

The research on interfaces between metals and semiconductors is playing a very important role in the recent developments of science and technology. Silver thin film deposited on silicon substrate is one of the typical examples for the metal/semiconductor system and has been studied by several techniques [1]. It is well known that a thin noble metal film exhibits anomalous light absorption in the visible and infrared regions, i.e. the local electric field is enhanced at the thin film surface. Such systems as Ag on Ge and Si have been extensively studied [2] and it is known that this phenomenon has not been explained well by classical theory and effective dielectric functions. In order to reveal this electric field enhancement, it is necessary to obtain structural information about Ag clusters deposited on the Si surface, since the local structure of Ag clusters might be related to this phenomenon. X-ray absorption fine structure (XAFS) has become apparent to be a technique for studying the local structure in a material from the short-range point of view and complementary to the conventional diffraction method based on long-range order.

The total conversion electron yield (TCEY) method used in the present work is a simpler and more convenient means than the fluorescence detection method for the XAFS study of thin films deposited on thick substrates. It detects mainly the Auger electrons emitted from the sample. Since the X-ray absorption coefficient is smaller for heavier atoms and heavy atoms with a hole in the core shell relax through fluorescence emission with higher probability than the Auger process, very thin films composed of heavy atom Ag could be expected to be a difficult system to study by the TCEY method [3, 4]. Our present experiments, however, indicate that the method was an appropriate choice for the present samples.

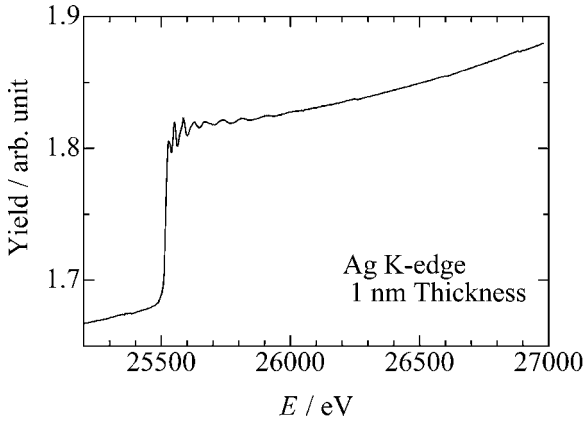

Fig. 1. X-ray absorption spectrum at Ag K-edge for 1 nm Ag film on Si wafer by a TCEY method.

2. Experimental

Silver films with various thickness, T, 1–10 nm in mass thickness were deposited on silicon wafer by electron-beam evaporation method in a vacuum chamber at 5×10^{-10} torr at room temperature. The thickness was evaluated by a quartz oscillator.

XAFS spectra at Ag K-edge (25.5 keV) were obtained at BL01B1 of SPring-8 by the TCEY technique. The sample wafers were stuck on a sample current electrode by conductive adhesive tape and helium gas was introduced into the CEY cell. The wafers were rotated within the sample plane in order to remove the diffraction peaks from Si substrate and Ag sample [5]. A Si(311) double-crystal monochromator was used. The incident X-ray was introduced to the sample surface at a grazing incidence angle of two degrees and the electric vector of X-ray was polarized in the plane of the sample. The photon flux and the stability of the beam at BL01B1 were high enough for measuring high energy XAFS employing the TCEY method for surface study. As an example, the Ag K-edge X-ray absorption spectrum for a sample with 1 nm Ag deposited on Si surface is shown in Fig. 1. The qualities of the XAFS data for very thin films by the TCEY technique were quite satisfactory.

The EXAFS analyses were performed by using XANADU [6] and FEFF 6.01 code [7]. For the curve-fitting procedure, the non-linear least square fitting method was applied to the experimental data as described in the following expression,

$$\chi(k) = \sum_j \frac{S_0^2 N_j}{k r_j^2} f_j(k, r_j) \exp(-2\sigma_j^2 k^2) \exp(-2r_j/\lambda(k)) \times \sin[2kr_j + \varphi_j(k)] \quad (1)$$

*e-mail: takaf@cc.hirosaki-u.ac.jp

where r, N and σ are the interatomic distance, the coordination number and the root mean square displacement, respectively, for each atomic pair. The phase shift $\varphi(k)$, the backscattering amplitude $f(k, r)$ and the electron mean free path $\lambda(k)$ are obtained from the FEFF6.01 calculation [4].

3. Results and Discussion

Figure 2 shows EXAFS $k\chi(k)$ spectra for several different Ag films in thickness. The amplitude of the oscillation function decreases as the Ag thickness decreases. Figure 3 shows the Fourier transforms of the EXAFS oscillations in the k-range of 3.3–13.3 Å^{-1}. Every spectrum has a strong peak at almost the same distance. It means that all these Ag films have an *fcc* structure and almost equal interatomic distances as Ag bulk. The intensity of |FT(r)|, however, changes with the thickness of the film. The intensity is closely related with the coordination number, N. The peak intensities for the nearest neighbor (2.8 Å) are almost the same for 10–7 nm samples, however, they become smaller when the films are thinner than 7 nm.

In order to obtain more detailed structural parameters, we applied the non-linear least square fitting (curve fitting) method to the first nearest peak. The results are summarized in Table I.

The coordination numbers, N, for the first nearest atoms are plotted in Fig. 4 as a function of Ag thickness, T. For the TCEY technique, it is not easy to determine the scale factor S_0^2 from the standard foil sample because of the self-absorption effect. Therefore we assume that the N value for a 10 nm Ag film is 12 because of the independence of the values for 7–10 nm samples on the thickness. The samples with smaller thickness are expected to have smaller N values than 12, which is caused by the surface effect. The expected values for the ideally flat *fcc* layer of Ag are calculated using the method proposed by Crozier *et al.* [8]. The calculated values are plotted in the same Figure by the X mark, in which the polarization of incident photons is not considered. For the case that the polarization is in the plane of the flat sample, the effective coordination number does not depend on the thickness and should be a constant of 12. The calculated N values clearly demonstrate the surface effect in the smaller thickness region (1–5 nm).

Table I. *Structural parameters obtained from EXAFS analyses.*

T/nm	r/nm	$\sigma/10^{-3}$ nm	N	L/nm	D/nm
1.0	0.288	9.7	8.9	1.8	5–10
2.0	0.287	9.7	9.9	2.1	—
3.0	0.289	9.7	10.8	3.6	10–20
5.0	0.288	9.5	11.4	8.8	30–40
7.0	0.288	9.9	12.1	—	—
8.0	0.288	9.7	12.0	—	—
10.0	0.288	9.7	12.0	—	—

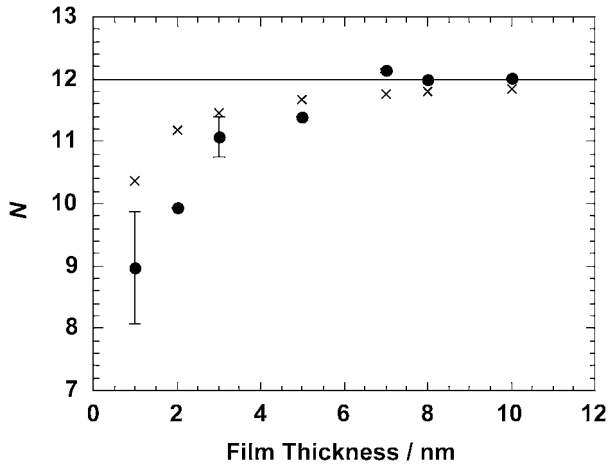

Fig. 4. Coordination number, N, of the first nearest neighbor as a function of film thickness (solid circle). Crosses indicate the values for ideally flat films [8].

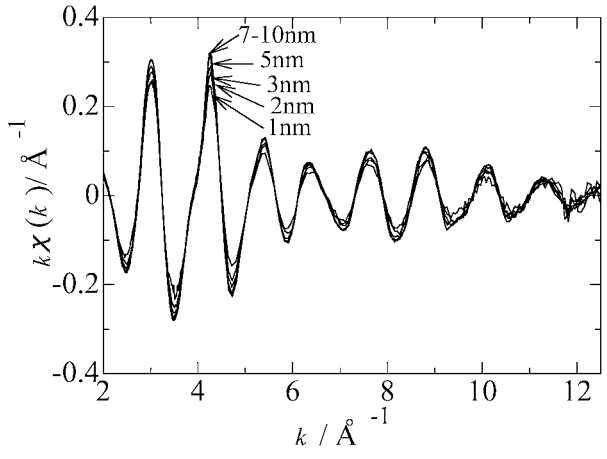

Fig. 2. $k\chi(k)$ spectra of Ag K-edge XAFS for 1–10 nm Ag films deposited on Si wafer.

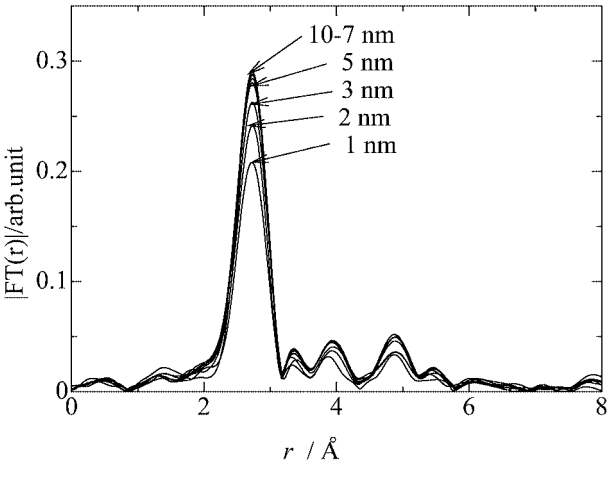

Fig. 3. Fourier transforms of Ag K-edge EXAFS for 1–10 nm Ag films deposited on Si wafer.

Very thin Ag films are known to form islands on the solid surface. Figure 5 shows FE-SEM (Field Emission Scanning Electron Microprobe) photographs for the present Ag films on Si wafer. Each scale bar in the photographs indicates 40 nm. The photographs display the island structure of Ag films and these islands are merged together gradually into larger islands with the increase of the thickness. Since the total area of superficies of island-shaped film is larger than that of the planar ones, we assume that this causes the decreased coordination numbers compared to the calculated N values for ideally flat samples. If the Ag clusters are assumed to form cubes with the edge length L, we can evaluate the L values from the effective coordination number [8], which are listed in Table I. In the table are also listed the average diameters, D, of the islands estimated from the FE-SEM images. While the L values obtained from the EXAFS should be compared with the D values from the FE-SEM for the ideal system, the L values are far smaller than the D values: For example, the 3 nm thickness sample gives 3.6 nm of L from the EXAFS but 10–20 nm of D from the FE-SEM images. For this discrepancy, we assume that

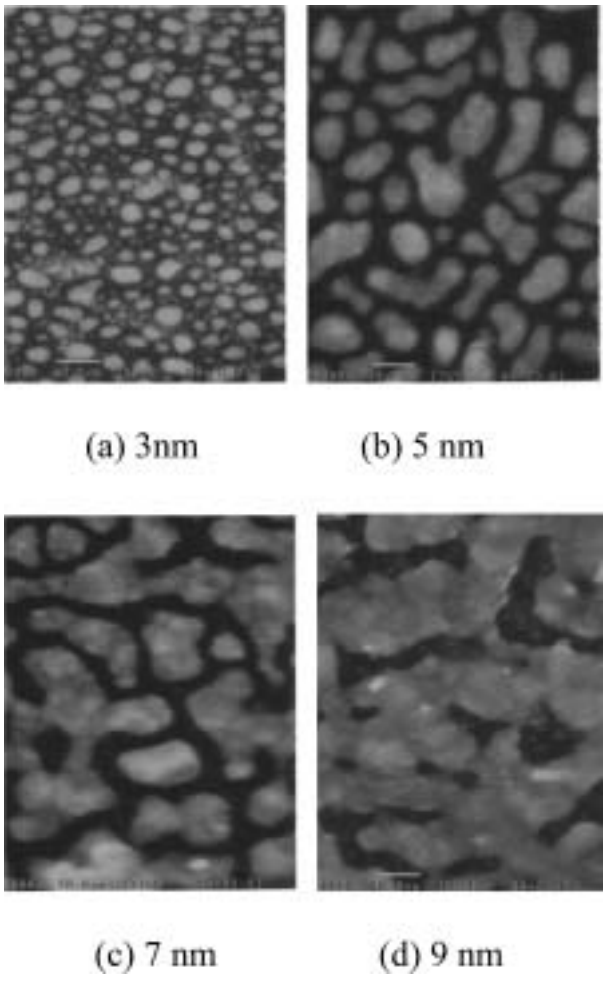

Fig. 5. FE-SEM (Filed Emission Scanning Electron Microprobe) photographs of Ag films on Si wafer with different films in thickness.

there exist vacancies or dislocations in the Ag clusters. As a result the net coordination number from the EXAFS is smaller than that expected from the real scale of clusters.

In the present EXAFS analysis, we have assumed that the mean free path (MFP) (or imaginary part of the self-energy) of the photoelectron does not depend on the size of Ag cluster. However, the MFP can possibly depend on the size of the system as pointed out by Zhao and Montano [9]. For more accurate analysis, such a higher order effect for X-ray absorption must be taken into account.

Finally we discuss the enhancement of the electric field at the surface as observed in the IR spectra. Figure 6 shows electromagnetic (EM) field intensities evaluated from the IR absorption coefficient for a $1025\,\mathrm{cm}^{-1}$ peak due to methanol molecules adsorbed on Ag film as a function of the film thickness [10]. The EM field intensity becomes the most intense at around 7 nm in film thickness. It is interesting to observe that the position of the peak in Fig. 6 coincides to the position where the N value levels off at 12 as shown in Fig. 4. In general, physical properties of Ag film or particle depend on the number of free electrons in Ag, which is considered to decrease if the coordination number of Ag atoms decreases. The electric field intensity changes as the number of free electrons: that is the smaller number of free electrons or the smaller coordination number of Ag, the weaker electric field intensities in the thickness range of film smaller than 7 nm. On the other hand, when Ag film covers the whole region of Si wafer, the interaction between electromagnetic wave and free

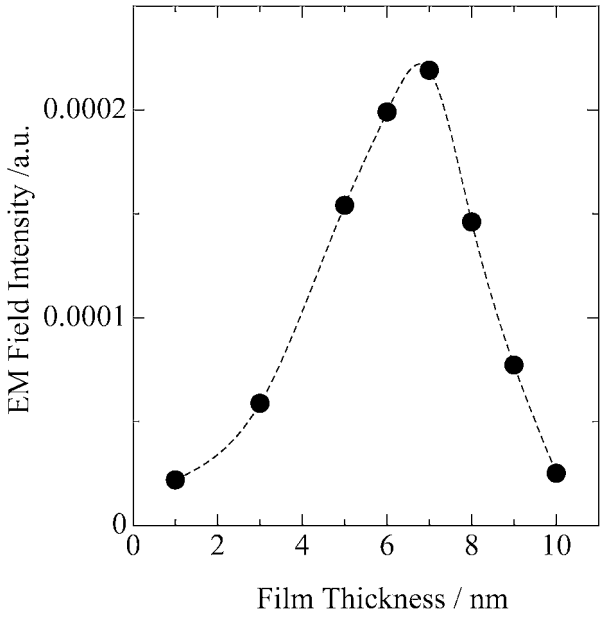

Fig. 6. Electromagnetic (EM) field intensity evaluated from the IR absorption coefficient for a $1025\,\mathrm{cm}^{-1}$ peak of methanol molecules adsorbed on Ag films as a function of the film thickness.

electron decreases. So the EM field intensity decreases again in the thickness range larger than 7 nm.

4. Conclusion

We have investigated the local structure of Ag nano-clusters deposited on silicon wafer surface. Total conversion electron yield method was applied to obtain Ag K-edge XAFS. It is found that these clusters take an *fcc* structure and have the same interatomic distances irrespective of the film thickness. The coordination number of the Ag atom, however, varies with the thickness of the film. Coordination number for the first nearest atoms as a function of the film thickness is compared with the theoretically expected values taking into account the surface effect. For thinner films, the observed coordination numbers are smaller than the expected values. We observed a good correlation between the dependencies of the coordination number and electromagnetic field intensity at the surface upon the film thickness. The local electric field at the surface must be related to the morphology of Ag nano-cluster particles on Si substrate.

Acknowledgement

The XAFS experiments were performed at SPring-8 under the approval of JASRI (Proposal No. 2001A0221-NX-np/BL01B1, No. 2001B0165-NX-np/BL01B1, and No. 2002B0544-NX-np/BL01B1).

Abstract

We have synthesized a new lead-based oxide $Pb(Pb_{1/3}Ta_{2/3})O_3$ of the $PbB'_nB''_mO_3$ perovskite-type, where B′-sites are occupied by Pb^{2+} ions. The perovskite-type structure with cell parameter $a = 4.14$ Å was determined by powder X-ray diffraction. We have studied the XAFS of the Pb L_{III}-edge in $Pb(Pb_{1/3}Ta_{2/3})O_3$. Our analysis confirms the presence of Pb^{2+} = B′-site cations having a distorted octahedral oxygen coordination with a nearest-neighbour Pb-O bond length of $R = 2.45$ Å. The Pb-O distances for Pb^{2+} = A-site cations was found to be equal to $R = 2.89$ Å, that is typical of perovskites. The presence of superstructural lines on the X-ray diffraction pattern as well as non-diffused permittivity maximum strongly support the presence of 1 : 2 long-range ordering in $Pb(Pb_{1/3}Ta_{2/3})O_3$.

1. Introduction

Lead-based ternary 1 : 2 perovskites of the $A(B'_{1/3}Ta_{2/3})O_3$ type are technologically important microwave ceramics for use as a dielectric resonators because these compounds have a high dielectric constant, low losses (high quality Q values) and a small temperature coefficient of resonant frequency. When disordered $A(B'_{1/3}Ta_{2/3})O_3$ (B′ and Ta ions arranged randomly on the B-site) has a cubic perovskite structure in which corner shared, BO_6 octahedra describe a cubooctahedral A-site interstice. Mg^{2+}, Ni^{2+}, Co^{2+}, Zn^{2+} and other ions with relatively small ionic radii can occupy the B′-site in the perovskite structure. The ordered compound in which B′ and Ta ions occupy alternate (111)-planes of the pseudocubic structure in a 1 : 2 ratio, adopts a trigonal symmetry [1–3]. We have synthesized a new lead-based oxide $Pb(Pb_{1/3}Ta_{2/3})O_3$, where B′-sites are occupied by Pb^{2+} ions with considerably larger ionic radius.

In this paper, crystal structure and local surroundings of the Pb atoms in novel $Pb(Pb_{1/3}Ta_{2/3})O_3$ perovskite by X-ray powder diffraction and EXAFS are investigated.

2. Experimental procedure

Polycrystalline sample of $PbPb_{1/3}Ta_{2/3}O_3$ was synthesized by solid state reaction. High purity powders of $PbCO_3$ and Ta_2O_5 were used. Sample was characterized by X-ray powder diffraction. X-ray powder diffraction data were measured at room temperature with a DRON-3M diffractometer using Cu $K\alpha_1$ radiation at 33 kV and 25 mA. The diffraction pattern was scanned in the 2Θ range of 10°–90° with a counting time 4 s step^{-1}. The XRD pattern was analyzed by the Rietveld method, using the PCW-2,3 refinement program [4]. The initial unit cell parameters and atomic coordinates for the Rietveld refinement were calculated. Rietveld refinement was performed using a pseudo-Voigt function to describe the reflection profile. The seven-order polynomial background, zero point shift, scale factor, unit cell parameters and peak shape parameters were varied in the fitting procedure. The overall thermal parameters and atomic coordinates were not refined.

The Pb L_3-edge XAFS spectra were measured in transmission at the EXAFS-spectrometer of Synchrotron Radiation Siberian center with the storage ring, operating at beam energy of 2 GeV and current of 80 mA. The X-ray beam was monochromatized using a Si (111) double crystal in the energy range of 12500–14100 eV (the Pb L_3-edge energy is 13040.6 eV). The intensities of both incident and transmitted X-ray beams were measured with ionization chambers filled with Ar gas. Samples were prepared as a sandwich between two layers of Maylar film.

Data analysis has been performed using UWXAFS code [5]. XAFS data analysis was carried out using standard procedure. The EXAFS functions $\chi(k)$ were obtained from the X-ray absorption spectra by subtracting a Victoreen curve background removal, normalization on the height of the edge and reduction of the absorption data $\mu(E)$ to the EXAFS functions $\chi(k)$, where k is the photoelectron wavevector. The threshold energy E_0 was defined as the maximum of the first derivative of the absorption edge.

Fourier transform of the k^2-weighted spectra has been performed over the range $3.0 < k < 13$ Å^{-1}. The fitting to the experimental spectra has been performed using theoretical spectra simulated by means of FEFF7 [6]. The initial parameters refined in fit were obtained from crystallographic data of $BaPb_{1/3}Ta_{2/3}O_3$ [7].

3. Results and discussion

Figure 1 shows the powder X-ray diffraction pattern and refinement of $PbPb_{1/3}Ta_{2/3}O_3$. XRD analysis using the Rietveld method was carried out and it was found that this lead-based

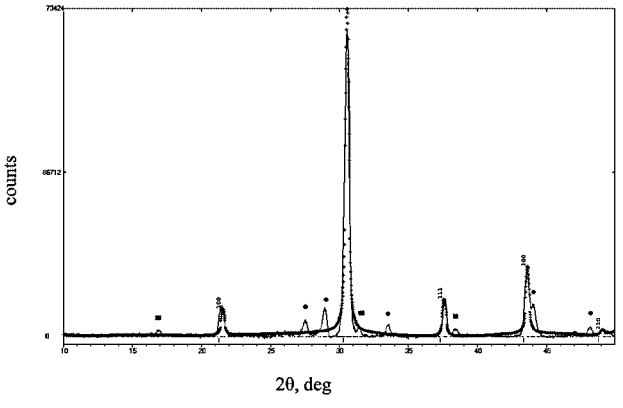

Fig. 1. Powder X-ray diffraction pattern of $PbPb_{1/3}Ta_{2/3}O_3$. The experimental data are represented by solid line, while the calculated pattern is shown by crosses. Peaks marked by ■ correspond to the superstructure Bragg lines; peaks marked by ● correspond to the $Pb_3Nb_4O_{13}$ pyrochlore phase.

[1] vlasenko@ip.rsu.ru

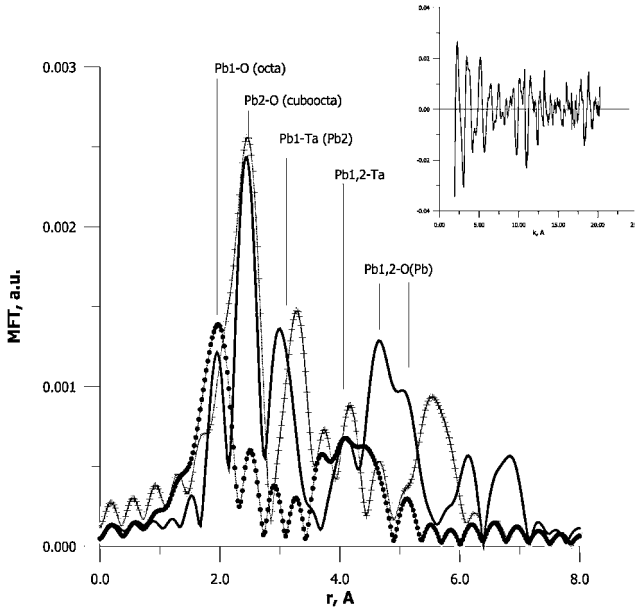

Fig. 2. Fourier Transforms for $\chi(k)$ Pb L_{III} EXAFS spectra of $PbPb_{1/3}Ta_{2/3}O_3$ (solid line), the models $PbTaO_3$ (open circles) and $PbPb_{1/3}Ta_{2/3}O_3$ (filled circles). The inset shows the experimental $\chi(k)$ Pb L_{III} EXAFS.

oxide $Pb(Pb_{1/3}Ta_{2/3})O_3$ has a cubic perovskite structure with the Pm-3 m (221) space group. The lattice parameter was found to be $a = 4.14$ Å. In the XRD pattern some weak extra peaks that do not correspond to the $Pb(Pb_{1/3}Ta_{2/3})O_3$ are observed. These reflections can be indexed to lead tantalate compound with the pyrochlore structure similar to $Pb_3Nb_4O_{13}$ [8].

According to Fig. 1, a weak superstructure reflections, that originate from the 1 : 2 order are visible in XRD pattern of the $Pb(Pb_{1/3}Ta_{2/3})O_3$. This is likely to be due to the fact that the Pb^{2+} and Ta^{5+} cations are distributed on individual (111) planes of the perovskite subcell with alternating (Pb, Ta, Ta) layers. This assumption is strongly supported by the non-diffused permittivity maximum observed at about 220 °C.

Fourier transform of k^2-weighted $\chi(k)$ for the $PbPb_{1/3}Ta_{2/3}O_3$ is presented at Fig. 2. The inset illustrates the experimental PbL_{III}-edge EXAFS. The Fourier transforms of models calculated for $PbYb_{1/2}Ta_{1/2}O_3$ [9] (where Yb was replaced by Pb) and $BaPb_{1/3}Ta_{2/3}O_3$ [7] (where Ba was replaced by Pb) are shown together with experimental Fourier transform. As seen, the Fourier transform of the experimental spectrum exhibits two well-resolved peaks at about $r = 1.98$ Å and $r = 2.52$ Å corresponding to the first and the second coordination shells around the Pb^{2+} ions. According to our models the first peak originates from 6 oxygen atoms in octahedral positions, while the second one corresponds to 12 oxygen atoms in cubooctahedral positions. The fitting obtained interatomic distances are $R = 2.45$ Å and $R = 2.89$ Å for Pb^{I}-O and Pb^{II}-O bonds correspondingly. Thus, the results obtained clear show that the Pb^{2+} ions occupy 1/3 octahedral positions in the $Pb(Pb_{1/3}Ta_{2/3})O_3$ perovskite.

4. Conclusion

A new lead-based oxide $Pb(Pb_{1/3}Ta_{2/3})O_3$ has a perovskite-type structure with Pm-3m space group and a cell parameter $a = 4.14$ Å. Some evidence of the 1 : 2 long-range ordering for the perovskite cell is found. The Pb^{2+} ions occupy 1/3 octahedral positions in the $Pb(Pb_{1/3}Ta_{2/3})O_3$ perovskite.

Abstract

Hydrated thin films of nickel vanadium oxide ($Ni_{1-x}V_xO_y$), made by reactive DC magnetron sputtering, were studied by X-ray absorption spectroscopy at the Ni and V K-edges using synchrotron radiation. The XANES signals were analysed within the full-multiple-scattering formalism, whereas EXAFS data were modelled within the multi-shell multiple-scattering approach. We found that transparent films exhibit a nanocrystalline NiO-type structure with homogeneous distribution of V ions substituting Ni ions. Exposure of the films to ozone resulted in dark brown coloration associated with an appearance of Ni^{3+} ions and accompanied by a modification of the local electronic and atomic structures of the V and Ni ions. The largest changes occurred in the environment of the V ions, which presumably change their valence state from V^{4+} to V^{5+} and displace into off-centre positions by ∼0.4 Å.

1. Introduction

Electrochromic (EC) materials are able to reversibly alter their optical properties upon charge insertion-extraction caused by the application of an external voltage [1]. These materials can be used for a variety of applications, such as in architectural "smart widows capable of changing their transmittance thereby providing improved visual and thermal comfort for the occupants in conjunction with energy efficiency for the building. An EC device is characterised by a number of features, such as optical modulation, physical size, durability, etc.

Thin films of hydrated nickel oxide and nickel based oxides are of much interest. One reason for this is their ability for coloration upon ozone exposure [2], which allows charge balancing in order to make the films ready for facile device assembly consistent with large-scale production. Recent reviews of EC devices are found in [3].

The present paper presents X-ray absorption spectroscopy data of $Ni_{1-x}V_xO_y$ thin films at the Ni and V K-edges. The emphasis is on changes of the local atomic and electronic structures of Ni and V ions in transparent and ozone-coloured states of the films.

2. Experimental details and data analysis

Transparent hydrated $Ni_{1-x}V_xO_y$ thin films were deposited onto quartz and Kapton foil substrates by reactive DC magnetron sputtering from a non-magnetic $Ni_{93}V_7$ (wt %) target with a diameter of 5 cm. A base pressure of $\sim 4 \cdot 10^{-5}$ mTorr was reached in the deposition unit, and sputtering was carried in a mixture of $Ar/O_2/H_2$ (99.998% pure) at 35 mTorr and 200 W. The gas flows ratios were 50/2/4. Coloured films were produced by exposure during 6 minutes to ozone using a UV lamp [2].

Optical measurements were carried out on a Perkin-Elmer double-beam spectrophotometer operating at 300 to 2500 nm in wavelength.

X-ray absorption spectra of transparent and coloured thin films, and of reference compounds (crystalline *c*-NiO and *c*-V_2O_5), were recorded at the Ni and V K-edges using synchrotron radiation from the LURE DCI storage ring. A standard transmission setup at the D21 (XAS-2) beam-line, with a Si(311) double-crystal monochromator and two ion chambers containing N_2 gas, was used. All experiments were done at room temperature with an energy resolution of 1 to 2 eV.

The X-ray absorption spectra were analysed, following standard procedures, by the EDA software package [4, 5]. The EXAFS part of the spectra was singled out by the Fourier filtering procedure and best-fitted within the multi-shell Gaussian/cumulant models using the theoretical amplitudes and phase shift functions, calculated by the FEFF8 code [6], for the two reference compounds. The E_0 position, defining the zero-photoelectron wave-number ($k = 0$), was set to provide the best match of the experimental and calculated EXAFS signals for the reference compounds. The XANES signals were analysed qualitatively by comparison of experimental spectra with the ones calculated by the FEFF8 code [6] within the full-multiple-scattering (FMS) approach. In all calculations, the complex Hedin-Lundqvist exchange-correlation potential [7] was used to account for the inelastic losses of the photoelectron, and the cluster potential was calculated self-consistently.

3. Results and discussion

Figure 1 shows the optical response of a ∼650-nm-thick $Ni_{1-x}V_xO_y$ thin film upon ozone exposure. The spectral absorptance $A(\lambda)$ was calculated from measured transmittance $T(\lambda)$ and reflectance $R(\lambda)$ as $A(\lambda) = 1 - T(\lambda) - R(\lambda)$. A huge modulation of the optical properties is observed within the solar range; it corresponds to a change of the visible colour from transparent to dark brown.

X-ray absorption spectra, measured at the Ni and V K-edges, allowed us to follow the modifications in the local electronic and atomic structures as the films were coloured in ozone.

Experimental XANES signals are shown in Fig. 2(a). At the Ni K-edge, a difference between the *c*-NiO reference and a $Ni_{1-x}V_xO_y$ film is present in the pre-edge peak intensity and in the fine structure located above the edge. The pre-edge peak is associated with a transition from the 1s(Ni) state to the 3d(Ni) states mixed with the 2p(O) states. The pre-edge intensity is smaller in the films than in *c*-NiO, as was also observed previously in pure nanocrystalline NiO films [8]. This effect was interpreted

*Esteban.Avendano@angstrom.uu.se

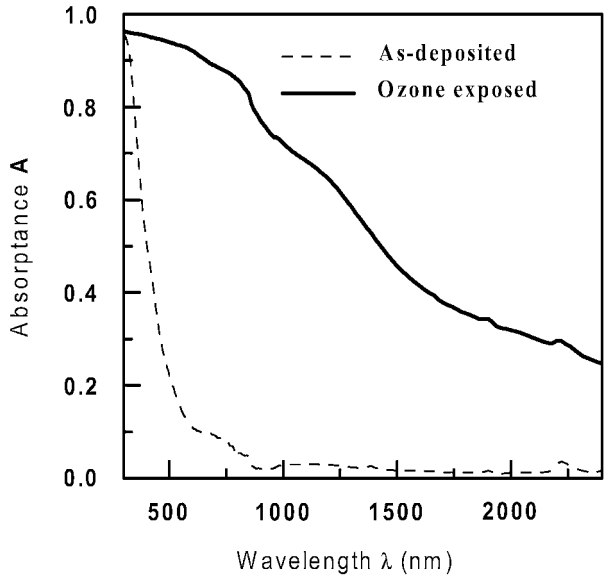

Fig. 1. Spectral absorptance within the solar range of $Ni_{1-x}V_xO_y$ thin films in the as-deposited (transparent) and ozone-exposed (coloured) states.

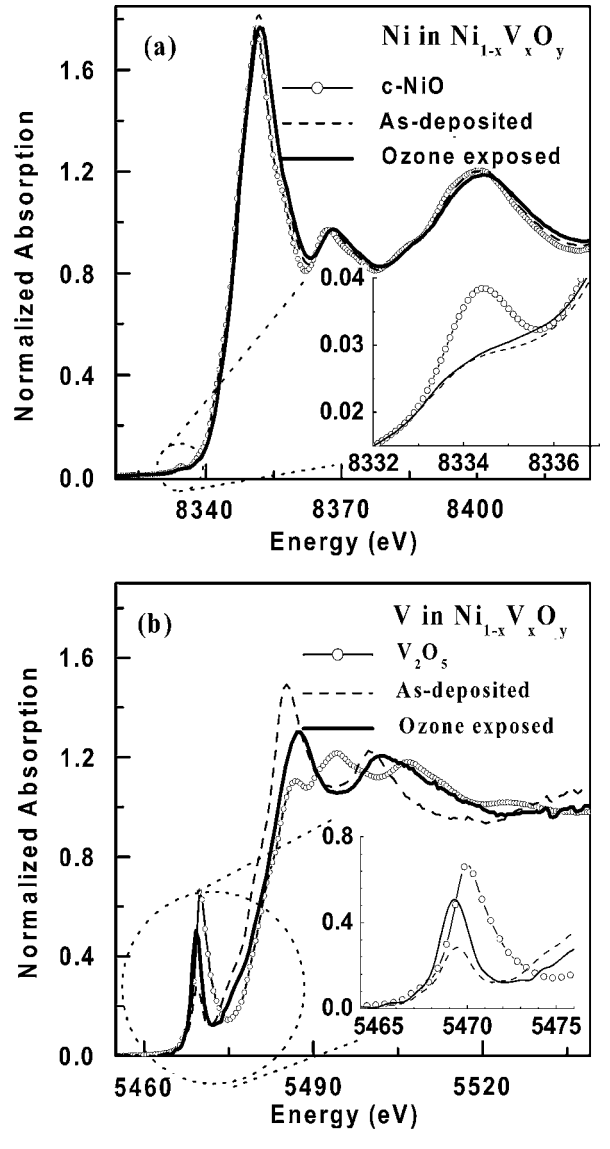

Fig. 2. Experimental XANES signals for the Ni (a) and V (b) K-edges in as-deposited (transparent) and ozone-exposed (coloured) $Ni_{1-x}V_xO_y$ thin films. XANES data for the reference compounds *c*-NiO and *c*-V_2O_5 are shown in parts (a) and (b), respectively.

within the Zaanen-Sawatzky-Allen model [9] as being due to an increase of the oxygen-nickel charge transfer energy accompanied by a reduction of the amount of ground state configurations with holes in the 2p(O) states. Thus a decrease of the pre-edge in the films can be associated with the fact that the Ni-O bonding becomes less covalent. It is noted that no significant change of the pre-edge peak occurs upon ozone exposure.

The V K-edge in the thin films is compared with data for *c*-V_2O_5 in Fig. 2(b). The pre-edge peak is related to the transition $1s(V) \rightarrow 3d(V) + 2p(O)$. A comparison of two reference compounds, i.e. *c*-NiO and *c*-V_2O_5, shows that the intensity of the pre-edge peak is much higher in vanadium oxide because the 3d(V) states are more strongly mixed with 2p(O) states due to shorter V-O bonds and lower local symmetry at the V sites. The pre-edge intensity is relatively small in a transparent film but increases strongly upon coloration. Such behaviour can be associated with the change of valence states from V^{4+} to V^{5+} [10]. Our preliminary FMS calculations suggest that this process is accompanied by an increase of the local distortion, responsible for a modification of fine structure located above the V edge.

Figure 3 shows Fourier transforms (FTs) of the EXAFS signals for the Ni and V K-edges. A comparison of the FT signals for the films and for *c*-NiO allows to conclude that the films have a nanocrystalline structure; specifically, the peak amplitudes decrease more for the outer shell due to the

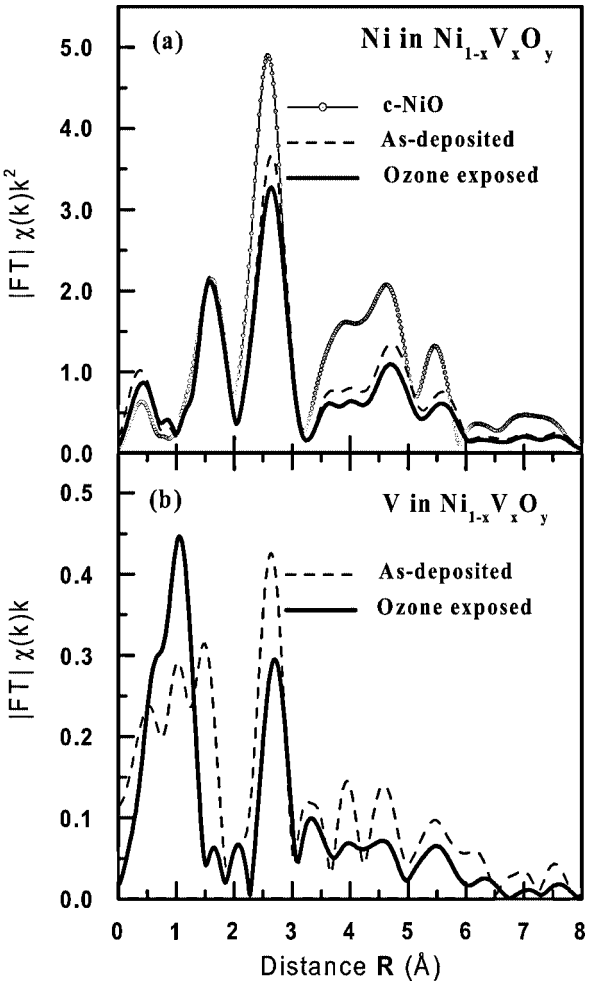

Fig. 3. Fourier transform (FT) moduli of EXAFS signals at the Ni (a) and V (b) K-edges in *c*-NiO (part a) and $Ni_{1-x}V_xO_y$ thin films in the as-deposited (transparent) and ozone-exposed (coloured) states.

size effect [8, 11]. The first peak at 1–1.5 Å corresponds to the first coordination shell of Ni/V ions, composed of six oxygen atoms. The second peak at about 2.5–2.7 Å is due to three contributions: (*i*) nickel (Ni_2) atoms in the second shell; (*ii*) oxygen (O_3) atoms in the third shell; (*iii*) two double-scattering signals, generated within the 90°-triangular paths as $M_0 \rightarrow O_1 \rightarrow O_1 \rightarrow M_0$ and $M_0 \rightarrow O_1 \rightarrow Ni_2 \rightarrow M_0$ where M_0 is the Ni_0 or V_0 central/absorbing atom. Our multi-shell fitting procedure of the Ni K-edge EXAFS signals suggests that, on average, the film structure resembles that of *c*-NiO. However, some relaxation of the first coordination shell of the Ni ions, comprising six oxygen atoms, occurs in the films and leads to a decrease of the mean Ni-O distance by ∼0.02 to 0.04 Å. At the same time, the second shell Ni-Ni distance increases by ∼0.01 to 0.02 Å. The difference between the two films is mainly related to some increase of the disorder in the coloured film, which is probed by the Debye-Waller factor and resulted in a relative decrease of the peaks for the outer shells in the FT. The nanocrystallite size was estimated roughly by an approach proposed before [8]; it is based on the model of Ref. [11] and gave a nanocrystal diameter of ∼10 Å.

The analysis of the V K-edge EXAFS signals suggests that V ions substitute Ni ions in the NiO-type structure and are distributed without any evidence for clustering. This conclusion is derived from the comparison of the experimental V K-edge EXAFS signals with the theoretical ones, calculated by the FEFF8 code for the V ion(s) placed at the Ni ions sites in NiO structure. Our best-fit modelling suggests no presence of vanadium ions in the second coordination shell of vanadium, but indicates clearly the vanadium first shell modification upon coloration. In transparent films, V ions are located at the centre of oxygen octahedra, whereas they shift to off-centre positions upon coloration. The displacement is ∼0.4 Å in the [100] direction towards the nearest oxygen atom. Thus, V ions introduce a significant degree of disorder into the NiO-type structure of coloured thin films.

4. Conclusions

X-ray absorption spectroscopy at the Ni and V K-edges allowed us to reconstruct the local electronic and atomic structures of nickel vanadium oxide thin films in transparent and coloured states. We found that, while the main contribution to the optical properties of the films ensues from the Ni sublattice, the V ions are strongly affected by an ozone treatment.

Abstract

Visible light sensitive zeolite photocatalysts have been prepared by metal ion-implantation of Ti-containing mesoporous molecular sieves with V ions (V/Ti-HMS) which can operate under visible light irradiation ($\lambda > 450$ nm). The metal ion-implantation with V ions was effective to shift the absorption band of Ti-containing molecular sieves to longer wavelengths. This V/Ti-HMS performed the photocatalytic reactions for the NO decomposition under visible light irradiation, while no reaction proceeded on the original Ti-HMS. XAFS analysis indicated that implanted V-oxide moieties existed having tetrahedral coordination and interacted with the tetrahedrally coordinated titanium oxide moieties. These XAFS results as well as the analysis with UV-VIS absorption measurements indicate that the charge transfer excited state of the tetrahedrally coordinated titanium oxide moieties interacting with the tetrahedrally coordinated vanadium oxide moieties plays a significant role in the photocatalytic reaction under visible light irradiation.

1. Introduction

Zeolites involving transition metal ions within the zeolite framework have opened new possibilities in many research areas not only for catalysis but also for various photochemical processes [1–6]. Especially the titanium oxide species prepared within the zeolite framework have revealed a unique local structure as well as a high selectivity in the oxidation of organic substances with hydrogen peroxide [2, 3]. Although TiO_2 has octahedral coordination, titanium oxide having tetrahedral coordination can be prepared in silica matrix such as zeolites and mesoporous molecular sieves. Ti-zeolites with tetrahedrally coordinated titanium oxide moieties showing unique reactivities for various photocatalytic reactions under UV-irradiation (220–260 nm) [5–10] are good candidates as efficient and selective photocatalysts. Although these tetrahedrally coordinated Ti-oxide moieties can exhibit the unique photocatalytic reactivity, they can only adsorb and utilize UV light at around 220–260 nm to form the charge transfer excited state as active species. It is also vital to develop Ti-zeolites which can operate efficiently under visible light irradiation. Recently it has been successfully made the application of metal ion-implantation using accelerated metal ions to design unique TiO_2 photocatalyst realizing a breakthrough in the development of the efficient photocatalytic system and the utilization of solar light energy [11–13]. Metal ions are the charged atoms whose kinetic energies can be controlled by acceleration of the metal ions under a controlled electronic field. The application of metal ion-implantation [11] to modify the Ti-zeolites is very interesting. In this study, it has been found that metal ion-implantation with V ions has been applied on Ti-containing mesoporous molecular sieves to design photocatalysts which can operate under visible light irradiation.

2. Experimental

2.1. *Catalysts*

Ti-containing mesoporous molecular sieves (Ti-HMS) (Si/Ti = 50) were synthesized using tetraethylorthosilicate and titanium-isopropoxide as the starting materials and dodecylamine as a template [14–16]. The gelation of the material mixtures were carried out at room temperature for 24 h. The product was collected by centrifugal filtration, washed with distilled water, and dried in air at 353 K. To remove the occluded organic molecules, the samples were heated under a flow of dry air at 773 K for 5 h. The surface area of Ti-HMS is about 700 m^2/g.

This Ti-HMS photocatalyst (100 mg) was pressed into a wafer of 13 mm diameter and 1 mm thickness. V ions implanted Ti-HMS (V/Ti-HMS) was prepared by the metal ion-implantation method. The implantation of V^+ ions to Ti-HMS was carried out using an ion-implanter consisting of a metal ion source, mass analyzer, and high voltage ion accelerator (150 keV) [11–13]. In this method, the metal ions are accelerated in the electronic field and injected to the sample target (Ti-HMS wafer) as an ion beam. The ion-implanted samples were heated under a flow of dry air at 773 K for 5 h.

2.2. *Photocatalytic reaction*

Prior to spectroscopic measurements and photocatalytic reactions, the powdered catalysts were degassed at 723 K for 2 h, heated in O_2 at the same temperature for 2 h and then finally evacuated at 473 K for 2 h to 10^{-6} Torr. The photocatalytic reactions of NO molecules were carried out with the catalysts (100 mg of the catalyst involving zeolite) in a quartz cell with a flat bottom (90 ml) connected to a conventional vacuum system (10^{-6} Torr range) [7]. The light irradiation of the catalysts in the presence of NO (17 μmol) was carried out under visible light ($\lambda > 390$, 420 nm) using a 75 W high-pressure Hg lamp at 275 K and color filters. The reaction products were analyzed by gas chromatography. The photocatalytic oxidation of propene (16 μmol) with O_2 (32 μmol) was carried out with the catalysts (50 mg) under UV light irradiation ($\lambda > 250$ nm, $\lambda > 340$ nm) at 295 K. The products collected in the gas phase and after heating of catalysts at 573 K were analyzed by gas chromatography.

2.3. *Characterization*

The diffuse reflectance absorption spectra were recorded with a Shimadzu UV-2200A spectrometer at 295 K. The XAFS spectra (XANES and EXAFS) were measured at the BL-9A facility [17] of the Photon Factory at the National Laboratory for High-Energy Physics, Tsukuba. A Si(111) double crystal was used to monochromatize X-rays from the 2.5 GeV electron storage ring. The Ti K-edge absorption spectra were recorded

in the fluorescence mode at 295 K. In a typical experiment, 50 mg of the sample pressed in to a disc was loaded into the *in situ* cell having Kapton windows. The normalized spectra were obtained by a procedure described in previous literature [18] and Fourier transformation was performed on k^3-weighted EXAFS oscillations in the range of 3–10 $Å^{-1}$. The preedge peaks in the XANES regions were normalized for atomic absorption, based on the average absorption coefficient of the spectral region from 5050–5200 eV [19]. Curve-fitting of the EXAFS data was carried out by employing an iterative nonlinear least-squares method and the empirical backscattering parameter sets extracted from the shell features of reference compounds.

3. Results and discussion

The results of the XRD analysis indicate that Ti-HMS has the structure of HMS mesoporous molecular sieves having pores larger than 20 Å and the Ti-oxide moieties are highly dispersed in the framework, while no other phases are formed [14, 15].

Figure 1 shows Ti K-edge XANES spectra of the Ti-HMS. The XANES spectra of the Ti containing compounds at the Ti K-edge show several well-defined preedge peaks that are related to the local structures surrounding the Ti atom. These relative intensities of the preedge peaks provide useful information on the coordination number surrounding the Ti atom [4, 19]. As shown in Fig. 1, Ti-HMS exhibits an intense single preedge peak, indicating that the titanium oxide species in the Ti-HMS has a tetrahedral coordination. Figure 1 also shows Fourier transforms of Ti K-edge EXAFS of Ti-HMS. The data are given without corrections for phase shifts. Ti-HMS exhibits a strong peak at around 1.6 Å (uncorrected for the phase shift) which can be assigned to the neighboring oxygen atoms (a Ti-O bond), indicating the presence of a highly dispersed titanium oxide species on Ti-HMS. From the results obtained by the curve-fitting analysis of the EXAFS spectra, it was found that the Ti-HMS consist of tetrahedrally coordinated titanium ions with an atomic distance of 1.83 Å.

The metal ion-implantation with V ions on Ti-HMS was carried out at 150 eV and the implanted sample was calcined in O_2 at 723 K after ion-implantation. Figure 2 shows diffuse reflectance UV-Vis absorption spectra of the original Ti-HMS and the V/Ti-HMS with various amounts of implanted V ions. Ti-HMS exhibited absorption bands in the wavelength region of 220–260 nm, shifting into the shorter wavelength region as compared to the bulk TiO_2. This absorption band is attributed to the LMCT (ligand-to-metal charge transfer) band of the highly dispersed

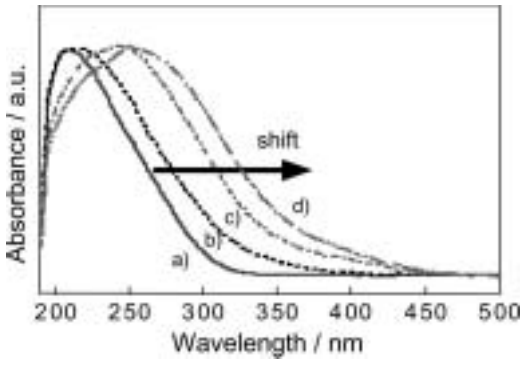

Fig. 2. Diffuse reflectance UV-Vis absorption spectra of the Ti-HMS (a) and V/Ti-HMS (b–d) with various amounts of V ion-implanted. Implanted V ions: (b) 0.66, (c) 1.3, (d) 2.0 (μmol/g-cat).

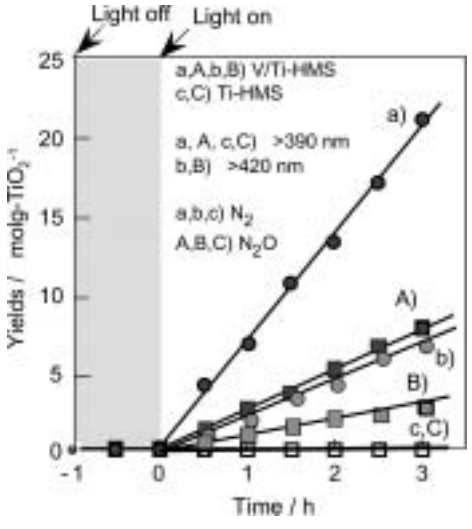

Fig. 3. Reaction time profiles of the photocatalytic decomposition of NO on Ti-HMS and V/Ti-HMS (V: 2.0 μmol/g-cat) under visible light irradiation ($\lambda > 390$ nm, 420 nm) .

titanium oxide species having a tetrahedral coordination [8, 9]. As shown in Fig. 2, the absorption band of V/Ti-HMS is found to shift to the longer wavelength region, the extent depending on the amount of V ions implanted. These V/Ti-HMS can absorb light at the visible light region (~450 nm). These results indicate that the metal ion-implantation is effective to modify the Ti-HMS to absorb the visible light and exhibit the photocatalytic reaction under visible light irradiation.

These V/Ti-HMS showed the photocatalytic reactivity under visible light irradiation ($\lambda > 420$ nm). As shown in Figure 3, visible light irradiation of these V/Ti-HMS in the presence of NO led the selective decomposition of NO into N_2 and O_2 and the yield of the photo-formed N_2 increased linearly with the irradiation time. On the other hand, the NO decomposition did not proceed on the un-implanted original Ti-HMS under visible light irradiation. These results clearly show that V ions implanted into the framework structures of Ti-containing zeolite does work to modify the electronic properties of the tetrahedrally coordinated titanium oxide moieties.

Table I shows the results of the photocatalytic oxidation of propene with O_2 under irradiation of light with various wavelengths ($\lambda > 250$ nm, $\lambda > 340$ nm). Under light irradiation with longer wavelengths ($\lambda > 340$ nm), the photo-epoxidation of propene with O_2 to form propene oxide proceeded on the

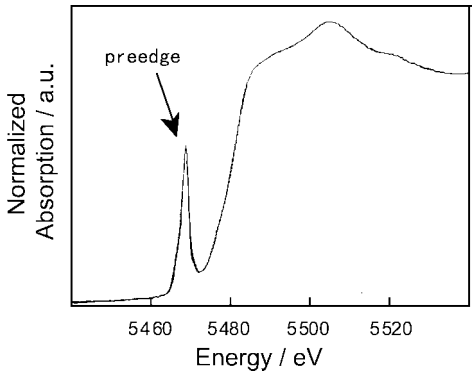

Fig. 4. V K-edge XANES spectrum of V/Ti-HMS (V: 1.3 μmol/g-cat).

ion-implanted V/-HMS, while no reaction occurred on the original un-implanted Ti-HMS.

Figure 4 shows V K-edge XANES spectra of the V/Ti-HMS. V/Ti-HMS exhibits an intense single preedge peak. The characteristic feature of both XANES spectra is the appearance of a preedge peak due to the so-called 1s-3d transition which is mainly caused by the mixing of the 2p orbitals of the oxygen molecules with the 3dp orbitals of the vanadium atoms. This p-d mixing suggests the presence of a terminal monoxo-vanadyl group (V = O). It was also found that the shape of the XANES spectrum of V/Ti-HMS is quite similar to that of the VO(O-i-$C_3H_7)_3$ complex, indicating that V/Ti-HMS consists of vanadium oxide moieties having a tetrahedral coordination in C_{3v} symmetry [20]. Figure 5 shows Fourier transforms of V K-edge EXAFS of V/Ti-HMS and V_2O_5 as reference and the data are given without corrections for phase shifts. V/Ti-HMS exhibit a peak at around 1.4 Å (uncorrected for the phase shift) which can be assigned to the neighboring oxygen atoms (V-O bonds), indicating the that vanadium ions are highly dispersed in the catalyst. On the other hand, the reference V_2O_5 exhibits two intense peaks at around 1.5 and 2.8 Å ascribed to the V-O bond and V-O-V linkage, respectively. For V/Ti-HMS, it was found that the second peak shifts to a shorter distance and its intensity is much lower than that of the reference V_2O_5. These results indicate that the next-neighbors of the V environment is not the same V-based ones but is the Ti-based tetrahedra forming V-O-Ti linkages.

The analysis using XAFS measurements indicate that the implanted V ions are highly dispersed in the tetrahedrally coordination and exist in the next neighbor position of tetrahedrally coordinated titanium oxide moieties having the formation of the Ti-O-V linkage which leads to the modification of the electronic properties of tetrahedrally coordinated titanium oxide moieties. This direct interaction between the implanted V ions and the tetrahedrally coordinated titanium oxide moieties can realize the absorption of visible light and leads to selective photocatalytic NO decomposition into N_2 and O_2 even under visible light irradiation. These results indicate that the metal ion implantation is also useful to create efficient and selective Ti-containing zeolite catalysts which can operate even under visible light irradiation.

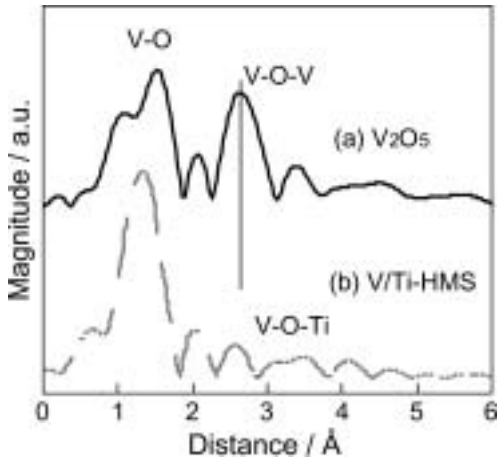

Fig. 5. Fourier transforms of V K-edge EXAFS of (a) V_2O_5 (reference) and (b) V/Ti-HMS (V: 1.3 μmol/g-cat).

4. Conclusions

The metal ion-implantation with V ions was effective to shift the absorption band of Ti-containing mesoporous molecular sieves to longer wavelengths. The ion-implanted V/Ti-HMS were found to exhibit photocatalytic decomposition of NO under visible light irradiation with longer wavelength ($\lambda >$ 450 nm). The direct interaction between the implanted V ions with a tetrahedral coordination and the tetrahedrally coordinated titanium oxide moieties can realize the absorption of visible light and create efficient photocatalytic reactivity even under visible light irradiation.

Abstract

The electronic and geometrical structure of A_2FeMoO_6 (A = Ca, Sr, Ba, $Ba_{1/2}Sr_{1/2}$) compounds has been investigated by means of X-ray absorption spectroscopy at the iron and molybdenum K-edges. The Mo-O distances extracted from the Mo K-edge EXAFS spectra are almost identical for all compounds while XANES spectra show small differences depending on the divalent metal. The XAS spectra at the Fe K-edge showed significant differences instead. Our analysis suggests an influence of the divalent A-metal in the electronic state of iron and molybdenum. Both the chemical shift at the iron K-edge and the interatomic Fe-O distances, closely correspond to Fe^{3+} for Sr_2FeMoO_6 and Ca_2FeMoO_6 while a mixed valence state (between +2 and +3) is deduced for the Ba sample. Accordingly, the Mo valency is higher for the barium sample.

1. Introduction

Recently, the emerging field of magnetoelectronics has spurred up interest in studying some ordered double perovskites $A_2BB'O_6$ (A = Ca, Sr, Ba; BB' = FeMo, FeRe, CrRe, etc.) that show half metallicity [1]. The perovskite B sites are occupied alternatively by different B and B' cations in these compounds. Among them, A_2FeMoO_6 are known to be ferrimagnetic with critical temperature (T_C) ranging between 330 and 420 K [2]. The lowest T_C corresponds to the Ba_2FeMoO_6 compound that shows the largest crystallographic cell with cubic symmetry [3]. The replacing of Ba with smaller cations leads to a diminution of the unit cell size together with a lowering of the crystal symmetry. In this way, Sr_2FeMoO_6 has the highest T_C and a tetragonal cell [3, 4] while Ca_2FeMoO_6 crystallises in a monoclinic cell [3, 5]. All of the samples have metallic behaviour in the whole temperature range studied. In addition, the T_C of Ca_2FeMoO_6 is slightly lower than that for Sr_2FeMoO_6, showing a competition effect between cell volume and structural distortion.

Previous band calculations proposed the antiferromagnetic coupling between localised Fe^{3+} and the single itinerant downspin electron provided by the Mo^{5+} [1]. However, later studies suggest that the physical properties strongly depends on the 2p (O) – 4d (Mo) hybridization [6]. Therefore, the knowledge of the oxidation states is very important to gain insight into both the conduction mechanism and the magnetic interactions. Previous attempts to ascertain the atomic electronic state of Mo and Fe gave rise to serious controversies. In this way while some X-ray magnetic circular dichroism data did not show any observable spin magnetic moment on Mo in the Sr_2FeMoO_6 [7], other authors report a measurable moment of $-0.32\,\mu_B$ confirming the ferrimagnetic ordering [8]. The Fe valency was also the subject of contradictory results. X-ray absorption spectroscopy data of Sr_2FeMoO_6 at the Fe L-edge conclude that iron is either in +3 state [7] or in an intermediate valence Fe^{2+}/Fe^{3+} [8, 9]. Furthermore, Mössbauer experiments were also interpreted in terms of Fe^{3+} [10] or in terms of Fe^{2+}/Fe^{3+} [11]. Accordingly, the oxidation state for Fe and Mo in these compounds is not well understood so far.

We here report X-ray spectroscopy data of both K-edges, Fe and Mo, in order to gain insight into the local electronic structure correlating the changes observed in both atoms. We have performed experiments on a selected set of samples with different A-atoms. This allows us to ascertain the role of the alkaline-earth atom, if any, in the electronic structure of Fe and Mo atoms. From XANES and EXAFS we will show that the charge state depends on the substituted divalent metal. The Ca_2(or Sr_2)$FeMoO_6$ samples are nearly described as Fe^{3+} Mo^{5+}, while for barium compounds an intermediate valence for Mo and Fe was found.

2. Experimental

The samples were prepared by solid state reaction. Stoichiometric amounts of $BaCO_3$, $SrCO_3$, $CaCO_3$, Fe_2O_3, 2/3 MoO_3 and 1/3 Mo were mixed, grounded, pressed into pellets and heated at 1200 °C during 4 h in a pure atmosphere of Ar. The Mo : MoO_3 ratio is higher than the theoretical one (1/6 : 5/6) to compensate further oxidation. This step is enough to form the Ca_2FeMoO_6 sample with minor impurities of CaO. The other samples instead contain significant amounts of secondary phases such as A_2MoO_4 (A = Ba, Sr). In order to remove the secondary phases, the samples were grounded, pressed and sintered at 1200 °C in a stream of H_2/Ar (2/98) during 1 h. The samples were characterised by X-ray powder diffraction using D-max Rigaku system with a Cu rotating anode. They were all single phases.

The X-ray absorption experiments were carried out in transmission mode at the beamline BM29, ESRF, Grenoble (France). The storage ring operating conditions were 6 GeV electron energy and 150–190 mA electron current. A Si(311) double-crystal monochromator was used for Fe K-edge and Mo K-edge measurements. The incident and transmitted beams were detected by means of ionization chambers. The energy resolution $\delta E/E$ was estimated to be about 6×10^{-5}. The spectra were collected at 30 K using a closed-cycle helium cryostat whose accuracy was estimated to be ±1 K.

3. Results

The Fe K-edge XANES spectra for A_2FeMoO_6 samples compared to $LaFeO_3$ (as reference) are shown in Fig. 1. Spectra for the different samples are very similar, as expected for the same crystallographic structure. A main resonance at the threshold (hereafter denoted as peak A), a weak pre-peak structure (denoted as peak B) at ∼15 eV below the peak A and a shoulder at intermediate energies between the previous features (denoted as C) can be seen. Features A and C correspond to dipolar transitions whose shape is due to the local geometrical structure.

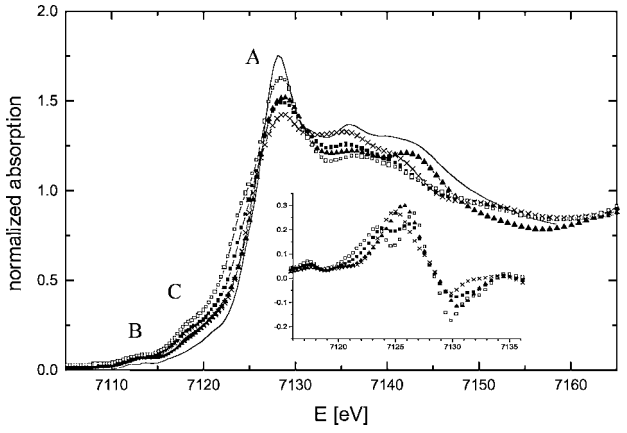

Fig. 1. XANES spectra of the series A_2FeMoO_6, *A*: Ba_2 (open squares), $Ba_{1/2}Sr_{1/2}$ (solid squares), Sr_2 (crosses) and Ca_2 (triangles) at the Fe-K absorption edge and at 30 K. The solid line corresponds to the reference $LaFeO_3$. Inset: first derivative near the absorption edge of the spectra (same symbols).

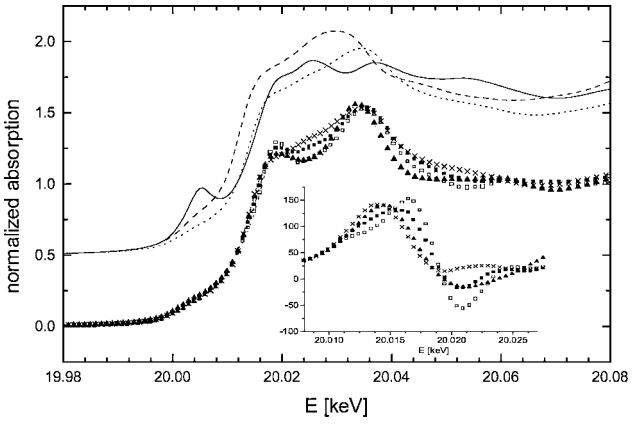

Fig. 2. XANES spectra of the series A_2FeMoO_6 at the Mo-K edge and at 30 K, where *A*: Ba (open squares), $Ba_{1/2}Sr_{1/2}$ (solid squares), Sr (crosses) and Ca (triangles). References are also plotted shifted upwards: The solid, broken and dotted lines correspond to MoO_3, $SrMoO_3$ and $SrFe_{2/3}Mo_{1/3}O_3$, respectively. Inset: The first derivative near the absorption edge of A_2FeMoO_6.

Differences among the spectra come from the different scattering power of the divalent metals and may be also due to small differences in the crystal symmetry. The intensity of the white line for A_2FeMoO_6 samples could be correlated with the change of symmetry in the series, from cubic to monoclinic. The weak pre-peak B is ascribed to $1s \rightarrow 3d$ transitions either quadrupole-allowed or dipole-forbidden. The latter becomes allowed due to strong mixing of O 2p and Fe 3d states. Some authors claimed that the mixing of d states between different neighbouring transition metal atoms, through hybridisation with the oxygen p-band, give rise to these pre-peaks [12]. Within this interpretation, the intensity of these pre-peaks shows a large mixing between 3d-Fe and 4d-Mo states.

The main important difference among the XANES spectra concerns the energy position of the absorption edge. The edge position is mainly ascribed to the Fe oxidation state in this case. Different contributions from geometrical effects to the absorption edge position should be negligible due to the very similar crystallographic structures. The edge (taken as the first inflection point at the derivative) with the highest energy corresponds to $LaFeO_3$, the reference for octahedral Fe^{3+}. Ca_2FeMoO_6 and Sr_2FeMoO_6 have their edges at energies slightly lower than the reference compound. Ba_2FeMoO_6 has the edge at the lowest energy whereas the value for $BaSrFeMoO_6$ is intermediate. Therefore, the maximum chemical shift is 1.5 eV between the spectra of Ba and Ca samples. It is noteworthy that the chemical shift between Fe^{3+} and Fe^{2+} is about 4 eV [13]. The derivative spectra are shown in the inset of fig. 1. The presence of two peaks in the derivative spectra for Ba and $Ba_{1/2}Sr_{1/2}$ samples indicate a fluctuating intermediate valence of the iron atom for both samples.

The Mo K-edge spectra for A_2FeMoO_6 samples are plotted in Fig. 2 together with selected reference samples: MoO_3 (Mo^{6+}), $SrFe_{2/3}Mo_{1/3}O_3$ (Mo^{6+}-perovskite structure) and $SrMoO_3$ (Mo^{4+}-perovskite structure). The Mo K-edge XANES of MoO_3 is characterised by a clear pre-peak at ~12 eV below the absorption edge. Such pre-peak has been reported in previous works as a shoulder of the main edge. The better energy resolution of our experimental set-up allows us to discern a peak that arises from the distorted octahedral coordination of α-MoO_3. The pre-peak transforms into a weak shoulder for the rest of the spectra in agreement with the nearly regular MoO_6 octahedra presented in either the double perovskites or the two other reference compounds. We note a chemical shift of 3.5 eV between $SrFe_{2/3}Mo_{1/3}O_3$ and $SrMoO_3$ attributed to the chemical shift between Mo^{4+} and Mo^{6+} in a perovskite structure. The spectra of the double perovskites show a relatively weak white line and strong resonances above the edge related to multiple scattering contributions that are absent in the reference compounds (see Fig. 2). The main absorption edge for Mo^{6+} references is located at 20015.5 eV. A chemical shift is present for double perovskites that can be better noticed in the derivative of the absorption coefficient, plotted in the inset of Fig. 2. The displacements of the absorption edges follow the opposite pattern to the previously observed at the Fe K-edge. The maximum edge energy corresponds to Ba_2FeMoO_6 (20016.4 eV) and the difference with respect to Sr_2FeMoO_6 and Ca_2FeMoO_6 is about 2.5 eV. The edge for $BaSrFeMoO_6$ lies at intermediate values of the previous samples. The EXAFS spectra, $\chi(k)$, of the series were also analysed using the XOP package [14]. The experimental EXAFS signal was extracted from the raw spectra following standard methods [15]. Background removal was performed and the atomic absorption coefficient was determined by a low order polynomial fit of the spectra. The Fourier transform (FT) of the $k\chi(k)$ spectra was

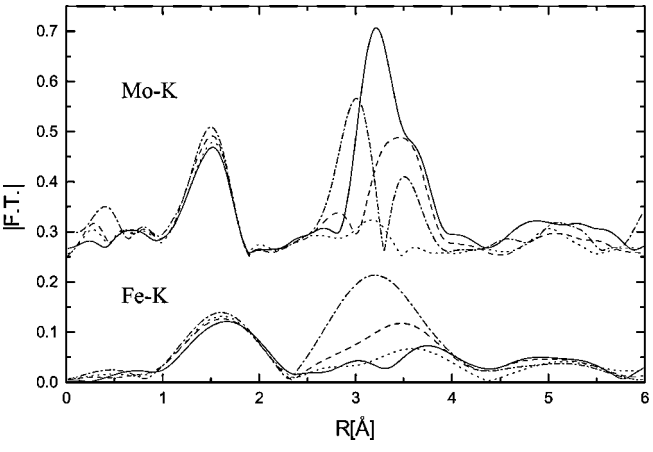

Fig. 3. Top: Fourier Transform spectra corresponding to the EXAFS at the Mo-K edge for the series A_2FeMoO_6 series, *A* being Ba (solid line), $Ba_{1/2}Sr_{1/2}$ (dashed line), Sr (dashed-dotted line) or Ca (dotted line). Bottom: Fourier Transforms of the EXAFS curves at the Fe K-edge for the A_2FeMoO_6 series, *A* being Ba (solid line), $Ba_{1/2}Sr_{1/2}$ (dashed line), Sr (dashed-dotted line) or Ca (dotted line).

Table I. *Distances r[Fe(Mo)-O] and relative Debye-Waller factors $\Delta\sigma^2$ obtained by comparison with experimental phases of the reference compounds ($LaFeO_3$ for the Fe K-edge and $SrMoO_3$ for the Mo K-edge) for the A_2FeMoO_6 samples. All the spectra were collected at 30 K. The estimated errors in bond-lengths are all less than 1%.*

	Fe K-edge		Mo K-edge	
A	$\langle r\rangle$	$\langle\Delta\sigma^2\rangle$	$\langle r\rangle$	$\langle\Delta\sigma^2\rangle$
Ba	2.06	0.0017	1.98	0.0019
$Ba_{1/2}Sr_{1/2}$	2.02	0.0020	1.95	0.0008
Ca	2.00	0.0016	1.96	0.0012
Sr	1.99	0.0014	1.94	0.0002

extracted using a gaussian window between 3 and 18 $Å^{-1}$ for the Mo K-edge and between 4.5 and 11 $Å^{-1}$ for the Fe K-edge. FT spectra are plotted in Fig. 3(b). They provide a qualitative description of the local structure around photoabsorber atoms. The radial distribution is different for each sample though they have a similar first peak in both edges. This peak corresponds to the six-oxygen first coordination shell. We observe a small variation of the first peak position for the Fe K-edge spectra, indicating an increase of the interatomic Fe-O distances on going from Ca/Sr to Ba samples. While for the Mo K-edge, the first peak position is nearly the same, showing that the Mo-O interatomic distance does not depend on the divalent metal. Further peaks, corresponding to higher distances, arise from different contributions: Fe(Mo)-*A* and Fe(Mo)-Mo(Fe) distances, and multiple scattering paths such as O-Fe(Mo)-O and Fe(Mo)-O-Mo(Fe). The shapes of these peaks depend strongly on the sample due to either the crystallographic symmetry or the different scattering power of the divalent cations. The most symmetric structure, cubic Ba_2FeMoO_6, presents a strong second peak at the Mo K-edge corresponding to a narrow distribution of Fe(Mo)-*A* distances. On the contrary, at the Fe K-edge the strongest peak is found for the tetragonal Sr_2FeMoO_6 sample. The monoclinic Ca_2FeMoO_6 instead, shows several weak peaks as expected for a broad distribution of interatomic distances.

The first shell contribution was extracted by Fourier filtering of the FT spectra between 0.8 and 2.3 Å at the Fe K-edge and between 0.9 and 1.9 Å at the Mo K-edge. The spectra were analysed by curve fitting using the first shell Fourier filtered experimental signals of $SrMoO_3$ and $LaFeO_3$ as references for the Mo K-edge and the Fe K-edge, respectively. Coordination number and ΔE_0 have been fixed to six and zero, respectively. The Fe(Mo)-O interatomic distances (r) and Debye-Waller factors (σ^2) were the fitting parameters. The best-fit results are summarised in table I. The data seem to be reasonable and agree with those reported from crystallographic studies. The main result is that Fe-O interatomic distances increase with increasing size of *A*.

4. Discussion

The description of the charge state of molybdenum and iron in A_2FeMoO_6 double perovskites is nowadays a matter of controversy. From the K-edge XANES spectra, we obtain that the Fe valency is close to 3+ for Sr_2FeMoO_6 and Ca_2FeMoO_6 samples, lower than 3+ for $BaSrFeMoO_6$ and Ba_2FeMoO_6 seems to have an intermediate value close to 2.6+. These results correlate fairly well with the Fe-O interatomic distances obtained from EXAFS analysis. Sr_2FeMoO_6 and Ca_2FeMoO_6 show interatomic Fe-O distances similar or slightly higher than the theoretical Fe^{3+}-O, 1.995 Å from ref. [15], while Fe-O in Ba_2FeMoO_6 has an intermediate value between the former and the expected for Fe^{2+}-O (2.13 Å). Accordingly, the Mo K-edge XANES spectra of Ca_2FeMoO_6 and Sr_2FeMoO_6 suggest an intermediate ionic state between Mo^{5+} and Mo^{6+} for these two samples. Meanwhile, electronic charge on the Mo atom in Ba_2FeMoO_6 and $BaSrFeMoO_6$ is higher (absorption edges are at higher energies) and very close to +6. This is not reflected in the interatomic distances deduced from Mo K-edge EXAFS. Mo-O bond-length differences in this series are lower than those obtained for Fe-O. Nevertheless, Mo-O distances seem to be few noticeable to the Mo valency. This may be due to the very similar ionic radii [16] of Mo^{6+} and Mo^{5+} (0.59 and 0.61 Å, respectively).

Our results show the high sensitivity of the charge state to the substituted divalent metal. Moreover, macroscopic properties of these materials (as saturation magnetization, or T_C) do not strongly depend on such substitution. These facts support that the description of these materials in terms of localized ionic states (Fe^{3+}/Mo^{5+} or Fe^{2+}/Mo^{6+}) seems to be meaningless. We think of an antiferromagnetic coupling between localized Fe^{3+} moments and an itinerant downspin electron as the best model to describe these compounds. The electronic and spin density of this electron projected in either Fe^{3+} or Mo^{6+} sites will highly depend on the substituted divalent metal and may also depend on the synthetic details. The latter could also explain that different research groups reported different results in their X-ray magnetic dichroism and L_2/L_3 X-ray absorption experiments on Sr_2FeMoO_6 [7, 8].

Abstract

In the present contribution we show that X-ray absorption spectroscopy may be an effective way to obtain a detailed insight into nano-granular structures embedded in a glass matrix. For the first time we have employed the single energy X-ray absorption detection method to determine the diameter distribution of metallic granules embedded in a glass matrix. In particular, we have estimated the diameter distribution of Pb granules confined in a $PbOSiO_2$ matrix.

1. Introduction

Lead-silicate glasses, due to their interesting and useful properties, find many industrial applications. As special materials they are used in the production of plate image amplifiers and scintillators [1]. For our present considerations it is most important that lead-silicate glasses submitted to reduction process (e.g. in hydrogen atmosphere), undergo dramatic structural changes. In particular, metallic Pb granules and/or separate neutral Pb atoms appear in reduced glasses. The structural changes are accompanied by remarkable changes of optical properties [2] and in surface electrical conductivity [3]. Moreover, reduced glasses have very high secondary emission coefficients, thus finding an application in the production of electron channel multipliers [3]. The metallic granules confined in a glassy matrix have been the subject of our recent studies [4, 5, 6, 7, 8]. The structural parameters describing the nearest neighbourhood of lead atoms (Pb-Pb and Pb-O pair distribution functions) and the mean size of metallic granules have been obtained for xPbO $(1-x)SiO_2$, $x = 0.3,\ 0.5,\ 0.7$ glasses. In the present contribution, we outline a new method of determination, or at least estimation, of the distribution of diameters of metallic granules embedded in a glass matrix using an X-ray absorption method called single-energy X-ray absorption detection [9].

The X-ray absorption coefficient in homogeneous sample of constant thickness d and atomic density ρ is given by a simple formula: $\alpha = \sigma\rho d$, where σ is the cross section for radiation absorption. During the first order phase transition a significant change in the absorption coefficient can be expected in the whole energy range, related to a change of structural and electronic properties. The most drastic changes in the absorption coefficient α are observed in the vicinity of the absorption edge. Thus, performing measurements of the X-ray absorption coefficient as a function of temperature for a given fixed radiation energy at which the greatest difference in the value of α appears, one can determine the phase transition temperature, and many other related physical quantities, as relative contributions of various phases, overheating/overcooling parameters, as well as structural parameters of the subsequent phases (due to the possibility of performing simultaneous X-ray diffraction and quick EXAFS measurements at each temperature).

As this method is sensitive enough to detect variations of the absorption coefficient at the phase transition of the first order even for nanometer-size objects, an effort to determine or at least estimate the nanogranule diameter distribution for Pb granules confined in a silica matrix has been undertaken.

2. Experimental details

The preparation procedure of the considered 0.7PbO $0.3SiO_2$ glass sample has been described in detail elsewere [8]. The reduction process was realised in hydrogen atmosphere at the temperature of $T_{red} = 400\,^{\circ}\mathrm{C}$, during time periods of $t_{red} = 70\,\mathrm{h}$. The presence of nano-sized granules was established by EXAFS/MD analysis and X-ray diffraction measurement.

The X-ray absorption measurements were conducted at the BM29 beam-line at the European Synchrotron Radiation Facility (Grenoble). Details on the experimental setup can be found in reference [10]. The raw results of the single-energy X-ray absorption measurements of the reduced glass and pure crystalline lead (as reference data) are shown in the lower panel of figure 1. In order to determine the optimal energy for the $\alpha(T)$ measurement, i.e. the energy corresponding to the most pronounced variations of the absorption coefficient during the phase transition, XANES spectra have been measured for each sample in the temperature range from 23 °C to 350 °C. The upper panel of figure 1 shows two such spectra, obtained for crystalline lead under and above the phase transition temperature $T_m \approx 327\,^{\circ}\mathrm{C}$. For all samples the greatest difference between the $\alpha_S(E)$ (solid) and $\alpha_L(E)$ (liquid) curves appeared at the energy of 13061 eV. This energy was used in our experiment. The heating/cooling rate of about 0.5 deg/s was applied.

3. Results

During heating, in the case of crystalline Pb a sharp discontinuity at $T_m \approx 327\,^{\circ}\mathrm{C}$ is observed, whereas for hydrogen-reduced 0.7PbO $0.3SiO_2$ glass the transformation takes place in a finite temperature range. The pattern recorded in the upstroke is not reversible in the downstroke (undercooling effect). The magnitude and shape of the obtained $\alpha(T)$ loop depend on the magnitude of changes in the short-range environment, on the presence of impurities, on the coupling strength between Pb clusters and the matrix, on the surface melting effect, and on the granule size distribution [9].

*e-mail: agnieszka@mif.pg.gda.pl

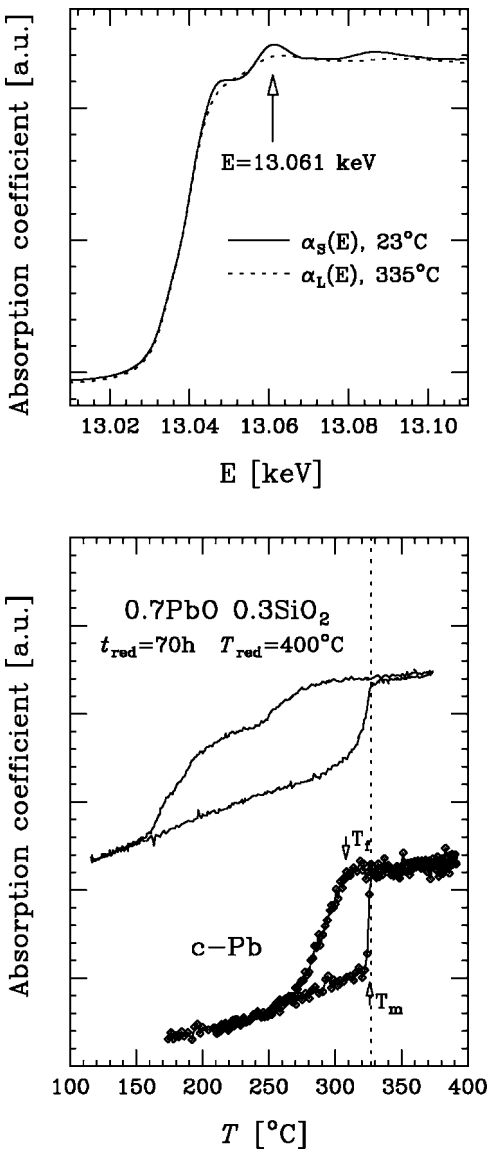

Fig. 1. The Pb L_3 edge measurement in the solid (23 °C) and liquid (335 °C) phases of crystalline lead (upper panel). Single-energy (13061 eV) X-ray absorption measurement results for samples containing powdered crystalline Pb and hydrogen-reduced 0.7PbO 0.3SiO_2 glass (lower panel).

In the simplest interpretative scheme for a lead granular structure confined in a glassy matrix, we assume that the shape of the $\alpha(T)$ melting curve is related mainly to the dependence between the melting temperature (T_m) and the granules' radii (r_g).

The melting of small particles has been described by two main models: (a) the homogeneous melting model [11], and (b) the liquid-skin melting model [12] (for details see [13, 14] and references therein). In numerous experimental and theoretical works dealing with the dependence of the melting temperature on the confined granule size (e.g. [15, 16, 17]), the homogeneous melting model (without a liquid skin) has been used in the first approximation. This model predicts a size-dependent melting temperature, T_m, that varies with the granule radius as follows:

$$T_m = T_0 - \frac{2T_0}{L\rho_S r_g}\left[\gamma_S - \left(\frac{\rho_S}{\rho_L}\right)^{2/3}\gamma_L\right], \tag{1}$$

where T_0 is the bulk melting temperature, L is the latent heat of fusion, ρ_S and ρ_L are densities in the solid and liquid phases, respectively, and γ_S and γ_L are surface energies in the solid and liquid phases, respectively. Assuming $T_0 = 327.5\,^\circ$C, $L = 23.2\,$J/g, $\rho_S = 11.34\,$g/cm^3, $\rho_L = 10.66\,$g/cm^3, and $\gamma_S = 0.61\,$J/m^2 [18], $\gamma_L = 0.48\,$J/m^2 [19], one can determine the $r_g(T_m)$ dependence from equation (1).

Simultaneously, a single-energy X-ray absorption detection experiment enables accurate determination of the relative atomic fraction melted at the temperature $T_m^{(i)} = T_i + \frac{T_{i+1}-T_i}{2}$, defined as:

$$\Delta f(T_m^{(i)}) = \frac{\alpha(T_{i+1}) - \alpha(T_i)}{\alpha_L - \alpha_S}. \tag{2}$$

Fitting the polynomial function to the experimentally obtained data, $\alpha(T)$, one can calculate this fraction with sufficient accuracy. In our analysis, $T_m^{(i)}$ was determined with the step $(T_{i+1} - T_i)$ equal to 0.1 °C. The $\Delta f(T_m^{(i)})$ dependence for 0.7PbO 0.3SiO_2 glass is shown in figure 2(a).

Then correlation between $\Delta f(T_m^{(i)})$ and the volume of granules melted at a temperature close to $T_m^{(i)}$ (equation (1)):

$$\Delta f(T_m^{(i)}) \sim N_g(T_m^{(i)}) \cdot \rho_L \cdot r_g^3(T_m^{(i)}),$$

leads to the distribution of granule size, $N_g(r_g)$.

The obtained distribution for reduced 0.7PbO 0.3SiO_2 glass is presented in figure 2(b). A maximum at $r \sim 75$Å can easily be distinguished. However, a single continuous diameter distribution covers the interval of 55–4000 Å. These results are compatible with our previous EXAFS/MD analysis [8].

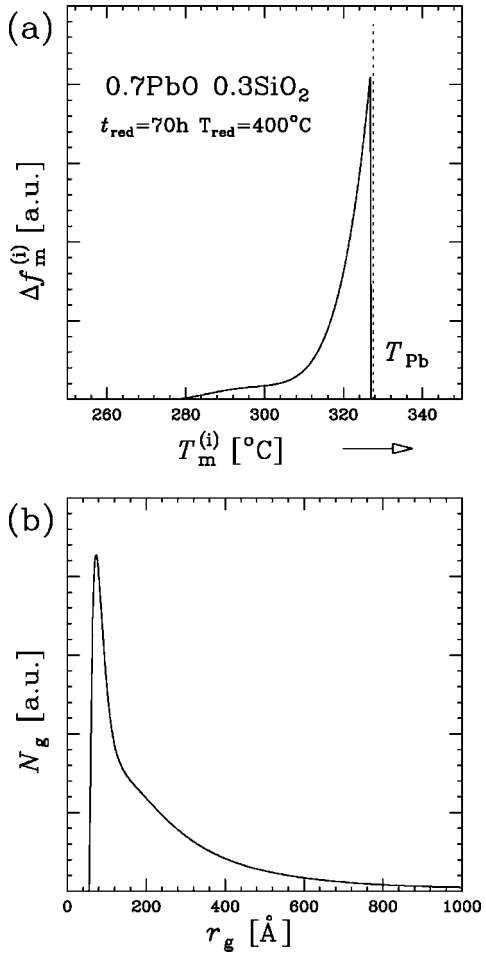

Fig. 2. a) Relative atomic fraction melted in the temperature range $[T_i, T_{i+1}]$ versus $T_m^{(i)}$. The dotted line marks the melting temperature of bulk Pb. b) Estimated granule radii distribution for reduced 0.7PbO 0.3SiO_2 glass.

4. Conclusions

The measurements and analysis of the $\alpha(T)$ characteristic for hydrogen-reduced lead-silicate glass have shown that the single-energy X-ray absorption method can be a useful source of information on confined granules embedded in glassy matrices.

Our interpretation scheme and usage of equation (1) may be considered merely as a first approximation. More precise analysis should take explicitly into account, first of all, the granules' confinement (i.e. the confinement-induced pressure, exact values of surface energy in the solid and liquid state specific for a given matrix, etc.) and the surface melting effect. Thus, the detailed results presented in the paper should only be considered as preliminary. However, we believe to have thus demonstrated the potential of the method for estimating the granule diameter distribution.

Abstract

The composition dependence of short-range structure was investigated for manganese borate glasses ($(MnO)_X(B_2O_3)_{1-X}$, $X = 0.21$, 0.30, 0.44, 0.52) by XAFS measurement. The manganese K-edge XAFS spectra of the glasses were measured at the beamline 4 (BL-4) station of the synchrotron radiation facility at Ritsumeikan University in Japan. From the XANES spectra, it was found that the manganese ion is divalent in the glasses and it does not vary with the MnO content. The EXAFS spectra indicate that the manganese ion is surrounded by four oxygen atoms with an interatomic distance of *ca.* 2.1 Å. A notable composition dependence of the Mn-O correlation is not observed for the glasses.

1. Introduction

It is well known that composition dependences of physico-chemical properties, such as density and thermal expansion coefficient, have maxima or minima from $X = 0.3$ to 0.4 for alkali borate glasses ($(M_2O)_X(B_2O_3)_{1-X}$ glasses, where M is an alkali metal). This is called the 'boric oxide anomaly' [1, 2]. For examining these irregularities, the structure of alkali borate glasses has been extensively investigated, e.g., by X-ray and neutron diffraction [3, 4], Raman spectroscopy [5], B^{11}-NMR [6], molecular dynamics simulation [7], IR spectroscopy [8]. It is proposed from these studies that various structural groups, such as boroxol ring, diborate, triborate, metaborate ring, and so on, are formed from the tetrahedral BO_4 units and the triangle BO_3 units in the alkali borate glasses [9]. However, we are not aware of any structural studies on glasses containing other metal ions, although the structural analysis is important for elucidating the effect of other metal ions on the structural group.

In a previous study, we investigated the short-range structure of manganese borate glasses ($(MnO)_X(B_2O_3)_{1-X}$) by high energy XRD (HEXRD) [10]. It was found that the coordination number of B-O increases with increasing MnO content. However, the coordination number of Mn-O has not been elucidated from the HEXRD because the Mn-O correlation is overlapped with B-B or O-O correlations in the total correlation function, $T(r)$. Especially, for manganese-containing oxide crystals, the coordination number and interatomic distance of Mn-O depend on the valency of manganese ion and its composition [11–14]. Therefore, it is important to investigate the valency and the short-range structure of manganese ions in different glasses.

In the present study, the structure of manganese borate glasses ($(MnO)_X(B_2O_3)_{1-X}$, $X = 0.21, 0.30, 0.35, 0.44$) was investigated by Mn K-edge XAFS measurements at the synchrotron radiation facility of Ritsumeikan University in Japan. We discuss the composition dependence of the valency and short-range order of the manganese ion from the XANES and EXAFS data, respectively.

2. Experimental

2.1. *Preparation of manganese borate glass*

The manganese borate glasses ($(MnO)_X(B_2O_3)_{1-X}$) were prepared in the range from $X = 0.21$ to 0.52. B_2O_3 and $MnCO_3$ were used as starting materials, mixed and then heated in alumina crucibles at 1373 K for 2 hours. The melt was rapidly quenched to ambient temperature by the twin-roller method [15]. The quenching rate was around 10^3–10^4 K/s. The amorphicity of the glasses was verified by the absence of sharp peaks in the XRD pattern. The composition of the glasses was analyzed by inductively coupled plasma atomic emission spectroscopy (ICP-AES) (Seiko Instruments Inc., SPS1500VR).

2.2. *XAFS measurement*

The glass samples were well-ground, mixed with boron nitride (BN) powder and then pressed into pellets of 10 mm diameter. Manganese K-edge XAFS spectra were recorded in transmission mode at BL-4 beam line with synchrotron radiation from the 575 MeV storage ring of the SR facility in Ritsumeikan University, Shiga, Japan. The absorption spectra were measured using a Ge(220) ($d = 2.000$ Å) double monochromator and two ionization chambers. The absorption coefficients, $\mu t (\mu t = \ln(I_0/I))$, were measured from 6300 to 7500 eV with a fixed accumulation time of 5 s per data point. The EXAFS interference function ($k^3\chi(k)$) and radial distribution function (RDF) were calculated by Rigaku, EXAFS Software (REX2, RIGAKU). The k^3 weighted $\chi(k)$ was extracted from the observed absorption spectrum by a cubic spline method. These were then Fourier-transformed with a Hanning window to evaluate the radial distribution functions (RDFs) [16].

3. Results and discussion

3.1. *XANES spectra of manganese borate glasses*

Figure 1 shows normalized XANES spectra at the Mn K-edge of $(MnO)_X(B_2O_3)_{1-X}$ ($X = 0.21$, 0.30, 0.44, 0.52) glasses. The spectra of manganese carbonate and manganese dioxide are also displayed for reference. The absorption edges of Mn for the manganese glasses are found in the range from 6450 to 6550 eV. It is noted that the position of the Mn K-edge of the glasses does not change with the MnO content, X. The XANES spectra of the glasses show that the absorption edge energy is similar to the one of manganese carbonate ($MnCO_3$), which indicates

*e-mail: kajinami@kobe-u.ac.jp

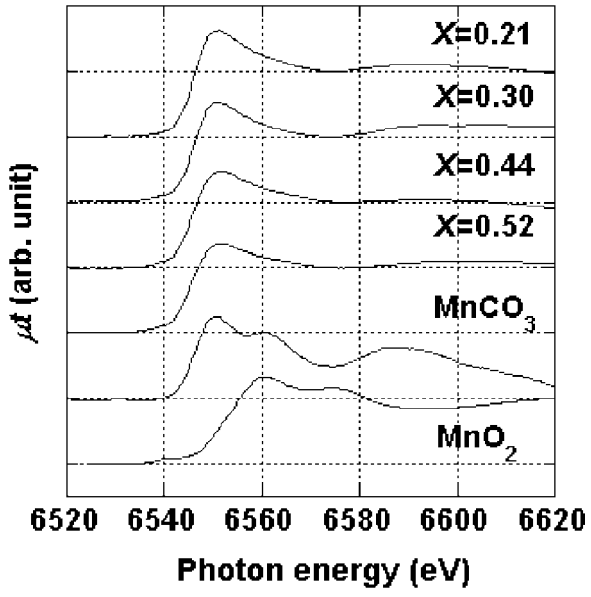

Fig. 1. XANES spectra of $(MnO)_X(B_2O_3)_{1-X}$ glasses, manganese carbonate, and manganese dioxide.

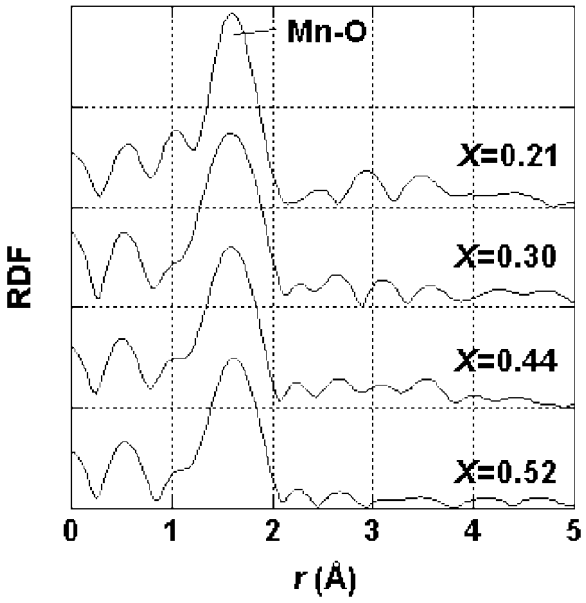

Fig. 3. EXAFS radial distribution functions (RDFs) of $(MnO)_X(B_2O_3)_{1-X}$ glasses.

that manganese ion is divalent (Mn^{2+}) in the glasses. A notable composition dependence of the valency is not observed in these glasses.

3.2. *EXAFS spectra of manganese borate glasses*

Figure 2 shows interference functions, $k^3\chi(k)$s, of the glasses, which include oscillations up to 10 Å^{-1}. It is found that the functions have similar frequency and amplitude, which implies that there is no composition dependence of the short-range structure of the manganese ion in the glasses. Figure 3 shows radial distribution functions (RDFs) of the glasses, calculated by Fourier transformation of the $k^3\chi(k)$s without correction for the phase shift. All patterns show a peak at *ca.* 1.6 Å, which is assigned to Mn-O correlation. The RDF was back Fourier-transformed from 1.2 to 2.1 Å to reproduce the interference function, $k^3\chi(k)$, of the Mn-O correlation. The structural parameters were evaluated by the standard EXAFS equation,

$$\chi(k') = \frac{N}{k'r^2} f(k') \exp(-2\sigma^2 k'^2) \cdot \exp\left(\frac{-2r}{\lambda}\right) \cdot \sin[2k'r + \phi(k')], \tag{1}$$

where $N, r, \sigma, \phi(k')$, $F(k')$ and λ are coordination number, interatomic distance, Debye-Waller factor, phase shift, back-scattering factor, and mean free path length of the electron, respectively [17]. k' denotes the corrected wave number as

$$k' = (k^2 - 2m\Delta E_0/\hbar^2)^{\frac{1}{2}}, \tag{2}$$

where ΔE_0 is the energy shift of the Mn K-edge ionization potential. Using Mckale's parameters [18], these structural parameters, r, N, σ, and ΔE, and λ are used to reproduce the $k^3\chi(k)$ oscillation of the Mn-O correlation by a least square fitting method [16]. Table I summarizes the optimized structural parameters. The results indicate that the interatomic distance of Mn-O correlation is about 2.1 Å for all glasses. A composition dependence of the Mn-O correlation is not observed in the range from $X = 0.21$ to 0.44. It is known that the Mn-O distances vary with composition of manganese ions in the range from 1.8 to 2.3 Å for other manganese containing glasses [19–21], where the composition dependence is related to the Mn oxidation state and the number of surrounding

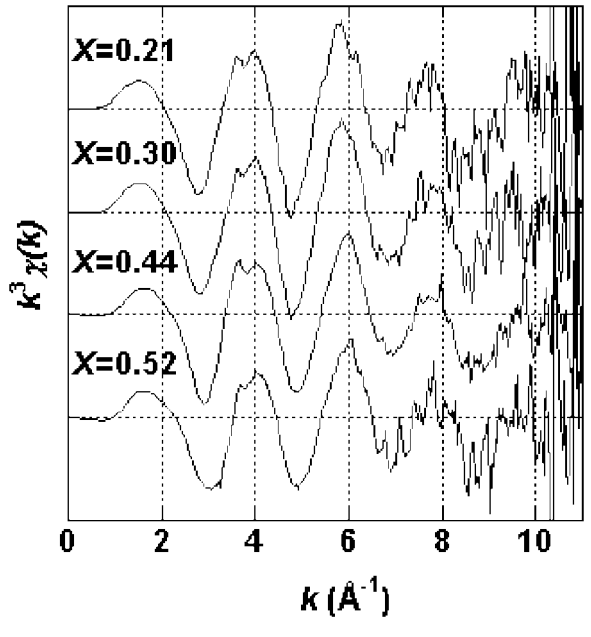

Fig. 2. EXAFS interference functions, $k^3\chi(k)$s of $(MnO)_X(B_2O_3)_{1-X}$ glasses.

Table I. *Structural parameter of $(MnO)_X(B_2O_3)_{1-X}$ glasses obtained by the curve fitting method. N: coordination number of Mn-O correlation, r: Mn-O distance (Å), σ: Debye-Waller factor (Å), ΔE: E_0 shift (eV), and λ: mean free path length of photo-electron (Å).*

X	N	r	σ	ΔE	λ
0.21	3.96	2.13	0.086	1.61	3.79
0.30	3.96	2.12	0.093	1.88	4.00
0.44	3.86	2.11	0.094	2.51	3.63
0.52	3.67	2.11	0.086	5.07	3.37

ions. In the crystalline structure, the Mn-O distances become shorter with increasing oxidation state [11–14]. The fixed value of Mn-O distances in Table I may be due to the unchanged valency of the manganese ion in the glasses.

From Table I, it is found that the coordination number for the Mn-O is about four, which indicates that the manganese ion has tetrahedral structure with oxygen. In the crystalline structure of MnB_4O_7 (i.e. $(MnO)_{0.33}(B_2O_3)_{0.66}$), there is a similar short-range structure, in which the manganese ion is surrounded by four oxygen atoms at *ca*. 2.1 Å [22]. The deconvolution of the total correlation function, $T(r)$, from HEXRD measurements [10] also shows that the coordination number is about four, which agrees with the assignment to the tetrahedral structure of manganese ion in the glasses.

4. Conclusions

The interatomic distance and coordination number of the Mn-O correlation were investigated by XAFS measurements to study the modification of the short-range structure in manganese borate glasses. It is found that no composition dependence of the short-range structure was observed for the glasses, in which the manganese ion is bivalent and has tetrahedral structure with oxygen ions. The detailed structure will be elucidated by further studies such as neutron diffraction, IR, Raman measurements and NMR by the authors.

Acknowledgment

The authors wish to thank Ritsumeikan University SR center and SPring-8 for supporting the XAFS measurements by 'Nanotechnology Comprehensive Support Project' of Ministry of Education, Culture, Sports, Science and Technology (MEXT) in Japan. We would like to thank to 'Center for instrumental analysis' in Kobe University for using the ICP-AES spectrometer.

Abstract

0.2 mass% Mo in a high-strength steel has been investigated using X-ray absorption fine structure (XAFS) technique. Mo-K edge X-ray fluorescence XAFS spectra show the transition from Mo in solution in α-Fe matrix to Mo in carbides when the steel is annealed at 650 °C. We have evaluated the atomic fraction of Mo atoms in solution and in carbides from curve fitting parameter of XANES spectra and from coordination number of iron surrounding Mo in the α-Fe matrix derived from an EXAFS analysis.

1. Introduction

Metals added into steel (micro-alloying elements) dramatically change many properties of steel product, such as strength and anti-corrosion property. It is important to understand the mechanisms of improvement of the properties by adding the elements in order to design micro alloyed steel with superior performance. The micro alloying elements often play very important roles on the properties by forming precipitates with a small size. Transmission electron microscopy (TEM) is a powerful tool for direct observation, and compositional and structural analysis of precipitates with sizes down to a few-nm [1]. Atom-probe field-ion microscopy (AP-FIM) has been applied to direct imaging of atoms in steel [2]. There are difficulties however in obtaining structural and quantitative information of precipitates with sizes of less than a few-nm especially at the early stage of precipitation.

X-ray absorption fine structure (XAFS) spectroscopy is widely used in material science to clarify the short-range structure of the elements in interest. Although this technique has been often applied to amorphous metals [3], the study on the micro-alloying steel (crystal) is few [4–6]. In this study, we present Mo K-edge XAFS spectra recorded for a 0.2 mass% Mo-added high-strength steel and discuss the results in terms of change of chemical states of Mo with annealing. We also discuss the quantitative chemical state analysis of Mo using the XAFS spectra.

2. Experimental

The 0.04 wt% C–1.5 wt% Mn steel containing Mo of 0.2 mass% was soaked at 1250 °C and then water-quenched from about 650 °C (starting material). The starting material was water-quenched just after the annealing at 650 °C for 0.5 min–60 min. A piece of steel with the same composition was quenched from 900 °C after the soaking is prepared as a reference of Mo which is substitutional in α-Fe matrix (a bcc structure). A residue extracted from steel aged at 675 °C by electrolytic extraction method was prepared as a reference of Mo in precipitated carbides. The measured surfaces of the steel specimens were carefully mirror polished.

The XAFS measurements were carried out at BL27B of Photon Factory, KEK (2.5 GeV, Tsukuba, Japan), with a two-crystal Si (111) monochrometor. The Mo-K edge XAFS spectra were measured in an X-ray fluorescence mode using a Lytle-type detector (a photon-pass length of 100 mm) with a solar slit and Kr gas for the steel and residue specimens. The spectra were analyzed using a commercial software (Rex 2000, Rigaku corp.).

3. Results and Discussion

3.1. *Chemical states of Mo*

Figure 1 shows Mo-K edge XAFS spectra for the 0.2 mass% Mo steel annealed at 650 °C for 0.5 min–60 min [spectra (c)–(f)] as well as the spectra for the starting material [spectrum (b)], the specimen quenched from 900 °C [spectrum (a)], the residue electrically extracted from the thermal aged steel [spectrum (g)], and Mo_2C [spectrum (h)]. The X-ray absorption near-edge structures (XANES) for the starting material are indistinguishable from those for the specimen quenched from 900 °C. This shows that Mo atoms in the starting material are almost all substitutional in the Fe matrix. The spectra gradually change during the annealing, which shows that the annealing induces changes in the local environment of Mo atoms. A broad peak at about 20060 eV decreases in intensity and a peak at about 20045 eV increases with the annealing. The differential spectrum obtained by subtracting the spectrum of the starting materials from that of the specimen annealed for 60 min is shown in Fig. 2. Peak positions of the differential spectrum are close to those of the spectrum for the

(a) water-quenched from 900 °C, (b) starting material, annealed at 650 °C for (c) 0.5 min, (d) 2 min, (e) 10 min and (f) 60 min. FT for residue electronically extracted from thermal aged steel is also presented (g).

residue and Mo_2C, which strongly suggests that a part of Mo forms carbides in the annealed specimen.

The amplitude of extended X-ray absorption fine structure (EXAFS) oscillation in the photon energy range from 20050 eV to 20300 eV decreases by annealing, see Fig. 1. This phenomenon is clearly demonstrated in the Fourier transforms (FT) of the k^3-weighted EXAFS spectra shown in Fig. 3. The radial distribution (phase-shifts were not corrected) shows that peaks in the FT decrease in intensity by the annealing. The FT curves have a typical bcc structure for all steel specimens, which shows that the EXAFS oscillation is dominated by photoelectrons being scattered at Fe atoms surrounding Mo. The precipitated carbides show only weak amplitudes even for the thermal aged steel [spectrum (g) in Fig. 1 and Fig. 3]. The weak EXAFS amplitude for the precipitates may be due to their small size and structural deformation. From the above discussion, the reduction of the EXAFS amplitude is attributed to the decrease of the number of Mo atoms in solution in α-Fe matrix.

The XANES and EXAFS spectra show the transition from Mo in solution in α-Fe matrix to Mo in carbides when the steel is annealed at 650 °C.

3.2. *Quantitative chemical state analysis of Mo*

The XAFS spectra shown in Fig. 1–Fig. 3 provide us a chance to analyze the chemical states of Mo quantitatively. We have evaluated the atomic fraction of Mo in solution in the α-Fe matrix and in precipitates from the XANES and EXAFS spectra.

Table I. *Results of curve-fitting analysis for Mo-K EXAFS spectra.*

F: fixed numbers, CN of 2nd shell is fixed as 0.75×(CN of 1st shell).

A curve-fitting parameter of the XANES spectra is adopted for quantitative analysis. The reference spectra for dissolved and precipitated Mo are represented by those for the specimen quenched from 900 °C and for the residue from the thermal aged steel, respectively. The XANES spectra in the photon energy range between −50 eV and +100 eV from the absorption edge are used for the cave fitting after they are subtracted the background and normalized by μ_0. The atomic ratio of the two Mo states is evaluated for each specimen as a ratio of two reference spectra, in which the ratio well reproduces each spectrum.

The decrease of the coordination number of Fe atoms surrounding dissolved Mo atoms is another index (see Fig. 3). This is valuable because the EXAFS signal reflects mainly the dissolved Mo atoms as mentioned above. The coordination number was evaluated by a curve fitting of inverse FT curves (k^3-weigted) for the 1st and 2nd nearest neighbors (the strongest peak of FT in Fig. 3). The k-range for the FT is 3–12 Å^{-1} and the ratio of the 1st and 2nd nearest neighbors was fixed to 8/6. A backscattering factor, a phase shift, and a Debye-Waller factor were derived from the analysis of the reference specimen quenched from 900 °C and fixed in the analysis of other specimens. The results of the curve-fitting analysis are shown in Table I. The R-factors were between 0.8 and 1.3 for all specimens. The atomic fraction of Mo atoms in solution in the matrix was estimated from the coordination number assuming that the coordination number for the specimen quenched from 900 °C (a reference of dissolved Mo in Fe) is unity.

Figure 4 shows the atomic fraction of precipitated Mo estimated by the above two methods. Both curves show the same

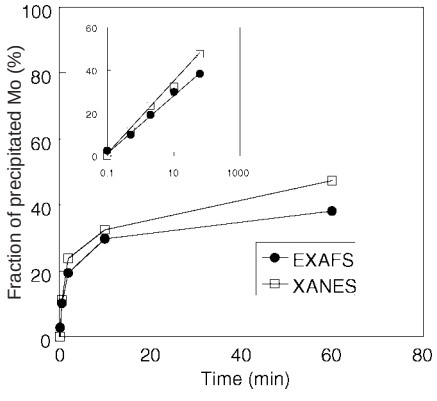

Fig. 4. The atomic fraction of precipitated Mo estimated from XANES and EXAFS spectra as a function of annealing time at 650 °C. Insert plots the results versus a legalistic time scale.

tendency as a function of the annealing time, although the values from the XANES spectra are higher than those from the EXAFS spectra. The insert in the figure clearly shows that the precipitation of Mo has already started even at an annealing time of 0.5 min and proceeds in proportion to the square root of time up to at least 60 min. These phenomena are first clarified by XAFS.

The atomic fraction of precipitated Mo estimated from the XAFS was compared with that from an electrolytic extraction method combined with chemical analysis for the thermal aged specimen. The EXAFS analysis provides about 15% higher value than the electrolytic extraction method. Precipitates with small size could dissolve into solution and/or leak through the filter during the extraction process for the latter method. Our results are indicative of the possibility that XAFS becomes a powerful tool for a quantitative chemical state analysis of small precipitates in steel. The XAFS technique, providing spatially averaged quantitative information on chemical states of micro-alloying elements, must be complemental to direct imaging techniques such as TEM and AP-FIM. This method is easily applied to bulk specimens, which is an advantage when compared with TEM, AP-FIM, and chemical analysis.

The difference in the atomic fraction of the precipitated Mo derived from XANES and EXAFS analysis (in Fig. 4) is a still problem. Two reasons should be considered. One is a selection of reference spectra for precipitated Mo. Residues extracted from steel are not always suitable when precipitates are very small. Another one is the difference of the spatial range probed by XANES and EXAFS analysis (the former would be wider than the latter).

4. Conclusion

The 0.2 mass% Mo in steel was studied by X-ray fluorescence yield XAFS. The XAFS spectra clearly show the transition from Mo in solution to carbides in steel at 650 °C. We demonstrate that the XAFS is applicable to non-destructive quantitative chemical state analysis of micro-alloying elements in steel.

Abstract

Resonant inelastic X-ray scattering is well suited to studying pre-edge features in x-ray absorption spectra. Here it is applied to the Ce L_3 edge in CeNi, $CeNi_2$, and $CeNi_7$. A relatively strong feature is observed corresponding to $4f^2$ final states. We show that its presence is not the consequence of $2p \rightarrow 4f$ quadrupole transitions but rather to final state interactions with conduction electrons and Ni $3d$ states.

1. Introduction

The interesting electronic properties of the lanthanides are due to the presence of itinerant (band-like) 5d6s valence electrons and of an integral number of localized (atomic-like) 4f electrons at similar energies [1]. The situation is less clear cut for elements at the beginning of the series where hybridization between the 4f electrons and the valence electrons can arise. This is notably the case for the mixed-valence behavior of Ce-based compounds [2]. High-energy spectroscopies have long played a major role in the investigation of the f-count in these materials. For instance, the comparison between X-ray absorption spectroscopy (XAS) at the Ce 3d edge and theoretical multiplet calculations of the $3d^{10}4f^n \rightarrow 3d^9 4f^{n+1}$ transitions have been used to determine the weights of the f^n configurations in the ground state [3]. In the case of the Ce $L_{2,3}$-edge XAS, empirical models are used to arrive at the f-count [4, 5]. X-ray photoelectron spectroscopy (XPS) on the Ce 3d core levels is another technique widely used to investigate both f-count and hybridization effects despite its high surface sensitivity [6]. The results of these core-level spectroscopies are usually interpreted within the framework of a single-impurity Anderson model proposed by Gunnarsson and Schönhammer (GS) [7]. The same set of parameters have been shown to account for Ce 3d XPS spectra, 4f photoemission experiments, and bremsstrahlung isochromat spectroscopy (BIS) of several Ce–TM (transition metal) compounds within the GS model [8].

Recently some limitations to the GS model have been put forward. For instance, configuration-dependent hybridization terms have been introduced leading to a significant improvement in the description of the XPS and BIS experiments, even for systems where the hybridization is strong [9]. New progress has also been made on the experimental side by recording high-energy Ce 3d photoemission spectra, which enhance bulk sensitivity and allow bulk information to be extracted [10].

Over the past decade, the availability of synchrotron radiation sources with increased brightness has made it possible to develop resonant inelastic X-ray scattering (RIXS) at intermediate energies, i.e., at the rare earth $L_{2,3}$ edges (see for instance Ref. [11]). In such experiments empty states are also probed, but because X-ray scattering leaves behind a weakly bound core hole (in the 3d shell for instance), fine structure can be identified. The latter is usually masked by the shorter lifetime of the 2p core-hole in the standard XAS experiment. Like XAS, RIXS is element selective, and like XAS studied in the fluorescence yield mode, it is bulk sensitive being a photon-in–photon-out process. The latter is a particularly important feature in respect to reactive materials.

Here we show that Ce 2p3d RIXS for three Ce–Ni intermetallic compounds (CeNi, $CeNi_2$ and Ce_2Ni_7) reveals the presence of a strong f^2-like feature at the Ce L_3-edge. This finding is discussed in relation to the standard interpretation of Ce L_3-edge XAS data.

2. Experimental

The RIXS experiments were performed at the European Synchrotron Radiation Facility on beamline ID12 which is equipped with a two Si(111) plane-crystal monochromator [12]. The incoming monochromatized radiation is focused to a spot of $\approx$40 μm in the vertical plane. This spot is the source of an ultra-high vacuum compatible cylindrically-bent quartz $(20\bar{2}3)$ spectrometer dispersing in the vertical plane [11]. The overall resolution for the present experiment is estimated to be $\approx$1.5 eV as determined from a study of the elastic scattering from the samples. The absorption spectra were recorded in the total yield fluorescence mode. All the experiments were performed at room temperature with bulk samples prepared by arc-melting under an argon atmosphere of high-purity constituents. X-ray diffraction was used to check the quality of the samples.

3. Results and Discussion

The Ce 2p3d RIXS spectra of CeNi, $CeNi_2$ and Ce_2Ni_7 are given in Figs 1, 2 and 3 respectively. The intensity of the scattered radiation is given as a function of the energy transfer, i.e., the difference $(\Omega - \omega)$ between the energy Ω of the incoming photon and the energy ω of the outgoing photon. The Ce L_3 XAS spectra are also given as an inset to each figure. The arrows on the XAS spectrum indicate the energies of the resonant excitation used.

*Also at LURE, Centre Universitaire Paris Sud, Bât. 209D, BP 34, 91898 Orsay Cedex, France.

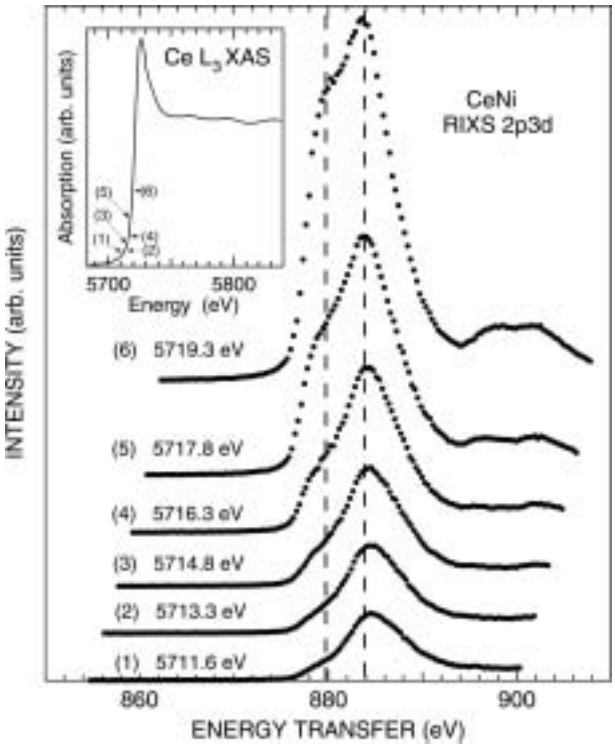

Fig. 1. Ce 2p3d RIXS spectra in CeNi excited at the energies shown by arrows on the Ce L_3 X-ray absorption spectrum (given in the inset).

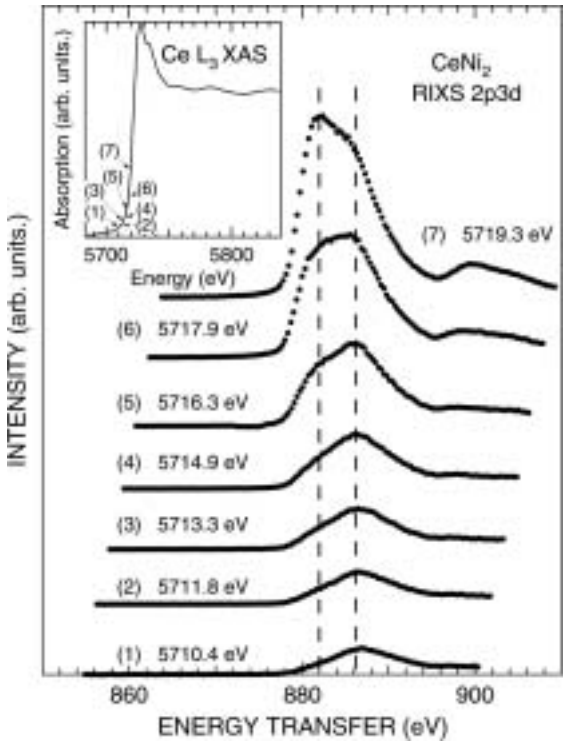

Fig. 2. Ce 2p3d RIXS spectra in $CeNi_2$ excited at the energies shown by arrows on the Ce L_3 X-ray absorption spectrum (given in the inset).

The XAS spectra exhibit a strong white line followed by a shoulder at ≈7 eV on the high energy side which are generally attributed to dipole transitions originating from respectively $4f^1$ and $4f^0$ configurations in the ground state. The higher energy shoulder increases in relative intensity across the series as the nickel content increases.

The RIXS data reported here correspond to excitation energies below the Ce $2p_{3/2}$ ionization threshold. When plotted on an energy transfer scale they clearly show-up two peaks at the Ce L_3-edge. The extra component in the pre-edge region is situated at ≈882 eV and the main peak at ≈886 eV with different relative intensities depending on the compound. We attribute the peak at lower energy transfer to a well screened Ce 3d core hole with a $4f^2$-like configuration. Excitation to the $4f^0$ peak is omitted because the signal is then mixed in with normal fluorescence from the ionized $4f^1$-edge.

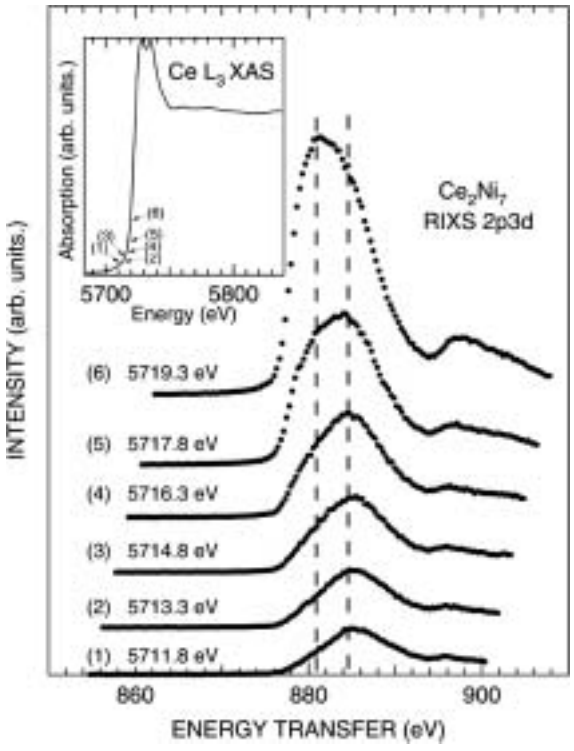

Fig. 3. Ce 2p3d RIXS spectra in Ce_2Ni_7 excited at the energies shown by arrows on the Ce L_3 X-ray absorption spectrum (given in the inset).

The role played by $2p \rightarrow 4f$ quadrupole transitions in rare-earth systems has been extensively discussed particularly in relation with the interpretation of X-ray absorption magnetic circular dichroism (see, e.g., Nakazawa *et al*. [13] for a recent discussion). RIXS performed on ionic CeF_3 [14] and LaF_3 [15] and confronted to theoretical calculations clearly corroborate the presence of a $2p \rightarrow 4f$ quadrupole transition but indicate that its intensity is only about 2% of the $2p \rightarrow 5d6s$ dipole transition. Thus in the following we examine the origin of the unexpectedly high intensity of the $4f^2$-like configuration in the Ce–Ni intermetallics.

Calculations involving both itinerant and localized electron states in the presence of a core hole are extremely diffcult to implement. Thus to analyse our RIXS data quantitatively we use a model already successfully applied to La 2p3d RIXS for lanthanum compounds [15]. In the ground state $|g\rangle$ La is known to have a purely $4f^0$ configuration with the $4f^1$ states lying too high in energy to make any significant contribution. Similarly the contribution from $4f^2$ in the ground state of Ce can be neglected but, as already stressed, both $4f^1$ and $4f^0$ contribute in the Ce mixed valent compounds:

$$|g\rangle = \sum_{i=0}^{2} a_i |f^i\rangle \quad (i = 0, 1, 2,), \tag{1}$$

where coefficient a_2 is negligible. In the intermediate (final) state the presence of an extra 2p (3d) hole, pulls the $4f^1$ and $4f^2$ states down (the hole is better screened) thus modifying the interaction

between the 4f and valence electrons. For the final state, we write

$$|\text{“}f^n\text{”}\rangle = \sum_{i=0}^{2} c_i^{(n)} |f^i\rangle \quad (i = 0, 1, 2,). \tag{2}$$

If we include the transition matrix elements implicitly in the *ac* terms, the intensity to the final state will be:

$$I(f^i) = \left| \sum_{j=0}^{2} a_0 c_j^{(i)} + \sum_{j=0}^{2} a_1 c_j^{(i)} \right|^2 . \tag{3}$$

In our model the densities of states are simulated by semi-ellipses located at different energies according to the whether the excitation is towards mainly $4f^2$, $4f^1$ or $4f^0$ states. The width is assumed to be determined by the 5d6s states themselves hybridized with the Ni conduction states. The RIXS spectrum is then built from a Gaussian excitation function whose amplitude is scaled according to the overlap with each configuration represented by the density of states convoluted with the 2p Lorentzian profile. As the width of the excitation is small compared to that of the 2p broadening we can simulate the final state by the convolution of the narrow 3d final state core hole with the sum of three gaussians centered at the excitation energy. Finally, further broadening is introduced to take into account the Gaussian spectrometer function. The energy offsets between the semi-ellipses and their width are chosen to give the best fit to the full set of experimental spectra using the excitation energy as the only variable. For more detail of the procedure see Ref. [15]. An example of the fit is shown in Fig. 4 for CeNi.

The values for the full-width at half-maximum of the 2p and 3d core-levels were taken to be 4.0 eV and 1.4 eV respectively. The width of the semi-ellipse was 5.5 eV. Other parameters are shown in the figures and the relative intensity of the $4f^2$ and $4f^1$ components are summarized in Table I. Values obtained by XPS are also given in this table.

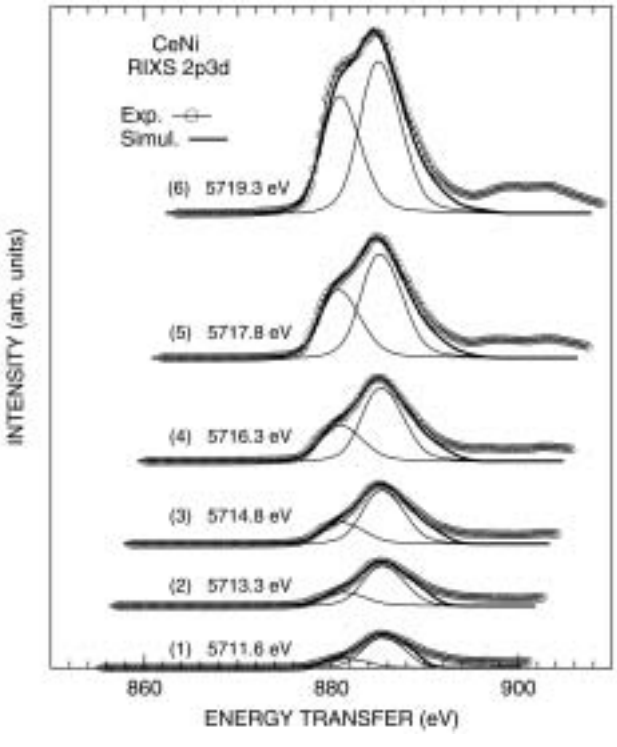

Fig. 4. Simulated Ce 2p3d RIXS spectra for CeNi.

Table I. *Relative intensities of f^2 and f^1 peaks as given from the simulation of the Ce 2p3d RIXS spectra. Values deduced from Ce 3d XPS spectra are also given.*

	$f^2/(f^1 + f^2)$			
	CeNi	$CeNi_2$	Ce_2Ni_7	$CeNi_5$
RIXS	0.16	0.21	0.20	—
XPS[a]	0.16	0.23	—	0.19

[a]From Ref. [6].

In the more straightforward case of La–Ni compounds where the ground state is not mixed valent it was found that the relative intensity of a $4f^1$-like final state increased as interaction with Ni 3d states in the final state increased. XAS measurements at the Ce L_3 edge show that the $4f^0$ peak increases in relative intensity as the Ni content increases. In such a case it is generally taken as directly related to the ground state coeffcients a_0 and a_1. It explains that XAS is widely used to measure f-count directly.

Our results indicate however that the structure at the Ce XAS L_3-edge is made up of two peaks one of which results from interaction with conduction states leading to a $4f^2$-like configuration. It is much stronger than would be expected from a quadrupole transition. It is also stronger in the two compounds with the larger Ni content. The values for the $f^2/(f^1 + f^2)$ ratios taken from XPS [6] are similar though they concern an ionized system unlike RIXS.

4. Conclusions

Ce 2p3d RIXS is able to reveal structure not observed in XAS measurements. The indications are that XAS may not be used as a straightforward method for estimating ground state f-counts because 4f–conduction-electron interactions in the intermediate state significantly modify the relative intensities of the peaks attributed to dipole transitions from the ground state configuration. The XAS peak originating from transitions from the mainly $4f^1$ ground state configuration has a component whose intensity increases with Ni content as its main component decreases. Because of the diffculty of constructing a reliable theoretical model, more detailed analysis across a large series of Ce compounds is required before quantitative corrections to XAS can be applied.

Abstract

The coordination environment of titanium atoms in the $x_1TiO_2\text{-}x_2BaO\text{-}x_3B_2O_3$ system, where $x_1 = 4\%$, 8%, 15% and $x_2/x_3 = 8/9$ (molar %), has been determined by X-Ray Absorption Near-Edge Structure (XANES) spectroscopy at the Ti K-edge. The environment of Ti atoms in BBT powder amorphous samples prepared using a chemical method is composed by $^{[4]}$Ti as the predominant specie but the $^{[6]}$Ti specie is also detected. After crystallization, titanium environment in powder samples is predominately composed by $^{[6]}$Ti species. The environment of titanium atoms in glassy samples produced by melting is very similar to that observed on the amorphous powdered samples. On the other hand, the environment of titanium in glass-ceramic samples is completely different from that of powder crystallized samples. A significant amount of $^{[4]}$Ti specie was found after the crystallization in the glass-ceramic samples.

1. Introduction

The crystallization process of the $BaO\text{-}B_2O_3\text{-}TiO_2$ (BBT) ternary system has been systematically studied [1, 2]. Depending on the composition, TiO_2 can act as a nucleating agent promoting the crystallization or inhibiting the crystallization process. According to the composition and the temperature of heat-treatment, the crystallization process can lead to the formation of interesting crystalline phases as the β-BaB_2O_4 (or β-BBO) phase [1, 2]. This phase has attracted the attention of many researches due its interesting optical non-linear properties, for example, a large effective second harmonic generation coefficient [3].

Recently, glass-ceramics samples containing non-centrosymmetric BaB_2O_4 (β-BBO) crystals by controlled devitrification of $x_1TiO_2\text{-}x_2BaO\text{-}x_3B_2O_3$ glasses, where $x_1 = 4\%$, 8%, 15% and $x_2/x_3 = 8/9$ (molar %) were prepared [2]. According to this work, for the $x_1 = 4\%$ sample we observed the formation of only the β-BBO crystalline phase whereas for the $x_1 = 8$ and $x_1 = 15\%$ samples the presence of a $BaTi(BO_3)_2$ phase was identified.

In order to better understand the role of TiO_2 on the crystallization process on the $BaO{-}B_2O_3\text{-}TiO_2$ system, we carried out the XANES analysis at the titanium environment from powder, glasses and glass-ceramics samples obtained from the $x_1TiO_2\text{-}x_2BaO\text{-}x_3B_2O_3$ system, where $x_1 = 4\%$, 8%, 15% and $x_2/x_3 = 8/9$ (molar % ratio).

2. Experimental details

Power samples (PW) from the $x_1TiO_2\text{-}x_2BaO\text{-}x_3B_2O_3$ system with $x_1 = 4\%$, 8%, 15% and $x_2/x_3 = 8/9$ (molar %), were prepared using the polymeric precursor method (Pechini Method) [4]. The heat treatments to produce powder samples were carried out in two stages: initial heating to 330 °C/5 h in an oxygen atmosphere at a heating rate of 10 °C/min to pyrolize the organic materials and "puff", followed soon thereafter by heating to 450 and 750 °C with a heat treatment time of 2 h.

Glass samples (GL) were prepared by mixing appropriate amounts of Commercial powders of reagents grade $BaCO_3$, TiO_2 and B_2O_3, and then melted in a platinum crucible in an electrically heated furnace for 3 hour at 1100 °C. To obtain glass-ceramics samples (GC), glass samples were mechanically polished to get a mirror surface, and then heat-treated in air in an electrically heated furnace at 620 °C during 120 h.

Ti K-edge edge X-Ray Absorption spectra were collected at the LNLS (Laboratório Nacional de Luz Sincrotron, Campinas, Brazil) facility using the XAS beam line [5]. The LNLS storage ring was operated at 1.37 GeV with a nominal ring current of 130 mA. Data were collected at the Ti K-edge (4966 eV) in transmission mode using a Si (111) "channel-cut" monochromator. Ionization chambers were used to detect the incident and transmitted flux. An energy step equal to 0.4 eV and 1.0 eV was used to collect the data at the near the region of the absorption edge. Due to the low critical energy of the machine, harmonic contamination from the monochromator is negligible at the energy of measurements [6]. To monitor the energy calibration, XANES spectra of a metallic foil was recorded at the same time as XANES spectra of the samples, using a third ionization chamber. From XANES data, the intensity of the pre-edge feature was obtained using a single Gaussian function. To compare the intensity and the position of the pre-edge features, all the XANES spectra were background corrected and normalized on the first EXAFS oscillation.

3. Results and discussion

The pre-edge region of the K-edge XANES spectra of some transition metal oxides are characterized by a pronounced feature several volts before the main rising edge. In transition metal oxides that crystallize in centrosymmetric structures, this pre-edge feature is very small or absent; in noncentrosymmetric structures it can be quite large. This pre-edge feature before the edge is commonly attributed to transitions from 1s energy levels of Ti to the Ti3d/O2p molecular orbital [7, 8]. A $1s \rightarrow 3d$ transition is Laporte forbidden by dipole selection rules but becomes allowed when p-d orbital mixing occurs such as which is located in a TiO_4 tetrahedron or a $(^{[5]}TiO)O_4$ site (i.e., without a center of symmetry) [8]. The height and position of this pre-edge feature are direct functions of the degree of p-d mixing, site distortion, oxidation state and experimental resolution [7, 8].

Recently, Farges *et al.* [8] showed empirically that the average coordination number of Ti in a range of titanium

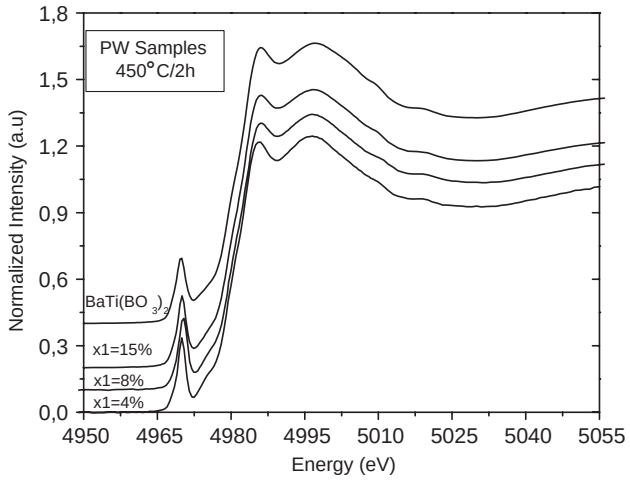

Fig. 1. Ti K-edge XANES spectra for powder amorphous samples (PW) compared to the XANES spectrum of $BaTi(BO_3)_2$ glassy phase.

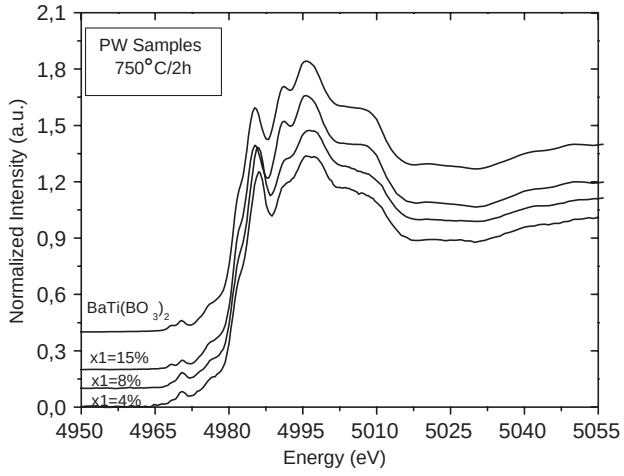

Fig. 2. Ti K-edge XANES spectra for powder samples (PW) crystallized at 750 °C during 2 h compared to the XANES spectrum of $BaTi(BO_3)_2$ crystalline phase.

oxide reference materials and titanium silicate glasses can be extracted reasonably well from plots of pre-edge intensity versus peak positions. Indeed, 4-, 5- and 6-fold coordinated Ti atoms appear to give pre-edge peaks at 4969.5, 4970.5 and 4971.5 ± 0.2 eV, respectively. Thus, the work of Farges *et al*. show that [4]Ti, [5]Ti and [6]Ti are distinguishable according to the position and height of the pre-edge peak [8]. This was the basis of a XANES study by Farges *et al*. in a large variety of minerals and glassy compounds [8].

Figure 1 shows the Ti K-edge XANES spectra of BBT powder samples (PW) heat-treated at 450 °C during 2 h. For comparison, the XANES spectrum of $BaTi(BO_3)_2$ glassy composition is also shown. According to X-ray diffraction measurements these samples are amorphous. The characteristics of the pre-edge structure for these PW amorphous samples and fot the $BaTi(BO_3)_2$ glassy composition are given in Table I. The pre-edge structure in all the amorphous PW samples is a unique and prominent peak at $4970,0 \pm 0.2$ eV, the same position of [4]Ti compounds [8]. However, the intensity of the pre-edge feature is lower than observed in [4]Ti compounds. The analysis of the pre-edge position and height in this series of samples, including the $BaTi(BO_3)_2$ glassy composition is characteristic of a mixture of [4]Ti and [6]Ti species.

Table I. *Pre-edge parameters for the pre-edge structure in PW (powder), GL (glass) and GC (glass-ceramic) samples and $BaTi(BO_3)_2$ glassy and crystalline phases.*

Sample	Position (eV) ± 0.2 eV	Normalized height (a.u.)
$BaTi(BO_3)_2$ glassy phase	4969.6	0.23
$BaTi(BO_3)_2$ crystalline phase	4970.3	0.04
PW $x_1 = 4\%$ TiO_2 450 °C/2 h	4970.0	0.30
PW $x_1 = 8\%$ TiO_2 450 °C/2 h	4970.4	0.28
PW $x_1 = 15\%$ TiO_2 450 °C/2 h	4970.1	0.28
PW $x_1 = 4\%$ TiO_2 750 °C/2 h	4970.4	0.05
PW $x_1 = 8\%$ TiO_2 750 °C/2 h	4970.4	0.05
PW $x_1 = 15\%$ TiO_2 750 °C/2 h	4970.5	0.03
GL $x_1 = 4\%$ TiO_2	4970.1	0.03
GL $x_1 = 8\%$ TiO_2	4970.1	0.03
GL $x_1 = 15\%$ TiO_2	4969.9	0.03
GC $x_1 = 4\%$ TiO_2	4969.8	0.23
GC $x_1 = 8\%$ TiO_2	4970.4	0.13
GC $x_1 = 15\%$ TiO_2	4970.0	0.16

Figure 2 shows the Ti K-edge XANES spectra of BBT powder samples (PW) heat-treated at 750 °C during 2 h. For comparison, the XANES spectrum of $BaTi(BO_3)_2$ crystalline phase is also shown. The characteristics of the pre-edge structures for these crystallized PW samples and for the $BaTi(BO_3)_2$ crystalline phase are also given in Table I. The pre-edge structure in all the PW samples heat-treated at 750 °C during 2 h is composed of two contributions at $4968,3 \pm 0.2$ and at $4970,3 \pm 0.2$ eV, the same position of [6]Ti compounds [8]. The intensity of the second contribution (associated to the dipolar transition) decreases as the amount of titanium increases. According to the literature, Ti atoms in the $BaTi(BO_3)_2$ crystalline phase are coordinated by 6 oxygen atoms located at 1.92 Å in regular octahedra [9]. This fact explains why the intensity of the pre-edge feature in this sample is smaller.

According to X-ray diffraction experiments, the $x_1 = 4\%$ and $x_1 = 8\%$ PW samples heat-treated at 750 °C could present the contribution of two crystalline phases, $BaTiO_3$ and $BaTi(BO_3)_2$. To verify this hypothesis, we simulated a mixing of the XANES spectra of these two crystalline phases. A good agreement was achieved when the simulated XANES spectra was supposed to the composed of 75% of the $BaTi(BO_3)_2$ phase and 25% of the $BaTiO_3$ phase. A similar result was obtained for the $x_1 = 8\%$ PW sample heat-treated at 750 °C.

Figure 3 shows the Ti K-edge XANES spectra of BBT glass samples (GL). For comparison, the XANES spectrum of $BaTi(BO_3)_2$ glassy composition is also shown. The characteristics of the pre-edge structures for these GL samples are given in Table I. As was observed for the PW amorphous samples, the pre-edge structure in all the GL samples is a unique and prominent peak at $4970,0 \pm 0.2$ eV, the same position of [4]Ti compounds [10]. Again, the intensity of the pre-edge feature is lower than observed in [4]Ti compounds. Thus, the pre-edge feature in these GL samples is characteristic of a mixture of [4]Ti and [6]Ti.

Figure 4 shows the Ti K-edge XANES spectra of BBT glass-ceramic samples (GC). For comparison, the XANES spectrum of $BaTi(BO_3)_2$ crystalline phase is also shown. The characteristics of the pre-edge structure for these glass-ceramic samples and that of $BaTi(BO_3)_2$ crystalline phase are also given in Table I. The pre-edge structure in all the GC samples is quite different when compared with the PW crystalline samples. Firstly, the XANES of GC samples presents a unique peak which intensity depends

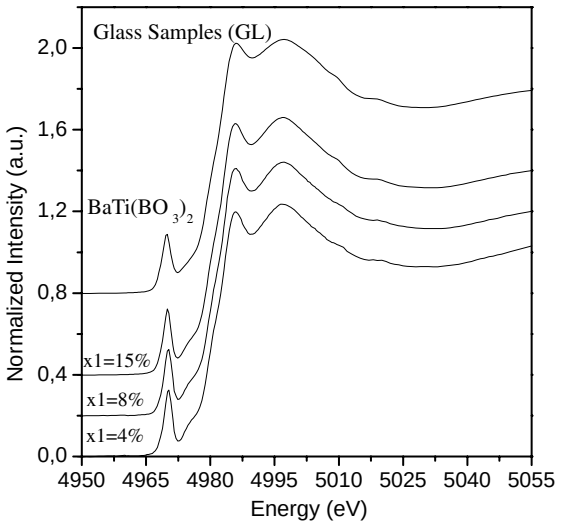

Fig. 3. Ti K-edge XANES spectra for glassy samples (GL) compared to the XANES spectrum of $BaTi(BO_3)_2$ glassy phase.

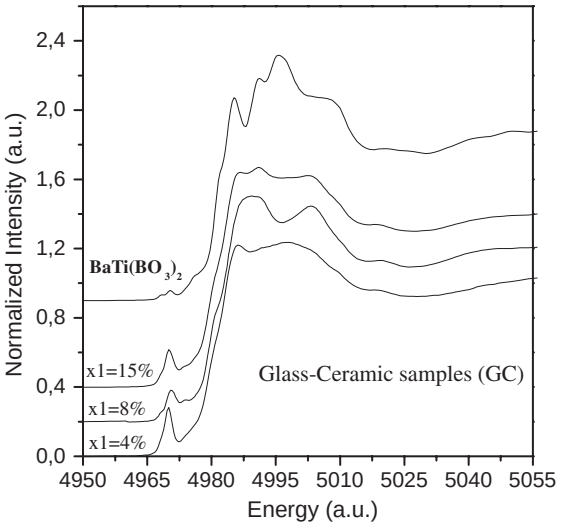

Fig. 4. Ti K-edge XANES spectra for glass-ceramic samples (GC) compared to the XANES spectrum of $BaTi(BO_3)_2$ crystalline phase.

on the amount of TiO_2: the intensity of the pre-edge feature for the $x_1 = 4\%$ GC sample is higher and comparable to that of the glass sample whereas in the $x_1 = 8\%$ and $x_1 = 15\%$ the intensity lower. For the three GC samples, the pre-edge feature is very different from that observed on the $BaTi(BO_3)_2$ crystalline phase. It seems that, although powder samples and glass-ceramic samples were obtained from a material presenting the same nominal composition, the crystallization process is influenced by the method used to prepare the samples, a chemical solution method and the melting method. According to the intensity and the position of the pre-edge feature of GC samples, we can infer that the pre-edge feature is characteristic in these samples contains the contribution from $^{[4]}$Ti and $^{[6]}$Ti, with the predomination of the $^{[4]}$Ti species.

4. Conclusions

XANES studies revealed that the local structure around Ti atoms in amorphous powder samples obtained using the polimeric precursor method is very similar to the local structure in glassy samples of same composition obtained by melting. In both set of samples, the pre-edge feature of the XANES spectra is characteristic of a mixture of $^{[4]}$Ti and $^{[6]}$Ti species. After crystallization, powder and glass-ceramic samples presents a different titanium local structure: in the powder samples, titanium atoms is present dominantly as $^{[6]}$Ti whereas in glass-ceramic samples, a mixing of $^{[4]}$Ti and $^{[6]}$Ti was observed. This difference can explain why we observed the crystallization of different phases on powder and glass-ceramic samples.

Abstract

Greigite Fe_3S_4 is one of the two natural magnetic iron sulphides. Its formula and structure make it the sulphide equivalent of magnetite Fe_3O_4, leading to frequent confusions between these two spinelles in paleomagnetic studies and possible wrong interpretation of some paleaomagnetization measurements.

We have carried out high resolution EELS experiments and recorded X-ray magnetic circular dichroic spectra at the iron $L_{2,3}$ edges on natural and synthetic samples. The natural samples present a core-shell structure of crystallized greigite surrounded by an amorphous iron oxide phase. The differences observed on the XMCD signal of Fe_3S_4 compared to Fe_3O_4 could be explained by the presence of iron vacancies, Fe_3S_4 being a lacunary iron sulphide.

1. Introduction

The study of rock magnetization gives information about the magnetic history of the Earth. Paleomagnetism, in association with other methods, allows to date precisely geological events like appearances and disappearances of animal species or to follow the movements of the lithospheric plates. Dating events thanks to this method is possible because the Earth magnetic field reverted its orientation several times at the geological scale of time.

Among the numerous iron-sulphide minerals, only two are ferrimagnetic, all the others being antiferromagnetic or having complicated magnetic structure (van Vleck paramagnetism). These two magnetic iron sulphides are pyrrhotite Fe_7S_8 and greigite Fe_3S_4. These minerals keep a print of the inversions of the Earth magnetic field. Thus their remanent magnetization is used as the starting point of paleomagnetic studies. Nevertheless, their electronic properties are not well known because they often occur as mixed phases and with an oxidized surface layer.

Fe_3S_4 is a sulphospinelle. Fe_3S_4 and magnetite Fe_3O_4 have the same cubic crystalline structure with octahedral and tetrahedral sites. They only differ by their anions. However, the repartition of Fe^{2+} and Fe^{3+} is not known in Fe_3S_4. Moreover, Fe_3S_4 presents a saturation magnetization by formula unit 2.5 times lower than Fe_3O_4 [1]. It has a different easy-magnetization axis ([100] instead of [111]) [2]. It shows no Verwey transition: whereas at temperature lower than 120 K, a distorsion of the cubic structure has been observed in Fe_3O_4, accompanied by a brutal decrease of the magnetic susceptibility, no such phenomenon has been seen on Fe_3S_4.

All these differences occur despite a similar crystal structure. Iron sulfiphides require a reducing environment. Iron should thus be mainly present as Fe^{2+}. But this would not be sufficient to account for the observed reduction of the magnetization. An other explaination for the reduced magnetization could be the presence of iron vacancies on the octahedral sites.

We have studied both natural and synthetic samples. The complexity of natural samples needs a preliminary observation by transmission electronic microscopy (TEM) associated with energy electron loss spectroscopy (EELS) in order to study the composition and crystalline structure of the sample and to investigate its stability on a period of time of several weeks. The study of the magnetic properties implies the use of X-ray absorption spectroscopy (XAS) and in particular X-ray magnetic circular dichroism (XMCD). To separate the contributions of Fe^{2+} and Fe^{3+} in the octahedral and tetrahedral sites, we followed an approch similar to that exposed in a companion paper by S. Brice-Profeta. However, in iron sulphides, the covalence of the bonds is stronger than in oxides. This implies that the multiplet structures are less visible than in oxides. In consequence, the selectivity of site and of oxidation state is less precise in sulphides than in oxides.

2. Samples description

The natural samples have been collected in the marine sediments uncovered by the errosion caused by the Crostolo River, Po Valley, Italy [3]. Fe_3S_4 is probably of biogenic origin, synthetized inside or around bacteria. Fe_3S_4 particles are separated from the sediment by a magnetic extraction in desoxygenized water. Using this method, we clear the sample from non-magnetic materials which can contain iron and disturb the XAS measurements. However, the resulting extracted sample may contain other magnetic particles among which some might bear iron.

We compared these natural biogenic samples to synthetic ones obtained by hydrothermal synthesis from Mohrs solution $Fe(NH_4)_2(SO_4)_2$ and sodium sulphide NaS_2 in desoxygenized water solution [4].

3. Experimental results

The TEM and EELS experiments have been carried out on the High Resolution TEM Akashi Topcon EM-002B of the LPS (Orsay, France) and on the 2010F Jeol microscope of the CP2M (Marseille, France). XAS measurements have been carried out on the SU23 beamline at LURE (Orsay, France) and on the BACH beamline at Elettra (Trieste, Italy). Spectra have been recorded at the iron $L_{2,3}$ edges.

3.1. *EELS: the core-shell structure of the particles*

The TEM study of the natural samples showed grains of about 50–200 nm wide, as presented in fig. 1. These grains are constituted of a core and a shell. The shell is about 10 nm thick when observed a few days after the extraction. It constitutes the totality of the grains after a few weeks. In the core, diffraction features appear clearly whereas the shell appears amorphous. We have recorded EELS spectra on both the core and the shell of several particles. We recorded spectra from a few eV after the

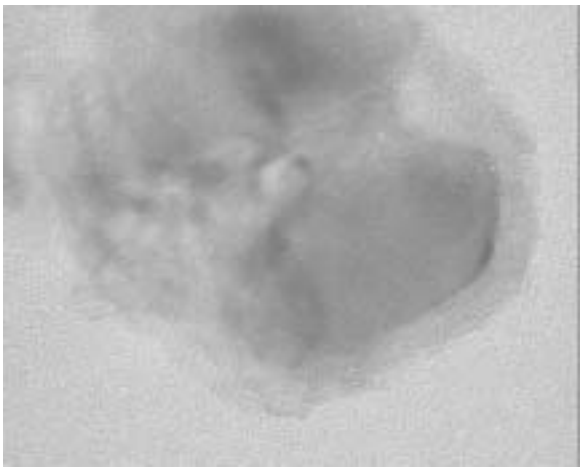

Fig. 1. TEM picture of a grain of crystalline iron sulphide surrounded by a shell of amorphous iron oxide.

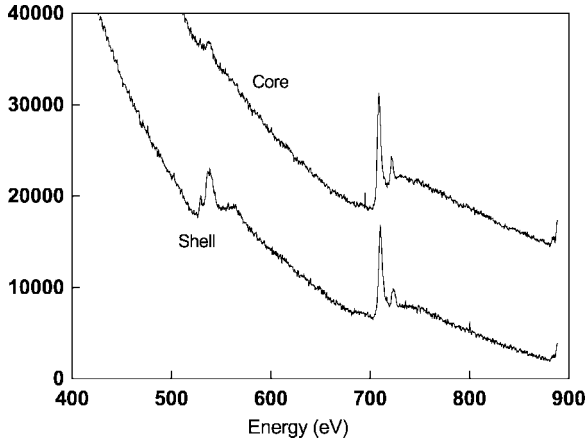

Fig. 2. EELS spectra recorded separately on the core and on the shell of a particle of natural Fe_3S_4: oxygen K-edge and iron $L_{2,3}$ edges.

elastic feature to 900 eV. The O K-edge to Fe $L_{2,3}$ edges range is shown on fig. 2. The spectrum recorded on the core shows absorption at the S and at Fe $L_{2,3}$ edges and slight absorption at the O K-edge. On the contrary, the spectrum recorded on the shell presents strong absorption at the O K-edge and Fe $L_{2,3}$ edges but not at the S $L_{2,3}$ edges. The Fe $L_{2,3}$ edges feature is typical of spectra obtained on iron oxides. The shell is thus contituted of an amorphous iron oxide phase. An electron diffraction on the core confirms that this crystalline iron sulphide phase is greigite.

TEM observations on the synthetic samples have shown crystallized greigite particles of a few hundred nanometers wide. The synthetic particles were observed a few days after the synthesis and did not present any feature of oxidation. No measurement was carried out after a few weeks or months thus we have no idea of the way synthetic greigite oxidizes when aging.

EELS spectra have also been recorded with a better energy resolution on both the core and the shell of several particles. The spectra are shown on fig. 3. One can notice that the signal recorded on the sulphide part of the particle also contains the contribution of the surface. Indeed, to reach the core of the particle, the electron beam goes accross the oxide shell, which can contitute up to 20% of the explored volume depending on the oxidation rate of the particles.

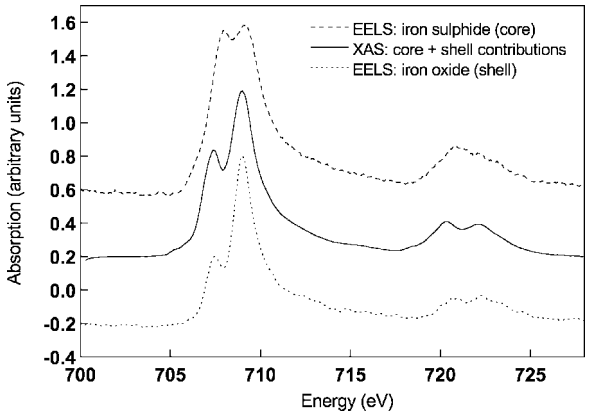

Fig. 3. Comparison of the iron $L_{2,3}$ edges spectra recorded by EELS respectively on the sulphur and on the oxide part of a particle and by XAS (fresh natural sample).

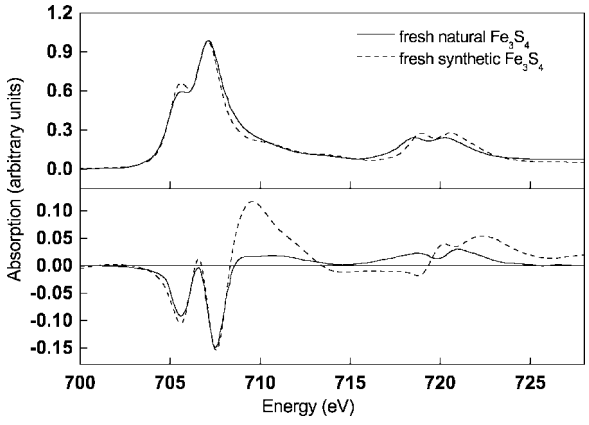

Fig. 4. Isotropic and dichroic spectra recorded at 4.2 K in a magnetic field of $+/-2$T on the natural and synthetic samples. The magnetization is saturated.

3.2. *XAS and XMCD*

Contrary to EELS, XAS and XMCD can give information on the magnetic properties. This spectroscopy does not bring as good spatial resolution as EELS, but brings a better energy resolution. The XAS spectra of natural greigite are the result of both contributions of the core and the shell of the particles (see fig. 3). In the same way, the XAS spectra of recently synthetized greigite is intermediate between the hematite spectra and the iron sulphur EELS spectra. It may be the result of a similar oxidation process that may yield a core-shell structure.

In order to determine the repartition between Fe^{3+} and Fe^{2+} in Fe_3S_4, we have recorded XMCD spectra on natural and synthetic Fe_3S_4. The signals are shown on fig. 4.

4. Interpretation

In samples as complexe as natural magnetic minerals, coupling the two techniques, EELS and XMCD, is necessary.

4.1. *Oxidation towards hematite*

XAS spectra on synthetic greigite have been recorded a few weeks after the synthesis and six months after. The isotropic spectra presented on fig. 5 show that the aging of greigite leads to an iron oxide very close to hematite α-Fe_2O_3, mineral containing only Fe^{3+} in octahedral sites. The spectrum of recently

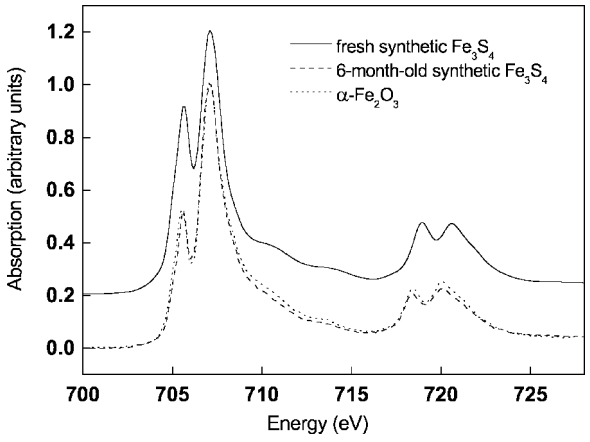

Fig. 5. XAS at iron $L_{2,3}$ edges spectra showing the evolution of synthetized Fe_3S_4 toward hematite.

synthetised Fe_3S_4 presents a stronger contribution for feature B. Fresh synthetic Fe_3S_4 shows dichroism (see fig. 4) whereas older synthetic Fe_3S_4 does not show any dichroic signal. Since the oxidized phases are stable, this result may evidence that the dichroic signal observed on fresh Fe_3S_4 is due to sulphide and not to oxide.

4.2. *No oxide contribution to the dichroic signal*

EELS spectra showed that the surrounding shell is contituted of amorphous iron oxide. This oxide probably leads to ferrihydrite or hematite α-Fe_2O_3. At 4 K, hematite is antiferromagnetic. The magnetic contribution of the shell to the spectra is thus a paramagnetic or antiferromagnetic contribution. Thus, whereas the isotropic spectra is the sum of oxide and sulphide contributions, the observed dichroic signal may be only due to the Fe_3S_4 core.

4.3. *Comparison between natural and synthetic samples*

The two samples present similar isotropic cross sections though XMCD signals are pretty different. We attribute the differences to various ratio of oxide *vs* sulphide contributions. The large positive bump after the L_3 edge is a clear sign of Fe-S hybridization. Fe_3S_4 structure can accomodate for various electronic and crystallographic modifications (Fe^{2+}/Fe^{3+} ratio or presence of vacancies) so that, even without spurious oxidation contributions, similar phases could yield quite different XMCD spectra. To illustrate this point, XMCD signals of γ-Fe_2O_3 and Fe_3O_4 are quite different although they are almost indistinguishable by diffraction techniques.

Compared to the dichroic signal obtained on Fe_3O_4 (presented on fig. 6), at the L_3 edge, the ratio of the two peaks is reverted: in Fe_3S_4, feature A is weaker than feature A′ and it is the contrary

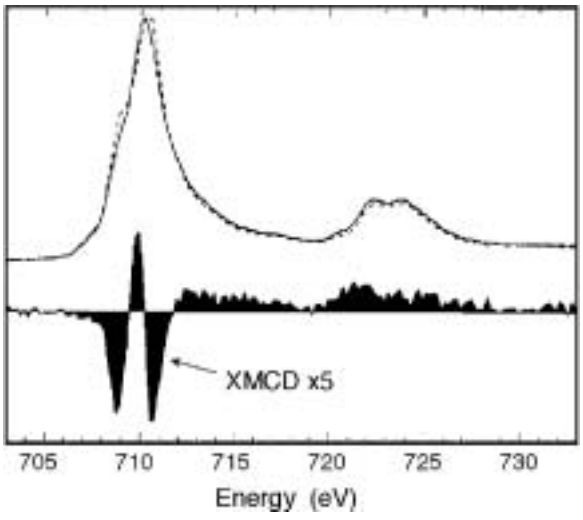

Fig. 6. Isotropic and dichroic spectra recorded on Fe_3O_4 [5].

in Fe_3O_4. This can be attributed to a contribution of Fe^{2+} in octahedral sites weaker in Fe_3S_4 than in Fe_3O_4.

5. Conclusion

EELS on natural greigite showed a core-shell structure composed of a core of well-crystalized Fe_3S_4 and a shell of amorphous iron oxide, possibly precursor of hematite α-Fe_2O_3. XMCD spectra more probably take into account only the sulphur contribution. The differences observed between the XMCD spectra of Fe_3S_4 and Fe_3O_4 can be explained by the presence of iron vacancies in Fe_3S_4 leading to a lacunary iron sulphide similar to the lacunary iron oxide maghemite γ-Fe_2O_3.

Abstract

The process of iron film epitaxial growth on the 4 × 6 reconstructed surface of GaAs(001) proceeds through a transition between island (Volmer-Weber) and layer (quasi-Frank-van-der-Merwe) growth. We have examined the growth of iron on GaAs(001)-(4 × 6) *in-situ* by polarization-dependent XAFS in the total reflection mode. The onset of greater ordering in the film has been observed through the development of tetragonally-distorted iron. The distortion towards lattice-matching between the iron in-plane and the GaAs substrate is clearly evident immediately after the transition between growth modes. The resulting body-centered tetragonal structure persists to 30 monolayers, the largest thickness studied.

1. Introduction

Iron films on GaAs substrates continue to attract interest for magnetic applications owing to the small (1.4%) mismatch between body-centred cubic (bcc) Fe and half the lattice constant of GaAs. Studies of the evolution of film stress, surface morphology and magnetic behavior have been performed [1–3] using the (4 × 6) reconstruction of the GaAs surface. Using this reconstruction minimizes reaction between the iron and substrate [4] and results in high-quality epitaxially-grown films [5] but with the possibility of macroscopic defects for thicker films [2].

Missing from the picture of iron on GaAs(001)-(4 × 6) is an understanding of how the structure changes with increasing thickness. There is a transition in growth modes from Volmer-Weber (island) to quasi-Frank-van-der-Mewe (layer) growth [5] that occurs near 4 monolayer (ML) thickness, and the iron is reported to be distorted to a body-centred tetragonal (bct) structure near 10 ML that favors lattice-matching to the substrate [6]. We have extended our polarization-dependent XAFS structural study [6] of the bct distortion with measurements above and below the transition in growth modes to better understand how these iron films on GaAs(001) evolve as a function of thickness.

2. Experimental

Samples were prepared and measured *in-situ* using the molecular beam epitaxy (MBE) facilities of the Pacific Northwest Consortium Collaborative Access Team (PNC-CAT) beamline – sector 20 of the Advanced Photon Source, Argonne National Laboratory [7]. Gallium arsenide (001) n-type wafer sections (American Xtal Technology) underwent a thermal desorb treatment before sputtering (500 eV Ar^+) and anneal to achieve the (4 × 6) reconstruction. Room temperature deposition was done with RHEED monitoring using Omicron EFM3 evaporators and growth rates of ∼0.5 ML per minute. Samples with Fe thicknesses of (ML-equivalent) 0.5, 2, 3.5, 5, 6, 9.3, 15, 16 and 30 were prepared. The 15 ML sample was prepared on top of the 3.5 ML sample; the 30 ML was on top of the 16 ML sample, after XAFS data on the first thickness were obtained. RHEED oscillations were not observed for the second thicknesses deposited.

XAFS measurements were done on the undulator beamline of the PNC-CAT. The Si(111) double-crystal monochromator was detuned to 75% of the maximum intensity at 7500 eV to reduce harmonic contributions. X-rays were incident in the total-reflection geometry with the polarization vector either (near) perpendicular or in the plane of the substrate (within 2° of (110), (−110) or (010) orientations). To minimize distortion of the spectra due to dispersion effects in the sample and adjacent media, the angle of incidence was set to approximately 2/3 of the critical angle at 7500 eV [8]. Fluorescence XAFS data were obtained using Argon-filled ionization chambers [9] or, for the two thinnest samples, a 13-element Ge(Li) detector (Princeton-Gamma-Technology). Helium-filled transmission chambers were used for normalization and reference data.

3. Results

EXAFS interference functions, $\chi(k)$, were extracted from the absorption spectra using AUTOBK [10]. Figure 1 shows the averaged EXAFS interference functions for perpendicular polarization measurements on each of the thicknesses measured. A reference Fe foil and a sample in-plane (16 ML) plot are also shown for comparison. The 16 ML in-plane and foil bear a much stronger resemblance to each other than to any of the out-of-plane data. This is particularly noticeable in the region 2.3–7 $Å^{-1}$. Noticeable differences exist between foil and film (out-of-plane) that indicate the persistence of the bct distortion up to and including the 30 ML film. In particular, both the reduced amplitude of the oscillation at 5 $Å^{-1}$ when compared to the foil and the absence of a feature at 6 $Å^{-1}$ for the out-of-plane 30 ML data are strong indications that the thickest film measured has not relaxed to body-centred-cubic. With decreasing thickness, fine structure in the $\chi(k)$'s decreases to the point that the two thinnest samples appear almost as single frequencies.

Fourier transforms, with k^2-weighting and 10% Gaussian windows, were taken and analyzed using WINXAS [11] and FEFF7 [12]. Transforms were taken over the range 2.37 $Å^{-1}$ to the end as plotted in Fig. 1, typically 14.2 $Å^{-1}$. Analysis was done over the first peak in the Fourier transform, as shown for the 16 ML and 6 ML samples in Figure 2 in order to extract nearest-neighbour and next-nearest-neighbour (*c*-axis) information. To allow for the presence of Ga or As beneath, on-top or within the film, alloying models were used in the FEFF simulations. Since gallium and arsenic are essentially indistinguishable in backscattering from each other and the element in between them,

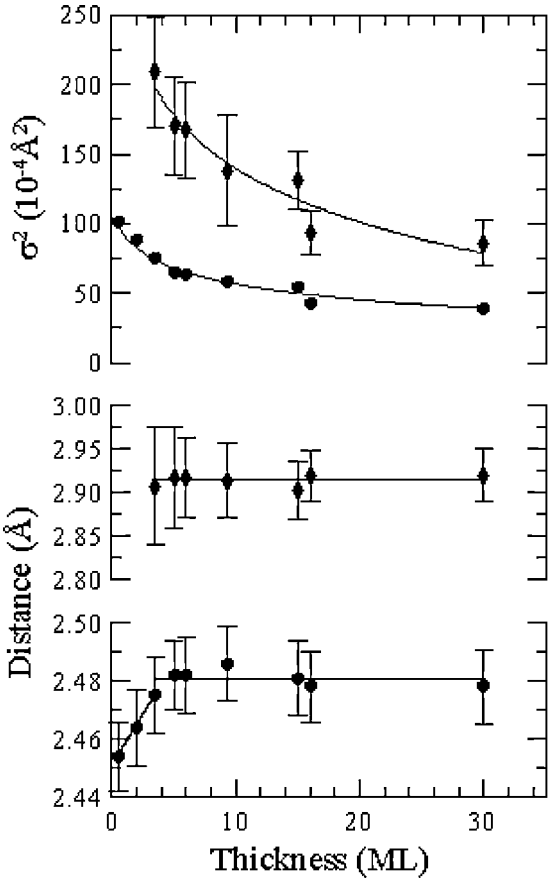

Fig. 3. Distances and mean-square relative displacements for the two shells (nearest-neighbour, lattice constant) contained in the first peak of the Fourier transform. Error bars for nearest-neighbour σ^2 are comparable to the size of the point. Curves are drawn as a guide for the eye.

germanium, we simplified the calculations by using Ge as the average of both. It is also challenging to distinguish Fe from Ga or As in backscattering. The extent of alloying (fraction non-iron species in film) was increased in the simulations with decreasing film thickness. This was done based on a starting structural model of a bct iron film capped below by Ga (for the gallium-rich 4×6 substrate surface) and above by As (As segregating to the film surface [5]), with the simplification of using Ge for Ga and As. With coordination numbers fixed according to this model, the influence of non-Fe species decreases for the average Fe atom with increasing Fe thickness. For 9.3 ML and higher, a pure Fe model give comparable fit results, indicating an insensitivity to non-Fe species at the 10% level or below.

Fit results for these two shells are summarized in Figure 3. Small offset corrections of order 0.01 Å were applied based on reference iron foil fit results. Distances for both Fe and non-Fe atoms (Ge in place of Ga and As) in a given backscattering path were constrained to be the same for both species present in that shell. The mean-square-relative-displacements for both species were similarly constrained. This did not result in any difficulty in fitting that would mandate a splitting of these into independent parameters. We were unable to obtain second shell information for the 2 ML and 0.5 ML samples. At 3.5 ML, we are at the transition point between growth modes and are able to obtain some second shell information. For 3.5 ML and higher, we observe fairly constant values for the nearest-neighbour and c-axis distances, with no detectable dependence of the distortion to bct on thickness up to 30 ML (30 ML roughly corresponds to a film 44 Å thick).

The σ^2 values increase with decreasing thickness, consistent with an increasing ratio of surface to interior atoms (fewer atoms bound inside the film) and may also reflect an increasing influence of substrate atoms within the iron film. For comparison, the foil and 16 ML in-plane values (in Å^2) for ${\sigma_1}^2$ and ${\sigma_2}^2$ are 0.0050(2) and 0.0064(5) for the foil, and 0.0051(5) and

0.0067(9) for the 16 ML film. The $\sigma_2{}^2$ values for the out-of-plane polarization plotted in fig. 3 are considerably larger than the in-plane or foil values. This may be due to increased disorder or (surface) roughness in the out-of-plane direction, but may also be due to the strained nature of the film itself. For both polarizations, the nearest-neighbour interactions are largely in-plane, since the nearest-neighbour in a bcc or bct structure is located approximately 36° above the plane (the angle between the [111] and [110] directions). Next-nearest neighbour interactions for in-plane are also in-plane, but, for the out-of-plane measurements, the next-nearest neighbour is 90° above the plane – entirely out of plane. The out-of-plane direction is the direction of response to the in-plane stress. It is not unreasonable to expect a larger dynamic contribution to the mean-square-relative-displacement in this case, but a temperature-dependent study would be required to confirm this.

For the 3.5 ML and below, the nearest neighbour distance appears to contract relative to the thicker films, approaching the Ga-As bond length in GaAs (2.448 Å) for the average iron atom as the Fe coverage tends towards zero monolayers. This suggests some reaction with the substrate where Fe could be occupying As or Ga vacancies at or near the surface. This is consistent with the observed tensile stress in such films [1] whose origin was attributed to diffusion of Ga or As out of the substrate and the possible re-occupation of the resultant voids by iron.

Acknowledgments

Experiments at the PNC-CAT beamline were made possible by support from the Natural Sciences and Engineering Research Council of Canada, through major facilities access and operating grants. Research at the PNC-CAT and the APS is also supported by the U.S. Department of Energy, Basic Energy Sciences under contracts W-31-109-Eng-38 (APS) and DE-FG03-97ER45628 (PNC-CAT).

Abstract

The magnetic behaviour of ferromagnetic/non-ferromagnetic/ferromagnetic trilayers is strongly dependent on the nature of the interface between layers, the strain in the layers and the extent of any interdiffusion or reaction between layers and substrate. In this paper, results are presented from a polarization-dependent *in situ* XAFS study of Fe/Pd/Fe trilayers epitaxially grown on GaAs(001)-(4 × 6). Fe and Pd K-edge spectra were obtained both above and below the critical angle for total reflection. The structure of iron grown on the Ga-terminated 4 × 6 reconstructed surface of the GaAs(001) substrate, for thicknesses greater than 6 monolayers, is tetragonally distorted from its natural bcc structure with contracted and expanded lattice constants in the in-plane and out-of-plane directions, respectively. The intermediate Pd layer shows distortion from its natural fcc structure. Alloying at the interface with the underlying Fe is restricted to a depth of 0.5–1.0 monolayers (ML). The upper layer of Fe shows tetragonal distortion similar to the layers of Fe grown on GaAs(001)-4 × 6. However, the upper distortion is stronger. There is also evidence of alloy formation at the interface involving the underlying Pd with the thickness of the alloy region being 2–2.5 ML.

1. Introduction

The small lateral dimensions of spintronic devices and high density memory bits require the employment of magnetic ultrathin metallic film structures. In magnetic trilayer systems of the form F/M/F the magnetic moments in the ferromagnetic film F are locked together by exchange coupling through the non-magnetic spacer layer M. The magnetic behaviour in these systems – the magnetic anisotropy and interlayer coupling – is strongly dependent on the thickness of the layers, the nature of the interface between layers, the strain in the layers and the extent of any interdiffusion or reaction between layers and substrate. Understanding the structure is a critical component of developing the correct interpretation of the magnetic behaviour. A molecular beam epitaxy facility was developed for use on the PNC-CAT undulator beamline to permit *in situ* epitaxial growth of metal films and their structural characterization by synchrotron radiation techniques.

In an earlier study [1] we used polarization-dependent XAFS in the total reflection mode to characterize the epitaxial growth of Fe on GaAs(001)-(4 × 6). The small lattice mismatch of 1.4% between bcc iron ($a = 2.866$ Å) and GaAs ($a/2 = 2.827$ Å) has made it a model system for growth of ferromagnetic materials on semiconductors. Quantitative analysis of our *in situ* XAFS data [1, 2] indicated a body-centered tetragonal (bct) structure with $c/a \sim 1.03$ starting at ~ 5 ML (monolayers) and persisting to 30 ML, the thickest film studied.

Here, we present *in situ* results of a polarization-dependent XAFS study both above and below the critical angle for total reflection from Fe/Pd/Fe trilayers epitaxially grown on GaAs(001)-(4 × 6). Palladium was chosen as the spacer layer for three reasons. 1) Pd is easily influenced magnetically by ferromagnetic species such as iron. 2) Pd has been grown on single crystal Fe(001) [3] and Fe has been grown on the surface of Pd(001) grown on MgO [4–6], but with different structural conclusions. 3) The lattice mismatch between the naturally occurring fcc structure of Pd and the in-plane lattice of bct Fe grown on GaAs(001)-4 × 6 is smaller than for single crystal bcc Fe(001). Thus Pd in the GaAs trilayer system will have a different elastic strain, different structure and consequently different magnetic response than when substrates of Fe(001) or Pd(001) are used.

2. Methods and Materials

Samples on GaAs(001)-(4 × 6) were prepared *in situ* by MBE on epiready n-type GaAs (American Xtal Technology) wafers as described elsewhere [1, 2]. Layer deposition was monitored by reflection high energy electron diffraction, RHEED, with the number of oscillations of specular (anti-Bragg) spot intensity giving the layer thickness in ML. These measurements were used as calibration for the rate of deposition.

In growing the Fe/Pd/Fe trilayer sample, 30 ML of Fe were first deposited. Ar^+ sputtering was then used to remove the less than 1 ML of As from the GaAs that is known to float to the surface during Fe deposition [1, 7]. The sample was annealed for 30 minutes at ∼150 °C and another 8.5 ML of Fe were deposited at the anneal temperature. This is referred to as the 38.5 ML Fe sample. Subsequently the following overlayers were grown: 3.5 ML Pd; 3.5 ML Pd for a total of 7 ML Pd; 4 ML Fe; and 6 ML Fe for a total of 10 ML Fe. The Fe and Pd deposition rates were ∼0.4 ML/min and ∼0.3 ML/minute, respectively.

XAFS measurements were made using the PNC-CAT undulator beamline, ID-20 [8]. The Si(111) double-crystal monochromator was detuned above the Fe and Pd K-edges to 75% of the maximum intensity to reduce harmonic contributions. X-rays were incident in the total-reflection geometry with the electric vector either (near) perpendicular, $\boldsymbol{E}_{\perp}$, or in the plane of the substrate, $\boldsymbol{E}_{||}$ (within 2° of (110) and (−110) orientations). To minimize distortion of the spectra due to anomalous dispersion effects in the sample and adjacent media, the angle of incidence was set to approximately 2/3 of the critical angle φ_C, at 250 eV above the respective K-edges [9]. Fe K-edge measurements, $\boldsymbol{E}_{||}$, were also made at $\sim 2\varphi_C$ after deposition of 3 ML Pd in order to examine the effect of growing overlayers of Pd on the structure of the underlying Fe. All XAFS data on the trilayers were acquired using total electron yield.

The EXAFS interference functions were extracted using AUTOBK [10] while fixing E_o at the first inflection point.

*crozier@sfu.ca

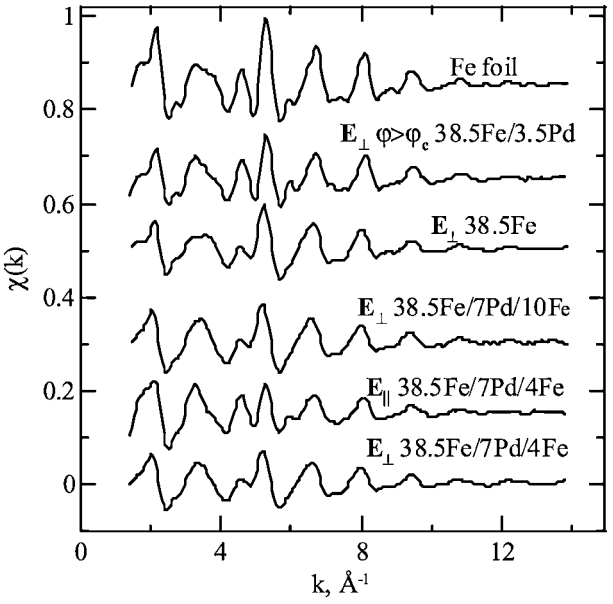

Fig. 1. The Fe K-edge EXAFS interference functions $\chi(k)$ for the X-ray polarization perpendicular to (along the normal to) and parallel to the GaAs(001) substrate for Pd and Fe films of different thickness. A reference iron foil $\chi(k)$ (top) is shown for comparison. The angle of incidence on the films is 2/3 the critical angle φ_C, except for the upper $\chi(k)$ where $\varphi = 2\varphi_C$.

Polarization-dependent XAFS amplitudes and phase shifts were calculated using FEFF 7 [11] and non-linear least squares fitting of the Fourier transform of $k\chi(k)$ was done using WINXAS [12].

3. Results

The characteristic differences between the $\chi(k)$ of iron foil over the range 3 to 7 Å^{-1} in Fig. 1 and $\boldsymbol{E}_\perp$ of the 38.5 ML sample indicate that the latter has a bct structure [1, 2]. When 3.5 ML of Pd are deposited and the structure of the iron probed by XAFS measurements at $2\varphi_C$, the similarity of $\boldsymbol{E}_{||}$ to iron foil indicates that the overlayer of Pd has not significantly changed the bct structure of the underlying 38.5 ML Fe. When 10 ML Fe are deposited on 7 ML of Pd, the $\boldsymbol{E}_\perp\chi(k)$ is similar to the $\boldsymbol{E}_\perp\chi(k)$ for the bct 38.5 ML Fe. However, for the initial 4 ML Fe grown on Pd, inspection of the $\chi(k)$ for $\boldsymbol{E}_\perp$ and $\boldsymbol{E}_{||}$ indicates differences over the 3 to 4 Å^{-1} range.

The $\chi(k)$ for the Pd K-edge are shown in Fig. 2. Relative to Pd foil, at high k, the $\chi(k)$ of the films have decreased amplitudes and appear to contain only a single frequency. There are differences over the range 3 to 5 Å^{-1}. The change of slope at 4 Å^{-1} is less pronounced for $\boldsymbol{E}_{||}$ in the 7 ML data than in the Pd foil. The $\chi(k)$ for $\boldsymbol{E}_{||}$ for 7 ML has a change of slope at 3 Å^{-1} not observed in the foil. $\boldsymbol{E}_\perp$ is different from $\boldsymbol{E}_{||}$ over the range 3 to 5 Å^{-1}. In the 3.5 ML data the $\chi(k)$ for $\boldsymbol{E}_\perp$ is similar to that for 7 ML. There are subtle differences between $\boldsymbol{E}_{||}$ and $\boldsymbol{E}_\perp$ in the 3.5 ML data.

Detailed analysis, done in R-space, indicates that in our Fe/Pd/Fe trilayer system in all three layers the Fe and Pd are distorted from their natural bcc and fcc structures, respectively. Alloy is formed at both Fe/Pd and Pd/Fe interfaces. The amount of alloying is smaller at the first interface compared to the second. Main aspects of the analysis are given below.

The magnitudes of the Fourier transforms of $k\chi(k)$ for the Pd data are shown in Fig. 3. Polycrystalline Pd has a fcc structure with n.n. distance $R_1 = 2.75$ Å and second n.n. $R_2 = 3.89$ Å.

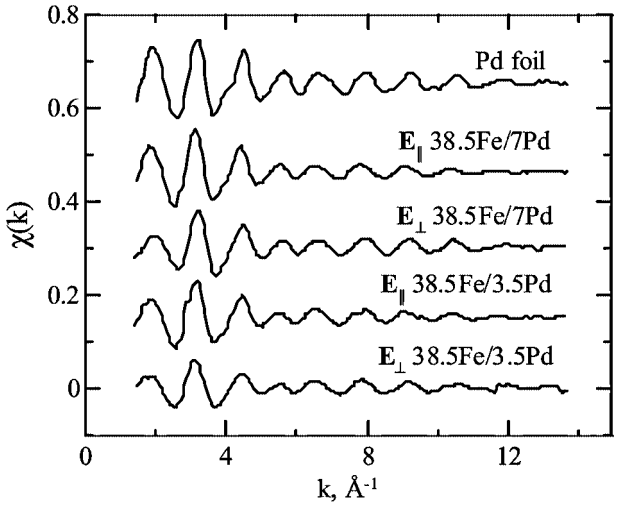

Fig. 2. The Pd K-edge $\chi(k)$ for the X-ray polarization perpendicular to and parallel to the GaAs(001) substrate for Pd films of different thickness. A reference Pd foil $\chi(k)$ (top) is shown for comparison.

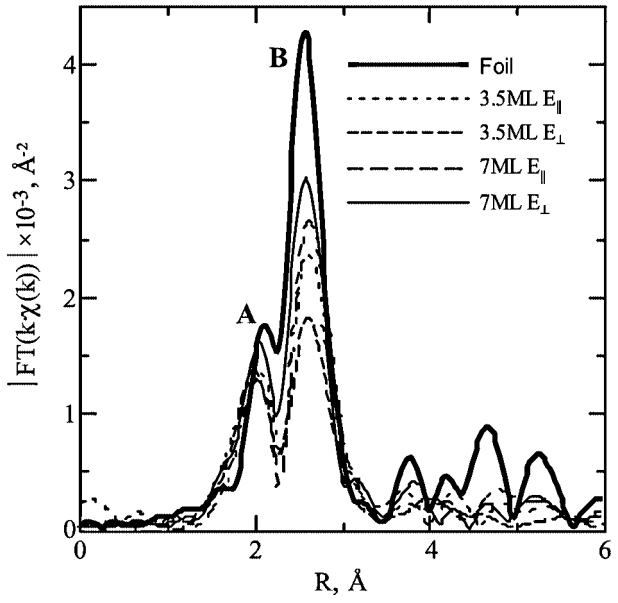

Fig. 3. The magnitude of the Fourier transform of $k\chi(k)$ for the Pd films and Pd foil. The transforms were calculated with a 20% Gaussian window over the k-space range 2.3–12.3 Å^{-1}.

The splitting of the main peak into A and B is produced by the k-dependence of the Pd backscattering amplitude, $f(k, \pi)$, when convolved with the n.n. distribution function. Using FEFF 7 the offset between the fit and crystallographic distances for Pd foil are ~0.01 Å for R_1 and 0.03 Å for R_2. Inspection of Fig. 3 reveals the peak ratio B/A decreases as the thickness of the film decreases. This is caused by backscattering from the underlying Fe, some of which has alloyed with Pd.

Fig. 4 shows the result of fitting 3.5 ML Pd with the electric vector parallel to the substrate. The imaginary parts of the Fourier transform for Pd-Fe and Pd-Pd are almost in-phase under peak A but become out-of-phase under peak B. This interference makes the fit sensitive to the Pd-Fe interface. Also shown in Fig. 4 is the magnitude of the Fourier transform obtained from a fit to the n.n. Pd-Fe distance and three Pd-Pd distances to 4.7 Å.

Analysis of $\boldsymbol{E}_\perp$ and $\boldsymbol{E}_{||}$ for the 3.5 ML Pd sample revealed that Pd has a fct structure expanded in-plane and contracted

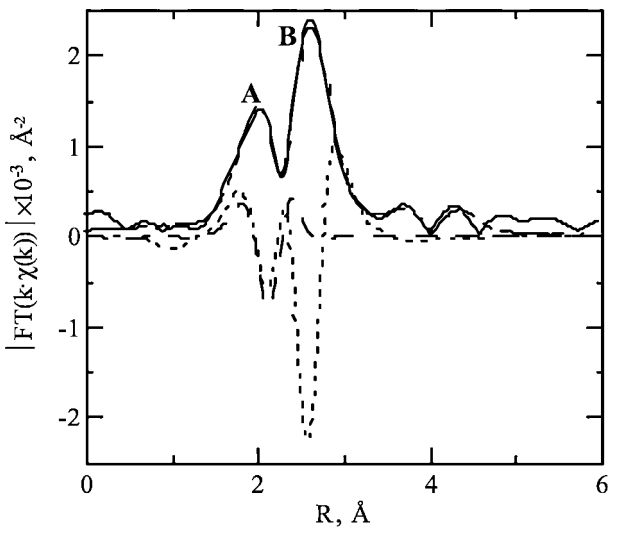

Fig. 4. The contribution of Fe and Pd to the transform of 3.5 ML Pd in the $\boldsymbol{E}_{||}$ configuration. The solid line is the magnitude of the FT of the data. The dashed and dotted lines are the imaginary parts of the Pd-Fe and Pd-Pd contributions to the fit of the data, respectively. The broken line indicates the magnitude of the fit including the n.n. Pd-Fe distance and three Pd-Pd distances out to 4.7 Å.

out-of-plane (with respect to fcc Pd) with $a = 3.93$ Å and $c = 3.87$ Å. Both polarizations indicate the presence of Fe under the first peak of the Fourier transform. The coordination number for the n.n. Pd-Fe distance and this distance itself, 2.60 Å (same for both polarizations) suggest the formation of an alloy within the first 0.5–1 ML Pd.

Analysis of 7 ML Pd showed that the fct structure of Pd is preserved. Analysis of $\boldsymbol{E}_{||}$ showed no presence of Fe, while $\boldsymbol{E}_{\perp}$ revealed a small amount of Fe, correlated through coordination numbers and Pd-Fe distance with the 3.5 ML Pd data, allowing one to speculate that no further alloying between Fe and Pd occurred when the additional 3.5 ML of Pd were deposited.

Analysis of the upper 4 ML Fe, both $\boldsymbol{E}_{||}$ and $\boldsymbol{E}_{\perp}$, revealed Pd to be present in greater amounts than the traces of Fe at the 38.5 ML Fe/Pd interface. Coordination numbers yield around 2–2.5 ML of Fe-Pd alloy consistent with Le Fevre and Chanderis [4]. Fe-Fe distances show that Fe has a bct structure with $a = 2.85$ Å and $c = 2.96$ Å which is more distorted from bcc than Fe grown on GaAs(001)-(4 × 6). Analysis of $\boldsymbol{E}_{\perp}$ for 10 ML of Fe, is in agreement with the 4 ML data, showing the same tetragonal distortion and the presence of some Pd. The Fe-Pd n.n. distance stays the same as for the 4 ML sample and equal to 2.63 Å.

Abstract

The valence of Ru at the Mn sites in $Pr_{0.5}Sr_{0.5}MnO_3$ has been studied using Ru K- and L_{III}-edge X-ray absorption near edge structure (XANES) spectroscopy. In comparison with XANES of tetravalent and pentavalent ruthenates, it was found that the Mn-site doped Ru is mainly in tetravalent state with a small amount of pentavalent Ru. This result indicates that the change of carrier density with Ru doping is not sufficient to induce the drastic enhancement of ferromagnetism observed in transport properties of Ru-doped $Pr_{0.5}Sr_{0.5}MnO_3$. The mixed valence state of doped Ru suggests that 4d orbitals of Ru are involved in electronic transport of the Mn^{3+}-O-Mn^{4+} network with the valence fluctuation $Ru^{5+} + Mn^{3+} \leftrightarrow Ru^{4+} + Mn^{4+}$. The prime role of Ru has been discussed in terms of Mn valence change and magnetic interactions between Mn and doped Ru ions.

$Pr_{0.5}Sr_{0.5}MnO_3$ has attracted great interest because of its particular magnetic and transport properties. In $Pr_{0.5}Sr_{0.5}MnO_3$, two magnetic ground states coexist in different temperature regimes, which results in the two magnetic phase transitions: the paramagnetic (PM) to ferromagnetic (FM) near 270 K and the FM to antiferromagnetic (AFM) transition around 150 K [1]. Furthermore its AFM ground state at low temperatures has an A-type structure [2] where the FM metallic planes are antiferromagnetically coupled to each other. This intriguing AFM state is related to the $d_{x^2-y^2}$ orbital ordering which is responsible for the 2-dimensional (2D) characteristics in magnetic and transport properties [2, 3].

Previously, several cations [4, 5, 6] were used to explore the Mn-site doping effects on $Pr_{0.5}Sr_{0.5}MnO_3$. Compared to the doping with variation of Pr and Sr contents, Mn-site doping will cause not only the changes of the carrier density and lattice distortion of the Mn^{3+}-O-Mn^{4+} network, but also the interesting interactions between Mn ions and the substituted cations. In the case of nonmagnetic cations, the valence and size of the substituted cation were suggested to govern the change of the magnetic phases. When the valence of Mn ion is increased by doping with divalent or trivalent cations, the AFM and PM phases were extended at the expense of the FM phase [5]. On the other hand, the pentavalent cation doping which decreases the Mn valence suppressed the AFM phase and induced the FM phase at low temperatures. In the case of the magnetic cation, Cr, the AFM insulating phase at low temperatures was rapidly destroyed and the FM metallic phase was induced with decrease of T_C [6]. Considering that Cr exists as trivalent cation in the Mn^{3+}-O-Mn^{4+} network [7] this insulator-to-metal transition caused by Cr doping at low temperatures indicates that the Mn-site doping with magnetic cations does not have the similar effects observed in the case of nonmagnetic cation doping. In order to understand such an exceptional effect it was proposed that magnetic elements could participate in the carrier transport with Mn ions, even introducing the FM phase by double exchange (DE) interaction [8].

Recently, Mn-site doping with Ru was reported to destroy the A-type AFM insulating state in $Pr_{0.5}Sr_{0.5}MnO_3$ [9]. In contrast to Cr doping, however, Ru doping increases T_C, which indicates that Ru could play a unique role in the Mn^{3+}-O-Mn^{4+} network compared to the other cations. Thus Ru can be considered as a most promising candidate for participating in carrier transport, as well as the DE interaction with Mn ions. In order to understand the origin of these drastic effects of Ru doping, it is important to address the valence state of doped Ru ion. In this paper, we have determined the valence of the Mn-site doped Ru in $Pr_{0.5}Sr_{0.5}MnO_3$ using X-ray absorption near edge structure (XANES) studies at the Ru K- and L_{III}-edge with reference samples, $SrRuO_3$ and Sr_2YRuO_6.

Polycrystalline samples of $Pr_{0.5}Sr_{0.5}Mn_{1-x}Ru_xO_3$ ($0.00 \leq x \leq 0.10$) and the reference materials for XANES measurements, $SrRuO_3$ and Sr_2YRuO_6 were prepared using the solid-state reaction method [9]. All samples were characterized as a single phase with nominal stoichiometry by X-ray diffraction patterns. The standard 4-probe method was used for resistivity measurement under magnetic fields, zero and 6 T using a 7 T superconducting magnet system. XANES experiments on Ru K-edge and L_{III}-edge were carried out at Pohang Accelerator Laboratory (PAL). Ru K-edge spectra were collected using a Si(311) double-crystal monochromator in transmission mode on the 7C1 Electro-Chemistry beam line. Ru L_{III}-edge spectra were recorded on the 3C1 EXAFS beam line using Si (111) double-crystal monochromator in fluorescence mode. Background subtraction and normalization for XANES data were carefully done according to the standard procedure.

Figure 1 presents the temperature dependence of resistivity for $Pr_{0.5}Sr_{0.5}Mn_{1-x}Ru_xO_3$ under zero and 6 T magnetic fields. For $Pr_{0.5}Sr_{0.5}MnO_3$, apparent slope changes in $\rho(T)$ are observed at $T_C \sim 270$ K and $T_N \sim 165$ K, which denote the boundaries of the PM, FM, and AFM states. Below T_N, $\rho(T)$ increases rapidly with decrease of temperature. When Mn is substituted by Ru, the low temperature AFM phase is drastically destroyed as shown in Fig. 1. $\rho(T)$ of $Pr_{0.5}Sr_{0.5}Mn_{0.98}Ru_{0.02}O_3$ displays a metallic behavior down to 2 K with a slightly increasing behavior below 120 K. As Ru concentration increases, the PM to FM transition shifts to higher temperature up to 317 K for 10% of Ru doped sample. This transition temperature is almost same with that of $Pr_{0.5}Sr_{0.5}MnO_3$ under 6 T magnetic field. Therefore the Ru doping at Mn-site extends the FM phase similarly to the application of magnetic field, but with greater efficiency.

Ru K-edge XANES spectra of $Pr_{0.5}Sr_{0.5}Mn_{0.9}Ru_{0.1}O_3$ are shown in Fig. 2 with those of the reference materials: well-known tetravalent ($SrRuO_3$) and pentavalent (Sr_2YRuO_6) ruthenates. The

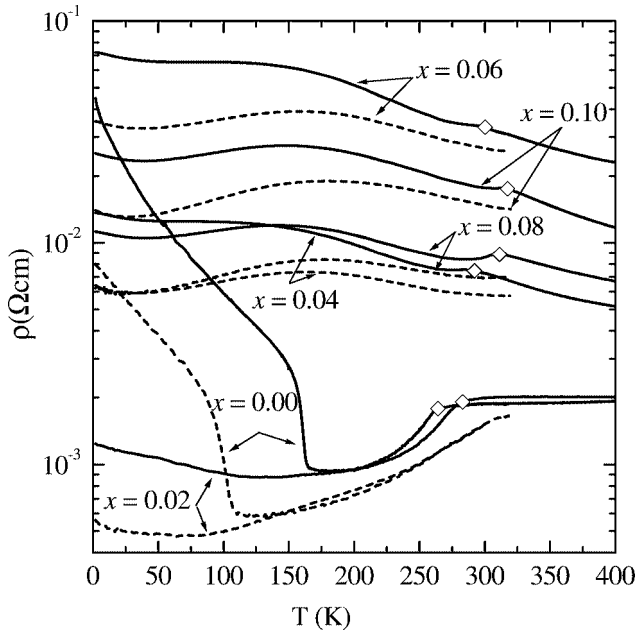

Fig. 1. Temperature dependence of resistivity under zero (solid lines) or 6 T (dashed lines) magnetic field for $Pr_{0.5}Sr_{0.5}Mn_{1-x}Ru_xO_3$ ($0.00 \leq x \leq 0.10$). FM transition point at zero magnetic field is indicated with the open diamond symbol on each solid curve.

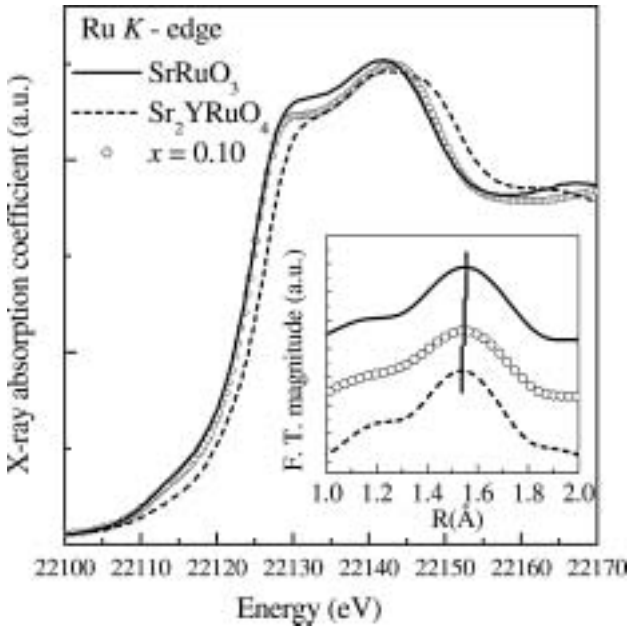

Fig. 2. Normalized Ru K-edge X-ray absorption spectra for $Pr_{0.5}Sr_{0.5}Mn_{0.9}Ru_{0.1}O_3$ compared to the reference ruthenates, $SrRuO_3$ and Sr_2YRuO_6. The inset shows the Ru-O bond peak in the plot of the *r*-space data for three samples.

main edge peak is assigned to a dipole-allowed transition from 1s to 5p states. From comparison of XANES spectra between tetravalent and pentavalent ruthenates, it is clearly shown that the main edge is shifted to higher energy by ∼1 eV as Ru valence increases from 4+ to 5+ [10]. The transition energy shift is attributed to the enhancement of Coulomb energy due to an increase of the effective charge for Ru ion. For Ru doped $Pr_{0.5}Sr_{0.5}MnO_3$, XANES spectra are similar to those of tetravalent ruthenates, which shows that the valence of the doped Ru is close to 4+. The inset of Fig. 2 presents the *r*-space data for three samples obtained from the Fourier Transform of the EXAFS

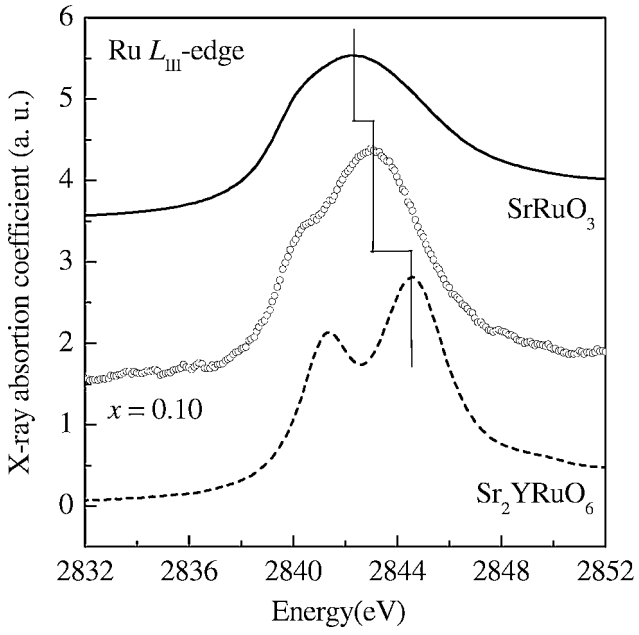

Fig. 3. Normalized Ru L_{III}-edge X-ray absorption spectra for $Pr_{0.5}Sr_{0.5}Mn_{0.9}Ru_{0.1}O_3$ compared to the reference ruthenates, $SrRuO_3$ and Sr_2YRuO_6.

oscillations above the edge. For comparison of Ru-O bond length between the samples, we plot the first peak corresponding to the Ru-O bond, which is sensitive to the Ru valence state. As shown in the inset of Fig. 2, the Ru-O bond length of $Pr_{0.5}Sr_{0.5}Mn_{0.9}Ru_{0.1}O_3$ is in between those of tetravalent and pentavalent ruthenates. These results indicate that Ru valence at the Mn-site is not exactly same as 4+ but probably, mixed-valence between 4+ and 5+.

The mixed valent state of Ru is more clearly observed in Ru L_{III}-edge XANES as shown in Fig. 3. In octahedra configuration, degenerate 4d orbitals of Ru are split into t_{2g} and e_g orbitals separated by crystal field. Two peaks in L_{III}-edge spectra are corresponding to $2p \rightarrow t_{2g}$ (lower energy peak) and $2p \rightarrow e_g$ (higher energy peak) transitions, which are observed in both cases of tetravalent and pentavalent Ru oxides. However, there are clear differences between L_{III}-edge spectra of Ru^{4+} and Ru^{5+}. The peak energy of t_{2g}-related and e_g-related peaks for tetravalent Ru is much closer to each other than pentavalent Ru case. Also, spectral weight for e_g-related peak becomes enhanced compared to t_{2g}-related peak and the peak position shifts to higher energy by ∼1.5 eV with increase of Ru valence from 4+ to 5+ as shown the XANES spectra for $SrRuO_3$ and Sr_2YRuO_6. The spectrum of Ru at the Mn sites in $Pr_{0.5}Sr_{0.5}MnO_3$ is similar to that of $SrRuO_3$, which is also consistent with Ru K-edge XANES result. However, the significant increase of spectral weight for e_g-related peak is observed in the L_{III}-edge spectra of Mn-site doped Ru. Also, there is a clear energy shift by ∼0.6 eV with respect to that of $SrRuO_3$. Such a chemical shift for Ru doped $Pr_{0.5}Sr_{0.5}MnO_3$ is attributed to the change of Ru valence [14]. Therefore the valence state of Ru at the Mn sites in $Pr_{0.5}Sr_{0.5}MnO_3$ is mixed valent state. This mixed valence state of Ru is crucial to understand the unusual enhancement of T_C.

Figure 4 displays Mn-site doping dependence of T_C for various dopants, Ga, Al, Sn, Ti, Cr and Ru in $Pr_{0.5}Sr_{0.5}MnO_3$. [4, 5, 6, 9, 11] For nonmagnetic cations, T_C is decreased rapidly with Mn-site doping concentration. In consideration of phase diagram of $Pr_{1-x}Sr_xMnO_3$, T_C is enhanced as Mn valence decreases from 3.5+, while T_C is suppressed as Mn valence increases. If T_C is determined dominantly with the change of Mn valence, T_C

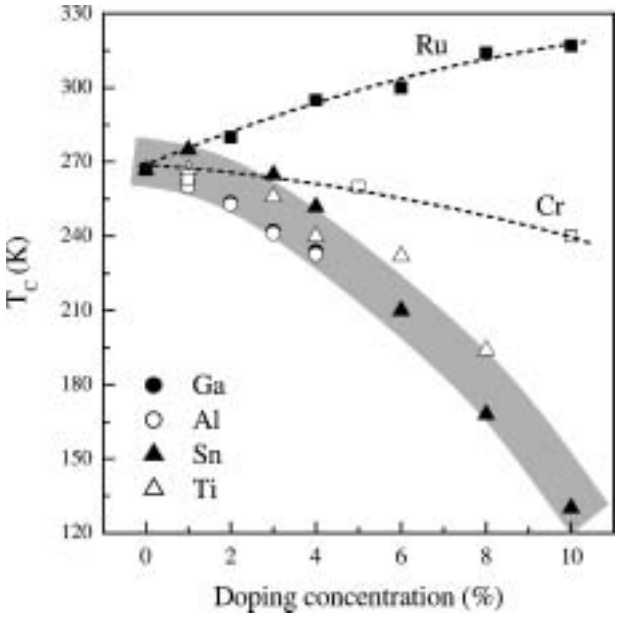

Fig. 4. T_C versus Mn-site doping concentration plot for $Pr_{0.5}Sr_{0.5}Mn_{1-x}M_xO_3$ (M = Al, Ga, Sn, Ti, Cr and Ru).

is expected to increase for tetravalent dopant such as Sn^{4+} or Ti^{4+} and to decrease for trivalent dopant such as Al^{3+} or Ga^{3+}. However, T_C decreases in both cases as shown in Fig. 4. In both cases, T_C was reduced as the concentration of the substituted cation increases, which indicates that the Mn-site doped cations disturb the carrier transport and weaken DE interaction in the Mn^{3+}-O-Mn^{4+} network. This reduction of T_C was strongly related to the lattice distortion due to the size difference between Mn and the substituted ion; for instance, smaller trivalent cation, Al^{3+} decreases T_C more drastically compared to Ga^{3+} and In^{3+}. Similarly Cr exists as a trivalent ion at the Mn sites and disturbed the carrier transport. However empty d orbitals of Cr can induce magnetic exchange interaction with Mn ions, so that T_C is not so much suppressed as the cases of other trivalent nonmagnetic dopants such as Al^{3+} or Ga^{3+}. Ru also have empty d orbitals like Cr, and 4d e_g^0 state of Ru^{4+} or Ru^{5+} is ferromagnetically coupled with e_g^1 state of Mn^{4+} [12]. In contrast to Cr doping, T_C is enhanced with Ru doping as shown in Fig. 4. Since Ru valence estimated from XANES study is between 4+ and 5+, which is higher than Cr valence, such difference could be attributed to Mn valence change due to Mn-site doping. However, T_C of 10% Ru doped $Pr_{0.5}Sr_{0.5}MnO_3$ is even higher than the maximum T_C in the series of $Pr_{1-x}Sr_xMnO_3$ as mentioned above. Moreover, Mn-site doping dependence of T_C for nonmagnetic dopants follows a general trend irrespective of valence of dopant, which suggests that valency effect is not a dominant origin for T_C enhancement.

Instead, the peculiar role of Ru is related to presence of the extended 4d orbitals. The mixed valence state for the Mn-site doped Ru found in XANES reveals that extended 4d orbitals of Ru are strongly hybridized with Mn orbitals and contributes to the band formation with valence fluctuation $Ru^{5+} + Mn^{3+} \leftrightarrow Ru^{4+} + Mn^{4+}$ [13]. Ru reinforces the ferromagnetism by FM coupling with Mn ions and does not hinder DE interaction within the Mn^{3+}-O-Mn^{4+} network. As a result, T_C is unusually enhanced by Ru doping in $Pr_{0.5}Sr_{0.5}MnO_3$.

In summary, XANES studies using Ru K- and L_{III}-edge spectra have shown that the valence state of Mn-site doped Ru in $Pr_{0.5}Sr_{0.5}MnO_3$ is mixed valent state, which is close to tetravalent state. The presence of mixed valent state of doped Ru is strong evidence for the valence fluctuation in the type of $Ru^{5+} + Mn^{3+} \leftrightarrow Ru^{4+} + Mn^{4+}$. Through this valence fluctuation, conduction path is formed in Ru-O-Mn path and delocalization of e_g carrier is maintained in contrast to other dopant. These effects of Ru doping enhance the ferromagnetism and increases T_C in $Pr_{0.5}Sr_{0.5}MnO_3$.

Abstract

Information about the local structure of amorphous carbon (*a*-C) films was obtained by comparing soft X-ray absorption spectra in the CK region of sputtered *a*-C films to reference carbon compounds such as hydrofullerene ($C_{60}H_{36}$), highly oriented pyrolytic graphite (HOPG), and carbon black. The spectra of the *a*-C films exhibited fine structures, which consisted of at least different six portions. Comparing the spectral features of the *a*-C films with the reference compounds and the spectral analysis by discrete variational (DV)-Xα molecular orbital calculations indicated that the fine structures of the *a*-C films are due to a hybrid of sp^2 and sp^3 carbon atoms.

1. Introduction

Amorphous carbon (*a*-C) films are important and interesting materials in industry and materials science. It is believed that they consist of a random structure of sp^2- and sp^3-configured carbon atoms and that the local structure or chemical bonding states determine their mechanical and optical properties. Thus, numerous researchers have conducted characterization studies of *a*-C films using various analytical methods such as Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), and electron energy loss spectroscopy (EELS) in order to clarify local structures and chemical bonding states. Recently, various carbon films have been characterized by soft X-ray emission and absorption spectroscopy using highly brilliant synchrotron radiation [1–6]. This method is effective for obtaining electronic-structure information about occupied and unoccupied orbitals, which directly reflects the local structure and chemical bonding states. However, the spectral features observed in the X-ray emission and absorption spectra of the *a*-C films have yet to be clearly assigned.

In our previous study [6], fine structures were clearly observed in the soft X-ray absorption spectra of sputtered *a*-C films, which were systematically deposited by various sputtering methods under varying conditions. These fine structures have rarely been measured by EELS [7, 8], which generally has a lower energy resolution than soft X-ray absorption spectroscopy using synchrotron radiation. Thus, in order to extract information on the local structures of *a*-C films from the fine structures, soft X-ray absorption spectra of *a*-C films were compared to reference carbon compounds. Reference compounds should be selected if they are fairly large molecules, which were composed of sp^2 and sp^3 carbon atoms. Hence, this study used hydrofullerene ($C_{60}H_{36}$), which is composed of twenty-four sp^2 carbon atoms and thirty-six sp^3 carbon atoms, as the reference compound.

This paper describes the comparison on the soft X-ray absorption spectral features between *a*-C films and reference compounds such as $C_{60}H_{36}$, highly oriented pyrolytic graphite (HOPG), and carbon black.

2. Experiments

The total-electron-yield (TEY) X-ray absorption spectra in the C*K* region of commercially available *T*-symmetry $C_{60}H_{36}$ [9], HOPG, and carbon black were measured in beamline BL-6.3.2 [10] at the Advanced Light Source (ALS). Powder samples of $C_{60}H_{36}$ and carbon were pressed and held on indium-sheet substrates. The estimated resolving power ($E/\Delta E$) of the TEY absorption measurements was approximately 1600 using a 600 lines/mm variable-line-spacing grating and a 20 μm exit slit. The incident angle to the sample surface was fixed at 45 degrees. The measurement conditions were the same as the previous measurement of sputtered *a*-C films [6]. The energy calibration was achieved by tuning the π^* peak energy of HOPG to 285.5 eV.

3. Results and Discussion

Figure 1 shows the TEY X-ray absorption spectra of the *a*-C films and reference compounds, $C_{60}H_{36}$, HOPG, and carbon black. The spectra of the *a*-C films were extracted from previously measured data [6]. The *a*-C films were deposited by RF, ion-beam, and electron-cyclotron-resonance (ECR) sputtering methods under various deposition conditions. For the RF-sputtered carbon films, the pressure of the source gas was 5×10^{-2} (R1), 1×10^{-1} (R2), and 1×10^{-2} Torr (R3). For the ion-beam-sputtered carbon films, the annealing temperature was 'not annealed' (I1), 400 °C (I2), and 700 °C (I3). For the ECR-sputtered carbon films, the acceleration voltage was −20 (E1), −75 (E2), and −100 V (E3). The spectra of *a*-C films displayed two peaks at 285.5 eV and 293 eV, which correspond to the energy portions of π^* and σ^* peaks in HOPG, respectively. Therefore, these peaks in *a*-C films are assigned to be π^* and σ^* peaks, respectively. Four other structures are also observed at 284.5 eV (denoted by *a*), at 287 eV (*b*), 288 eV (*c*), and 289 eV (*d*) among the *a*-C films. Although the relative peak intensities among these six structures depended on the deposition methods/conditions, the peaks were observed at constant energy positions, which suggests common local structures in the *a*-C films, but at different ratios. Similar structures, which correspond to the π^*, *c*, *d*, and σ^* in $C_{60}H_{36}$, were noted in the spectral feature of the *a*-C films. Therefore, it is estimated that the *a*-C films have local structures similar to $C_{60}H_{36}$. A broad π^* peak is observed in carbon black at 285.5 eV and the energy position of the lower-energy portion in this π^* peak corresponds to the lowest-energy fine structure *a* in *a*-C films. Carbon black is essentially composed from randomly-ordered polycyclic-aromatic-structures [11]. Hence, it is estimated that similar polycyclic- aromatic-structures partially exist in *a*-C films.

The local structures of *a*-C films were further estimated by comparing the spectral similarities to the spectral features of $C_{60}H_{36}$, which were analyzed by discrete variational (DV)-Xα molecular orbital (MO) calculations [12–13]. Figure 2 shows

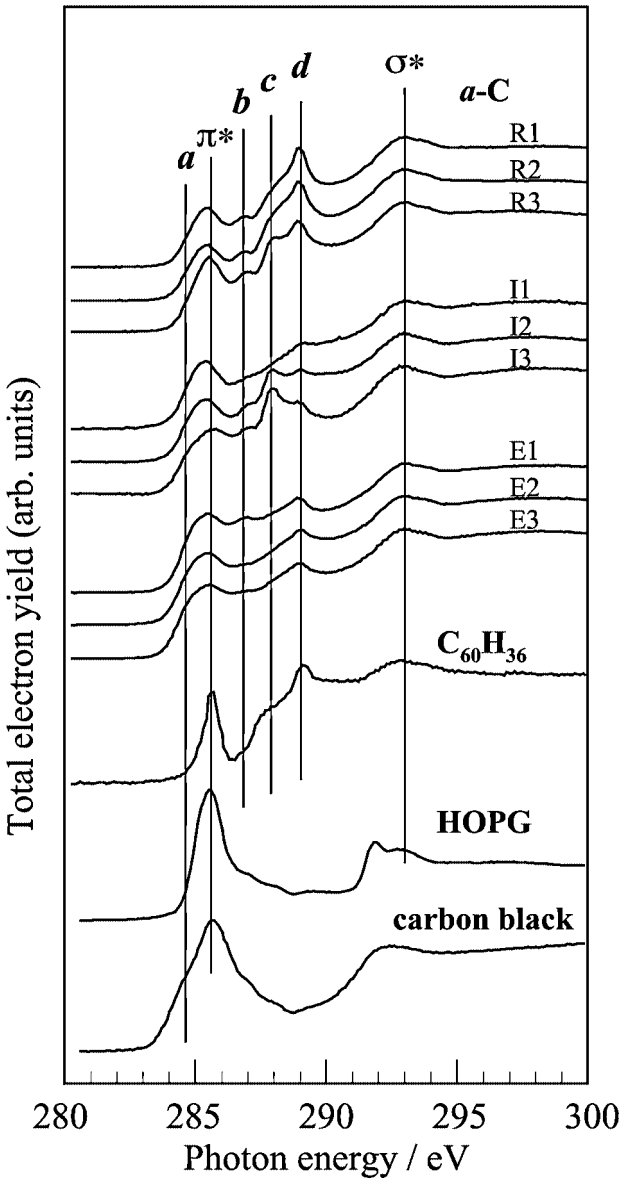

Fig. 1. TEY X-ray absorption spectra of *a*-C films for three different conditions when deposited by RF (R1-3), ion-beam (I1-3), and ECR sputtering (E1-3) [6] and $C_{60}H_{36}$ [9], HOPG, and carbon black are shown as references. *A*-*d*, π^*, and σ^* denote the specific spectral features consisting of at least six portions in the *a*-C films.

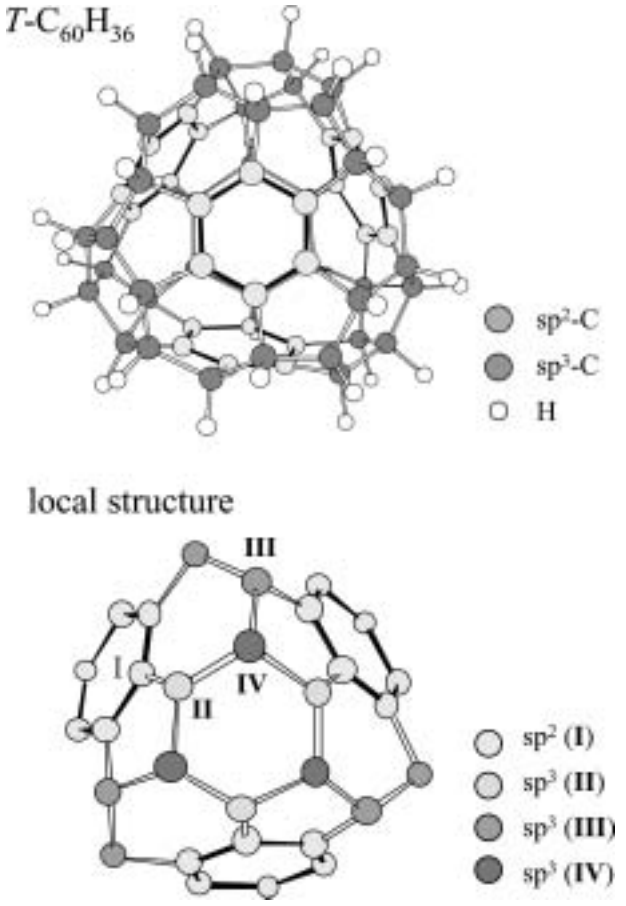

Fig. 2. Molecular structure (upper panel) and local structure (lower panel) of T-$C_{60}H_{36}$. Hydrogen atoms bound to sp^3 carbon atoms are not shown in the local structure. I–IV denote the four different types of carbon atoms.

the molecular structure of the T-symmetry $C_{60}H_{36}$ and its local structure. In T-$C_{60}H_{36}$, thirty-six of the carbon atoms are bound to hydrogen atoms that have a sp^3 configuration. The remaining twenty-four carbon atoms are sp^2 and form four six-membered benzene rings located in the tetrahedral positions. There are four structurally unique carbon atoms in T-$C_{60}H_{36}$. The twenty-four sp^2-C atoms (I) are identical and each is bound to two sp^2-C atoms and one sp^3-C atom. There are three types of sp^3-C atoms, twenty-four are sp^3-C atoms (II, III) each bound to two sp^3-C atoms, one sp^2-C atom, and one H atom, while the other twelve sp^3-C atoms (IV) are each bound to three sp^3-C atoms and one H atom. For the spectral analysis of the X-ray absorption, DV-Xα MO calculations on the electronic structure of the excited states, with the inner core holes and electrons in unoccupied orbitals, should be necessary to exactly reproduce the measured X-ray absorption spectral features [14]. However, the calculations on excited states are generally more difficult than those on the ground states, and the ground-state calculations provide approximated information on the X-ray spectral analysis especially in K-shell excitations. Thus, we show here the calculated spectra on the ground states as the first-order approximation. Figure 3 shows the unoccupied C2p- and C2s-DOS spectra of the individual sp^2- and sp^3-C atoms. The total C2p-DOS spectrum approximately reproduces the measured X-ray spectral features of π^*, c, d, and σ^*. Table I lists the unoccupied orbital populations of the individual carbon atoms. The π^* peak originates from π^* orbitals since the 2p orbitals of the sp^2-C (I) account for approximately 90% of the population at peak π^*. The orbital populations of peaks c, d, and σ^* peaks are shared by sp^2-C (I), sp^3-C (II, III), and sp^3-C (IV) with 11–45% of the 2p orbitals and up to 11% of 2s orbitals. In particular, the 2p orbitals of both sp^2-C (I) and sp^3-C (II, III) account for more than 30% of the population at peak c and the 2p orbitals of both sp^3-C (II, III) and sp^3-C (IV) account for more than 30% of peak d. This indicates that peak c has more sp^2 character than peak d. The σ^* peak is mainly due to the σ^* orbitals, which are mostly composed of sp^3-C (II, III) and sp^2-C (I). From this analogy, it can be estimated that the fine structures π^*, c, d, and σ^* in *a*-C films result from the hybridization of sp^2 and sp^3 carbon atoms. In addition, the higher the energy positions of the fine structure peaks, the more sp^3 character the hybridized carbon atoms have in the local structure.

4. Conclusion

The soft X-ray absorption spectra of *a*-C films, which were measured using synchrotron radiation, were compared to

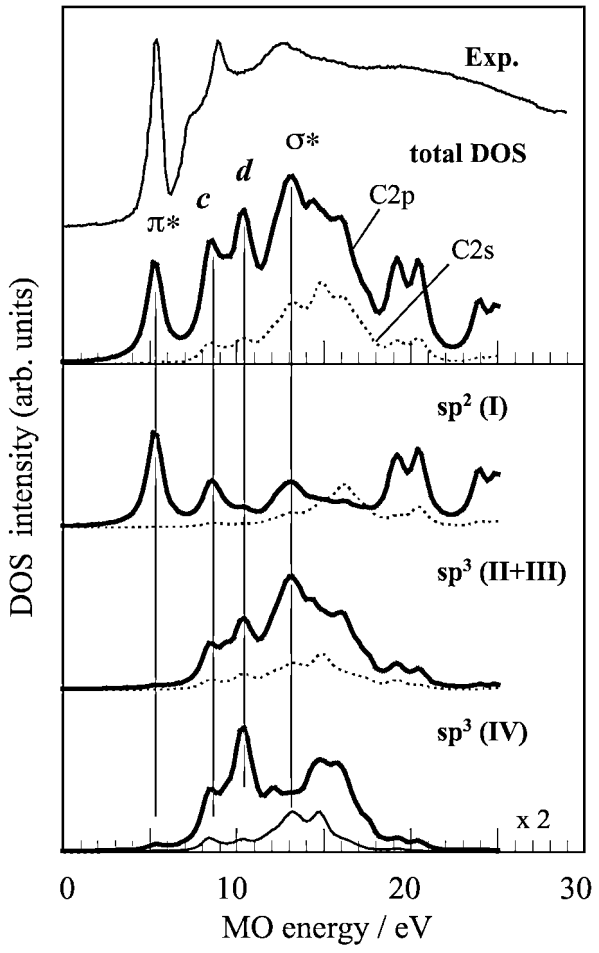

Fig. 3. Calculated total DOS spectrum and DOS spectra of individual carbon atoms (I–IV) in *T*-$C_{60}H_{36}$. The measured X-ray absorption spectra are also shown on the total DOS spectrum.

reference compounds, *T*-$C_{60}H_{36}$, HOPG, and carbon black. The *a*-C films had fine structures, which consisted of at least six portions.Four portions (π^*, *c*, *d*, σ^*) in the fine structure corresponded to the energy positions of four peaks in *T*-$C_{60}H_{36}$. Spectral analysis of *T*-$C_{60}H_{36}$ using DV-Xα MO calculations indicated that the origin of these peaks is the hybridization of sp^2 and sp^3 carbon atoms. Therefore, it is estimated that the fine structures observed between π^* and σ^* peaks in *a*-C films originated from the hybridization of sp^2 and sp^3 carbon atoms. The lowest-energy fine structure *a* in *a*-C films corresponded to the lower-energy portion in the broad π^* peak in carbon black.

Table I. *Orbital populations of the four different types of carbon atoms (I–IV) in unoccupied orbitals corresponding to the measured X-ray absorption peaks denoted by π^*, c, d, and σ^*.*

		Orbital population/%					
		sp^2-C(I)		sp^3-C(II&III)		sp^3-C(IV)	
peak	MO energy/eV	2s	2p	2s	2p	2s	2p
π^*	5.2	0.6	89.6	1.1	4.1	0.9	3.8
c	8.6	3.1	31.9	7.1	31.5	4.6	21.7
d	10.4	2.3	11.1	8.9	39.6	3.6	34.5
σ^*	13.2	6.1	17.9	11.0	45.0	8.1	12.0

Hence, it is estimated that the lowest-energy fine structure *a* in the *a*-C films originated from polycyclic-aromatic-structures. The reference compounds did not display the fine structure *b*. Thus, further experiments using different reference compounds are necessary to estimate the origin of the fine structures in *a*-C films.

Abstract

Glancing angle fluorescence XAFS analysis of Ta and Ti oxide thin films, which were obtained by oxygen gas cluster ion beam assisted deposition techniques (GCIB), was made to analyze the valence states and the structures of the 'amorphous' thin films at atomic level. Glancing angle XAFS measurement was made for Ta L_3-edge of the Ta oxide thin films and Ti K-edge of the Ti oxide thin films with 200 nm thickness, respectively, using the detection method of electron yield by conversion with He flow gas counter (CEY) at the beam line BL01B1 in the SPring-8. The Ta L_3-XANES results indicate that the assistance of the oxygen GCIB leads to the higher oxidation state of the Ta atom. The Ta L_3 and Ti K EXAFS results suggest that these metal oxide films obtained by the oxygen GCIB assisted deposition techniques have amorphous-like structure.

1. Introduction

The thin films metal oxides, for example Ta_2O_5 and TiO_2, will be widely used for semiconductor devices and multi-layer thin film for optical devices. The improvement of the optical properties requires accurate control of the refractive index and the optical transparency of the Ta_2O_5 and TiO_2 layer, i.e. high stoichiometry and so-called 'amorphous' structure. Glancing angle XAFS analysis is a suitable tool to analyze the structure of such 'amorphous' thin films at the atomic level instead of thin film X-ray diffraction [1]. Moreover, glancing angle XAFS analysis in the fluorescence mode, especially using the detection method of electron yield by conversion with He flow gas counter (CEY), is a highly sensitive and powerful tool to analyse the local structure of these 'amorphous' thin films.

In this study we measured the Ta L_3-XAFS of Ta oxide thin films and Ti K-XAFS of Ti oxide thin films, which were obtained by a recently developed innovative deposition technology, i.e. oxygen gas cluster ion beam assisted deposition techniques [2, 3] with different deposition conditions using glancing angle XAFS analysis in the CEY mode measurement.

2. Experimental

Glancing angle XAFS measurements were made using Si(111) monochromator and sample table with multi-rotation and translation axes, which are used for setting the glancing angle incidence condition, at the beam line BL01B1 of SPring-8 (Proposal No. 2001A0254-NX-np, 2002A0063-NX-np). The Ta oxide thin films with 200 nm thickness used in the Ta L_3-XAFS measurement are 1) Ta oxide thin film on Si wafer which were fabricated from a Ta oxide target by oxygen gas cluster ion beam assisted deposition (GCIB) with acceleration energy of 3 keV, 7 keV and 11 keV, respectively, 2) Ta oxide thin films deposited on Si wafer which were fabricated from a Ta metal target by GCIB with acceleration energy of 7 keV, ion current of 1 $\mu A/cm^2$ and deposition rate of 0.24 Å/s and acceleration energy of 7 keV, ion current of 0.2 $\mu A/cm^2$ and deposition rate of 1.2 Å/s, respectively, and 3) that by conventional electron beam deposition 4) together with those of 'Ta metal' deposited on Si wafer in the same chamber. Also the Ta L_3-XAFS of Ta film, low temperature form and high temperature form Ta_2O_5 crystalline powders were measured as reference spectra. Ti oxide thin films with 200 nm thickness used in the Ti K-XAFS measurement are 1) Ti oxide thin films which were formed by oxygen GCIB with acceleration energy of 3 keV and 2) that by conventional electron beam deposition. Also the Ti K-XAFS of Ti metal, two polymorphs of TiO_2, rutile and anatase, were measured as reference spectra. For thin film samples we measured typically four scans of Ta L_3-XAFS and Ti K-XAFS with energy range of 500 eV below and 1100 eV above the absorption edge in the CEY mode while the Ta L_3-XAFS and Ti K-XAFS of the reference samples were measured in both CEY and transmittance modes. Data were analyzed by the procedure proposed by Maeda *et al* [4]. The radial distribution functions were obtained by the Fourier transform of the k^3-weighted EXAFS functions typically in the k ranges between 2.0 and 15.3 $Å^{-1}$. The curve fitting analysis for the first Ta-O coordination shell typically between 1.1 Å and 2.0 Å in the radial structure functions was performed using the theoretical phase shifts and back-scattering amplitudes derived from FEFF code [5, 6].

3. Results and discussion

Fig. 1.a shows the first derivative Ta L_3-XANES spectra $d\mu/dE$ of Ta oxide thin films which were fabricated from the Ta oxide target together with those of Ta film, low temperature form and high temperature form Ta_2O_5. Comparison of the spectra of the films with the different deposition conditions indicates that the absorption edge, which corresponds to the first peak in $d\mu/dE$, shifts toward higher energy in the order of the electron beam, 3 keV, 7 keV and 11 keV GCIB conditions. This suggests that the assistance of the oxygen GCIB leads to a higher oxidation state

*E-mail: h-kageyama@aist.go.jp

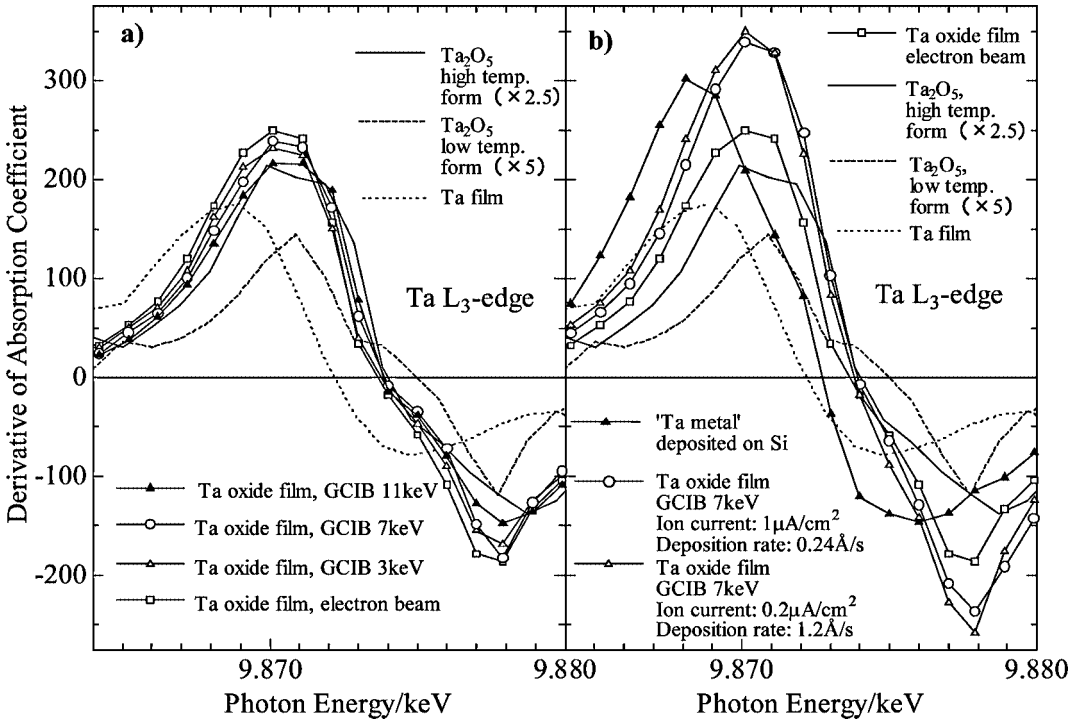

Fig. 1. The first derivative Ta L_3-XANES spectra $d\mu/dE$ of Ta oxide thin films which were fabricated from a Ta oxide target by oxygen gas cluster ion beam assisted deposition (GCIB) with acceleration energy of 3 keV, 7 keV and 11 keV, respectively, and electron beam deposition together with those of Ta film, low temperature form and high temperature form Ta_2O_5 (a). The first derivative Ta L_3-XANES spectra $d\mu/dE$ of Ta oxide thim films fabricated from a Ta metal target by oxygen GCIB with acceleration energy of 7 keV, ion current of 1 μA/cm^2 and deposition rate 0.24 Å/s and acceleration energy of 7 keV, ion current of 0.2 μA/cm^2 and deposition rate of 1.2 Å/s, respectively, and by the electron beam deposition together with those of 'Ta metal' deposited on Si in the same chamber, Ta film, low temperature form and high temperature form Ta_2O_5(b).

of the Ta atom. Fig. 1.b shows the first derivative Ta L_3-XANES spectra $d\mu/dE$ of Ta oxide thin films which were fabricated from the Ta metal target and those of 'Ta metal' deposited on Si in the same chamber. Also the comparison of the spectra of the films with the different deposition conditions indicates that an absorption edge shift toward higher energy is observed in the order of the electron beam, 7 keV, ion current of 0.2 μA/cm^2 and deposition rate of 1.2 Å/s, 7 keV, ion current of 1 μA/cm^2 and deposition rate of 0.24 Å/s GCIB conditions. This means that the assistance of the oxygen GCIB with higher dose per unit time would lead to the formation of the higher oxidation state of the Ta atom.

Fig. 2 shows k^3-weighted Ta L_3-EXAFS of Ta oxide thin films which were fabricated from the Ta oxide and Ta metal targets by different oxygen GCIB conditions and by electron beam deposition together with those of 'Ta metal' deposited on Si in the same chamber, Ta film, low temperature form and high temperature form Ta_2O_5. Comparison of the Ta L_3-EXAFS oscillations under the different deposition conditions indicates that the significant loss of long-range-order in the high k region above 10 Å^{-1} is observed for the thin films deposited with the assistance of the oxygen GCIB, especially for acceleration energy of 7 keV. This result suggests that the assistance of the oxygen GCIB would be effective for Ta oxide thin films with 'amorphous-like' structure compared with the electron beam deposition. Also a significant loss of long-range-order in the high k region is found for films deposited with assistance of oxygen GCIB, especially for acceleration energy of 7 keV, ion current of 1 μA/cm^2 and deposition rate of 0.24 Å/s. This result suggests that the assistance of the higher dose oxygen GCIB with optimum acceleration energy would be more effective for Ta oxide thin films with 'amorphous-like' structure than the conventional electron beam deposition. Table I shows results of curve fitting

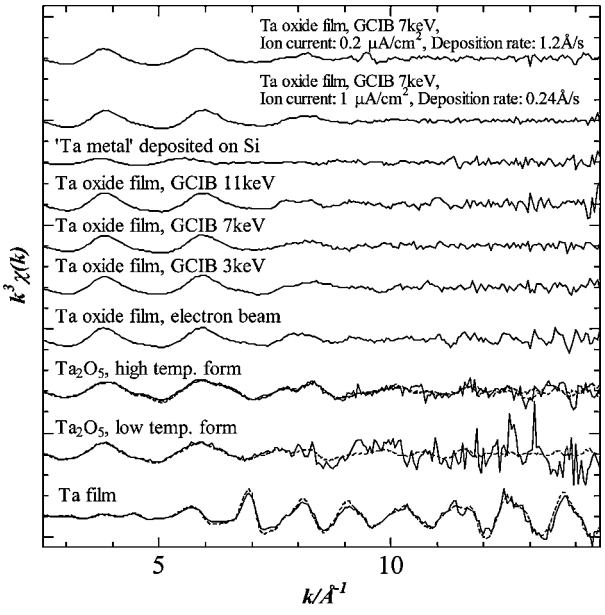

Fig. 2. k^3-weighted Ta La_3-EXAFS of Ta oxide thin films fabricated from a Ta oxide target by oxygen gas cluster ion beam assisted deposition (GCIB) with acceleration energy of 3 keV, 7 keV, and 11 keV respectively, those of Ta oxide thin films which were fabricated from a Ta metal target by the oxygen GCIB with acceleration energy of 7 keV, and ion current of 1 μA/cm^2 and deposition rate of 0.24 Å/s and acceleration energy of 7 keV, ion current of 0.2 μA/cm^2 and deposition rate of 1.2 Å/s, respectively, and that by the electron beam deposition together with those of Ta film, low temperature form and high temperature form Ta_2O_5. Solid line: electron yield (CEY) mode, broken line: transmittance mode.

analysis for the first Ta-O coordination shell. The shortest Ta-O distance is observed for the film deposited by assistance of 7 keV oxygen GCIB with ion current of 1 μA/cm^2 and deposition rate of 0.24Å/s although all the thin film samples have shorter

Table I. *Results of curve fitting analysis for the first Ta-O coordination shell using the theoretical phase shifts and back-scattering amplitudes derived from FEFF code [5, 6]. The lattice parameters and the atomic coordinates used for FEFF calculation were referred from the crystal structure in the ICSD database [7].*

Sample	Coordination number N	Interatomic ditance R [Å]	Mean square relative displacement σ^2 [Å^2]
Ta_2O_5, Crystallographic [7]	Short 5 and Long 1	1.931, 1.937 1.937, 1.947 1.947, 2.030	—
	Distances	Av. 1.955	
Ta_2O_5, Low temperature form	5.2(7)	1.961(3)	0.013(2)
Ta oxide film, Electron beam	5.3(11)	1.935(1)	0.0136(12)
Ta oxide film, GCIB 3 keV	4.9(7)	1.929(3)	0.0139(3)
Ta oxide film, GCIB 7 keV	4.9(5)	1.928(3)	0.0130(4)
Ta oxide film, GCIB 11 keV	5.1(11)	1.939(5)	0.0145(4)
Ta oxide film, GCIB 7 keV Ion current: 1 μA/cm^2, Deposition rate: 0.24 Å/s	5.0(5)	1.914(9)	0.0130(8)
Ta oxide film, GCIB 7 keV Ion current: 0.2 μA/cm^2, Deposition rate: 1.2 Å/s	5.0(11)	1.938(15)	0.0152(13)

Ta-O distances than those of low temperature form Ta_2O_5 and averaged one of the known crystallographic data. Lüzenkirchen-Hecht and Frahm mentioned that the thin films reveal smaller bond distances compared with the bulk reference in general and that this apparently reduced bond distance is a further indication for a highly disordered material and originates from the highly asymmetric pair distribution functions in amorphous solid [1].

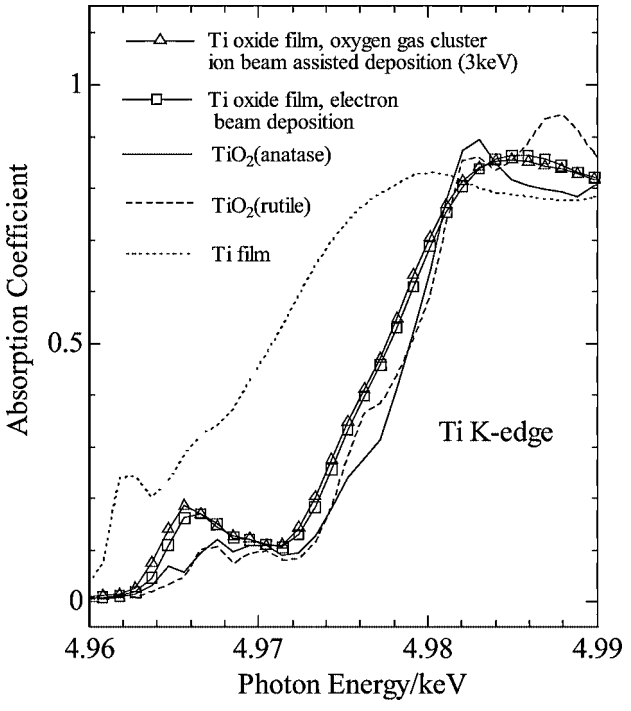

Fig. 3. Ti K-XANES of Ti oxide thin films, formed by the oxygen gas cluster ion beam assisted deposition (3 keV) and electron beam deposition together with those of Ti metal, TiO_2 (rutile) and TiO_2 (anatase).

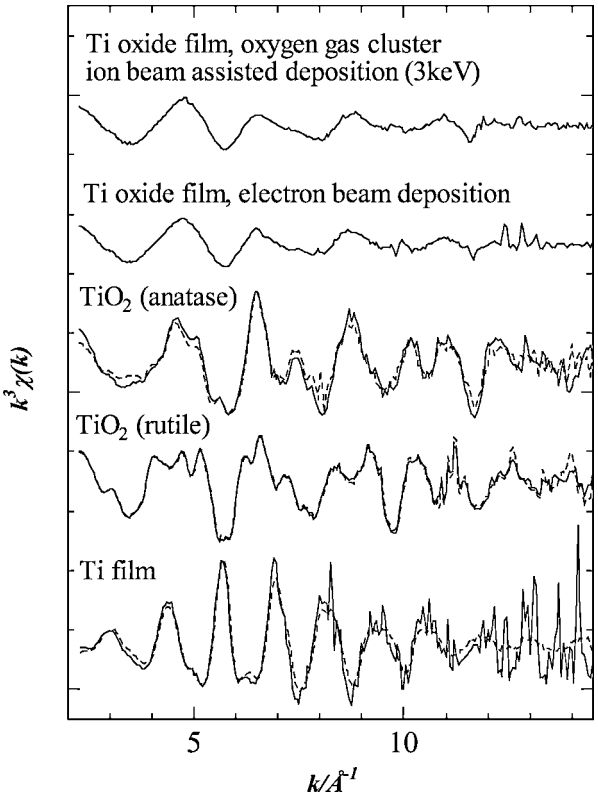

Fig. 4. Ti K-EXAFS of Ti oxide thin films, which were formed by oxygen gas cluster ion beam assisted deposition (3 keV) and electron beam deposition together with those of Ti metal, TiO_2 (rutile) and TiO_2 (anatase). Solid line: electron yield (CEY) mode, broken line: transmittance mode.

According to this discussion it is suggested that the film that was deposited by the oxygen GCIB assistance especially under the optimum deposition condition of 7 keV acceleration energy with ion current of 1 μA/cm^2 and deposition rate of 0.24 Å/s has the most amorphous-like structure.

Fig. 3 shows a comparison of the Ti K-XANES of the samples. A significant difference of the spectral features is observed between the films under electron beam and 3 keV oxygen GCIB conditions, and two polymorphs of TiO_2. This suggests that these thin films have different electronic state and/or local coordination structures from two polymorphs of TiO_2. Fig. 4 shows a comparison of the Ti K-EXAFS of the samples. Also a significant loss of long-range-order in the high k region is found for both films deposited with assistance of 3 keV oxygen GCIB and electron beam deposition. This suggests that these Ti oxide thin films have similar amorphous-like structures.

Abstract

Structures and electronic states in the ground state of endohedral fullerence are investigated by XAFS analysis and XANES spectrum. The distances between the Eu ion and the neighboring C atoms show clearly that the Eu ion is inside the C_{60} cage. The endohedral element, Eu, in C_{60} is located away from the central position of C_{60} cage by 1.4 Å. We show the detailed location of the Eu ion in the C_{60} cage by XAFS and the first principles calculation. The perturbation theory indicates that the distortion of C_{60} cage and the shift of the Eu ion are attributed to electron-nuclear interaction, pseudo-Jahn-Teller type interaction. XANES spectrum of Eu L_{III}-edge shows that the valence of the Eu ion is close to +2. The electron configuration is thus f^7, showing the total symmetry (A_{1g}) of I_h group. The details of the structures and the electronic states will be discussed with both the experimental and theoretical results.

1. Introduction

In the last few years, endohedral metallofullerences as new hopeful materials became of great interest [1]. In these materials, the $M@C_{60}$ (M = alkaline earth and lanthanide metal atoms) is the most fundamental molecule, and was discovered in the early stage of fullerene science. Several pioneers are trying to synthesize, to characterize, and to study the physics of these materials [2]. However, since the specimens of high quality are obtained with difficulty, not many publications, especially for $M@C_{60}$, are found in literature. In such situation, we have successfully isolated Y, Ba, Ce, Pr, Nd, and Gd@C_{60}'s for the first time [3–5]. Recently, Eu@C_{60} is extracted with aniline solvent from soot produced by arc heating of a graphite/Eu_2O_3 composite. We measured XAFS and XANES spectra for Eu@C_{60} to obtain the environmental information around endohedral Eu ions.

Electron-lattice interaction plays an important role in many fields of solid state physics. As one type of electron-lattice interactions, the Jahn-Teller effect is a well-known origin for lattice instability in the local environment or in the whole lattice [6–8]. Here, we will examine the pseudo Jahn-Teller type instability to explain the location of Eu ion in a large C_{60} cage. Recently the first principles calculation has been developed as powerful tool to study material properties. We will discuss the result of the first principles calculation with the pseudo Jahn-Teller effect.

2. Experimental

The specimen preparation is briefly described here. The detailed treatment is given in Ref. [3]. The soot containing Eu@C_{60} was prepared by an arc-discharge of graphite/Eu_2O_3 composite rod at 26 V and 80 A under He pressure of 80 Torr. Four-stage HPLC (High Performance Liquid Chromatography) was performed with Buckyclutcher I column and aniline solvent (flow rate: 0.75 ml/min.) after extraction from the soot with the aniline. The four steps HPLC shows a single peak. To confirm the existence of Eu@C_{60}, time-of-flight mass spectrum was observed, which suggested an endohedral structure in Eu@C_{60}. The solid sample for XAFS measurements was obtained by removing aniline solvent from the fraction under reduced pressure, and was dried by dynamical pumping at 10^{-6} Torr for 12 hours.

XAFS spectra were observed at BL12C of Photon Factory and at BL01B1 of SPring-8. The standard methods in both the transmittance and fluorescence modes were employed. Monochromatic X-ray beams were obtained through a double-Si [111]-crystal monochromater. The X-ray photon energy was calibrated with a Cu foil by assigning 8.9788 keV to pre-edge peak on the Cu absorption K-edge. The third harmonics were removed by two mirrors. The measurements were performed at room temperature. As the performance of the sample is of critical importance in the fluorescence mode, great attention was paid on the thickness and the mounting condition of the samples [9, 10].

3. Theoretical calculation

3.1. *Method*

A program "Osaka 2000" [11] with an *ab-initio* pseudopotential method based on local-density approximation (LDA) [12, 13] was used. This program expresses wavefunctions with a plane-wave expansion. Troullier-Martins potentials [14] with modification of Kleinman-Bylander type [15] were used for the pseudopotenials, and Ceperley-Alder formula [16] was used for the exchange-correlation functional.

At present, this program code is limited to non-spin polarization and non-relativistic case, which may have some consequences on the properties of 4f elements. Even if these effects can be ignored, the plane-wave expansion method has a disadvantage in studying 4f elements, because of their deep potentials and the slow convergence. In spite of these disadvantages, we examined this method in order to explore further study on the dynamical properties in future developments. In creating the pseudopotential of Eu, all components of s, p, d, and f orbital are included in valence electrons. Initially, the cutoff radius of the f potential was set to be 1.41 Å. In this case, the cutoff energy E_{cut} for plane-wave expansion becomes large (~1090 eV) in order to obtain a moderate convergence. Hence, the cutoff radius of the f potential was increased to 1.85 Å. In this setting, the plane-wave expansion shows acceptable convergence at E_{cut} = 490 eV, with 0.1 eV per atom.

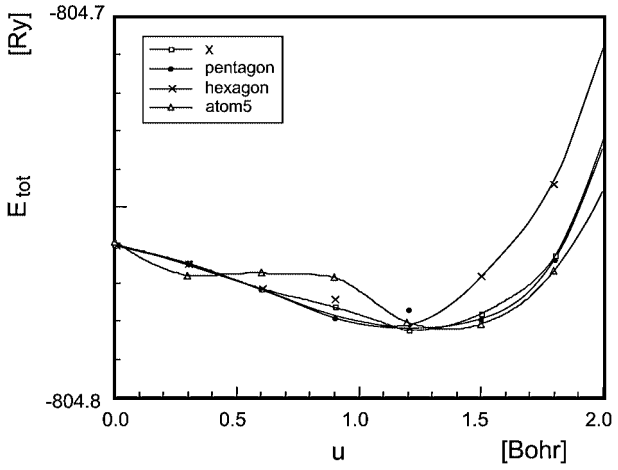

Fig. 2. The total energy versus Eu position measured from the center of C_{60}.

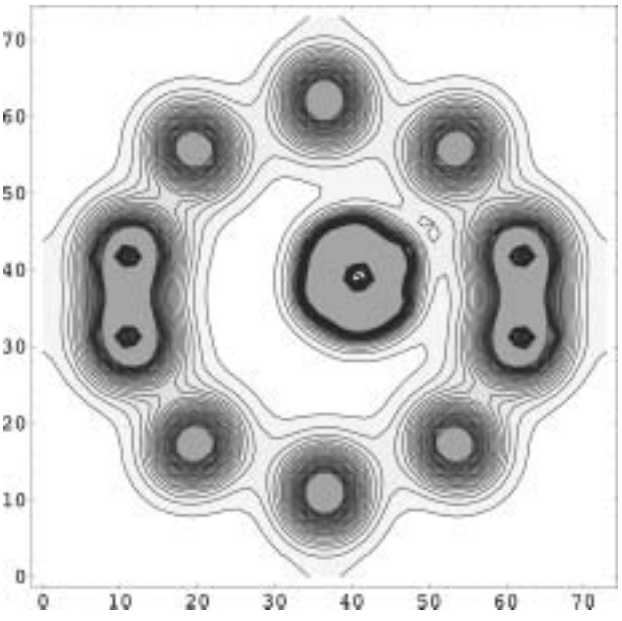

Fig. 3. The charge distribution of Eu@C_{60}. The contour map is divided by 20 from 0 to 0.2 [el/Bohr^3].

3.2. *Structural models*

The crystal structure of C_{60} is complicated due to a fact that many polymorphous phases, which have been found [17]. Any structure contains at least four units of C_{60} in the primitive cell. The differences between these phases are however only slight, for example, those differences in the orientation among different C_{60} units. The basic structure of C_{60} is almost the same; the radius of C_{60} is 3.62 Å, and the bond lengths of the intra C-C bonds are almost the same. Hence, we simplify the crystal structure of C_{60} by constructing a simple cubic structure containing only one C_{60} unit at the center, keeping the inter-molecular distance as shown in Fig. 1. This largely reduces computational task. The lattice parameter is set to be 10 Å, by considering the fact that the distance of adjacent C_{60} in the phase of $Pa\bar{3}$ is 9.92 Å.

3.3. *Calculated Results*

First, the pure C_{60} has been optimized with respect to all the atom positions. The intra C-C bond lengths are 1.404 (1.401 experiment) Å in the hexagonal edge and 1.437 (1.485) Å in the pentagonal edge. The agreement with experiment is good. Then, a Eu atom is inserted in the C_{60} crystal. When the Eu atom is placed at the center, the charge distribution shows that there is essentially no covalent bond between Eu and C atoms. The charge state is estimated by integrating the charge density inside a sphere with the center at Eu position. Taking the radius of the sphere a half the distance between the Eu and C atoms, we found that 1.33 electrons are deficient at the Eu position. This infers a singly ionized state.

We examined the total energy $E_{\rm tot}$ of the crystal as a function of the position of the Eu, with all the C atoms fixed. In Fig. 2, variations of $E_{\rm tot}$ are shown in four symmetry lines from the center to the cell boundaries. In all the directions examined, the energy minimum is located at a distance of 0.64 Å from the center. The value is different from the present experiment. We reexamined the adiabatic energy curves by raising the cutoff energy of the plane-wave expansion to 720 eV, with almost the same result. It seems that ignoring relativistic effects and spin polarization is the primary cause of this discrepancy. The spin polarization may affect those states near the Fermi level in this system.

The curvature of the adiabatic potentials at the energy minima is about 1 mdyn/Å. This amounts to the strong force constant of a Si stretching bond. This result seems rather surprising, because there is no strong covalent bond between Eu and C atoms. The strength of individual bonds Eu-C is still small. However, there are many C atoms surrounding the Eu atom, and accordingly the force constant becomes large enough as a whole. In Fig. 3, the charge distribution of the optimized structure is shown in the [020] plane. The charge density at the midpoint between Eu and C is 1/20 times smaller than that of Si covalent bond. An analysis of the charge distribution shows that 2.18 electrons are deficient in the Eu site. Thus, we can say that the charge state of Eu atoms at their equilibrium position is a doubly ionized one, Eu^{2+}.

4. Results and Discussion

The bond distances between the Eu atom and C atoms up to the second nearest neighbors were found by XAFS analysis. These values are 2.34 and 2.84 Å. Only the distance to the first nearest neighbors and the configuration number are not enough to decide if the Eu atom locates inside the C_{60} cage or at some position outside of C_{60}. The distance of the second neighbors gives the key information for it. Figure 4 shows the relation of distances. The dots in the figure indicate the distance between the Eu atom and

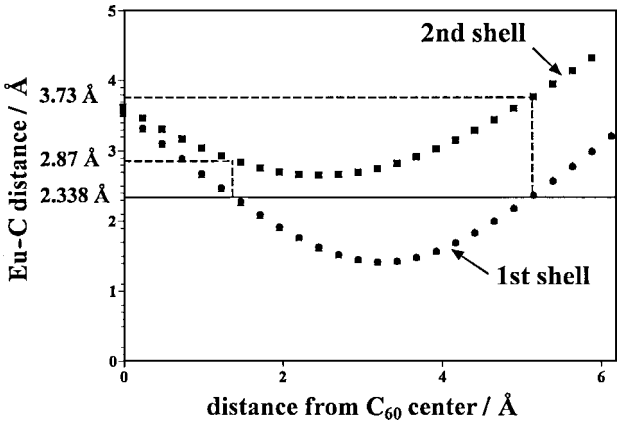

Fig. 4. Correlations of the distances between the Eu atom and the first neighbors and the second neighbors.

the C atom of the first and the second neighbors along the suitable line from the center of C_{60}. This figure indicates that the Eu atom is inside C_{60} cage, and furthermore that it locates away from the center of C_{60} cage by 1.4 Å toward the center axis of hexagonal network of the C atoms. XANES spectra of Eu C_{60} suggested that the valence of Eu atom is about +2 [5]. The electron configuration is thus f^7, showing the total symmetry (A_{1g}) of the I_h group.

The central instability of the Eu ion in the cage of C_{60} is also presented by first principles calculation. The calculated valency of the Eu atom is +2.18. This value excellently agrees with the experimental one. We will at first start with just +2 valency at the central position of the Eu atom. Under the condition, the charge distribution of the Eu^{++} (f^7) ion is spherical. The lowest unoccupied molecular orbital (LUMO) of C_{60} is a T_{1u} state, as well known. The +2 valence of the Eu atom means that the two electrons of the Eu atom transfer to C_{60} cage and occupy the T_{1u} state with a parallel spin. The two electrons may distribute uniformly over the whole C_{60} cage, giving total symmetry because of the repulsion force between the electrons. These situations suggest that the central position in the C_{60} cage is most stable inside the cage for the +2 valenced Eu ion, which is also the viewpoint of electro-static theory. However, the experimental observation and the first principles calculation indicate that the central position is unstable. Thus, we have to consider *ungerade* type instability to explain the observed phenomenon that the Eu atom shifts from the center along the high symmetric axis, that is, an *ungerade* charge distribution of the Eu ion and on the C_{60} cage should be taken into consideration. The electron density calculated by the first principles theory well simulates this state (see figure 3). However, two electrons in the T_{1u} orbital give a gerade symmetry in the wave function. As the cage of C_{60} with about 7 Å diameters is very big for an electron, the correlation of electrons should not be so strong. Thus, we may be able to treat the electrons independently. Under this assumption, the small shift of the Eu^{++} ion from the center of the cage lets itself recognize one electron. A vibrational mode of ungerade type plays an important role in this situation. It makes wave functions of gerade type mix those of ungerade type. The Hamiltonian for the expression of the interaction is represented as $\boldsymbol{H} = \lambda \boldsymbol{Q}_{T_{1u}}$, where λ is the coupling constant and $\boldsymbol{Q}_{T_{1u}}$ the normal coordinate with T_{1u} symmetry. Solving the interaction among the one electron with symmetry on the C_{60} cage and the f^7 electrons of the Eu^{++} ion, we obtain a double minimum potential along the $\boldsymbol{Q}_{T_{1u}}$ normal coordinate. It means the central instability of the Eu atom. This is just the pseudo Jahn-Teller effect.

Abstract

The near-edge fine structure of the F 1s absorption spectra of 3d metal fluorides was studied for the first time with high energy resolution. The spectra of these, the most ionic compounds of the 3d atoms, are analyzed comparing with the F 1s absorption spectrum of the molecular TiF_6^{2-} anion in solid K_2TiF_6. The latter spectrum was afore interpreted considering the fluorine spectra of the molecular PF_6^- anion in a KPF_6 crystal and of the gas-phase SF_6 molecule. The low-energy empty electron states in the 3d metal fluorides are shown to be formed due to covalent mixing of the metal 3d and fluorine 2p electron states.

1. Introduction

The covalent mixing (hybridization) between the transition-metal (TM) 3d electrons and ligand valence electrons leads to delocalization of the 3d states, decreasing the 3d electron density on the TM atoms and thus lowering the role of the 3d electron correlations. Although X-ray Absorption Spectroscopy (XAS) has been widely used for several decades for obtaining information on the energy distribution and spatial localization of unoccupied electron states in TM compounds, systematic XAS studies of the role of hybridization in the formation of the electronic structure of these compounds are nearly not available.

This paper presents F 1s absorption spectra measured for the first time with high photon-energy resolution for a series of binary fluorides TiF_4, VF_4, VF_3, CrF_3, CrF_2, MnF_3, MnF_2, FeF_3, FeF_2, CoF_2, NiF_2, CuF_2, and ZnF_2. We have selected fluorides because they are the most ionic among the simplest 3d-metal compounds. Their spectra and the electronic structure may provide a basis for understanding electronic properties of more complicated covalent compounds. The obtained spectra are analyzed in order to (*i*) elucidate the character of the covalent bonding and the way it is displayed in X-ray absorption spectra and (*ii*) study the conduction-band electronic structure along the whole series of TM fluorides.

2. Experiment

We investigated the Near-Edge X-ray Absorption Fine Structure (NEXAFS) of the F 1s spectra in binary fluorides KF, TiF_4, VF_4, VF_3, CrF_3, CrF_2, MnF_3, MnF_2, FeF_3, FeF_2, CoF_2, NiF_2, CuF_2, and ZnF_2, as well as in the gas-phase SF_6 molecule and in the PF_6^- and TiF_6^{2-} molecular anions of the solid compounds KPF_6 and K_2TiF_6. The 2p absorption spectra of titanium in TiF_6^{2-}, TiF_4, TiO_2 and of potassium in KF were investigated additionally as a tool for interpretation of the F 1s absorption structures in the spectra of titanium and potassium fluorides. Most of these spectra were measured at the Russian-German beamline (RGB) of the electron storage ring BESSY II [1], while the spectra of KF and CuF_2 were taken under similar experimental conditions at the D1011 beamline of the electron storage ring MAX II. Spectra from the solid samples (powders) were obtained by detecting the total electron yield. The absorption spectra of gas-phase SF_6 and Ne were measured with a gas cell by detecting the photoionization yield. Based on the linewidth analysis for the Ne 1s → 3p transition, the photon-energy resolution of the RGB in the range of the F 1s absorption edge (∼690 eV) was estimated to be approximately 115 meV. The absorption spectra were normalized to the incident photon flux. Photon energies in the range of the fine structure of the F 1s absorption spectra were calibrated using the known position (683.9 eV) of the first narrow peak in the F 1s absorption spectrum of K_2TiF_6 [2], which was recorded before and after measurement of each spectrum of all fluorides.

3. Results and discussion

The high-resolution F 1s absorption spectra of the TM fluorides were measured over a wide photon-energy range (675–760 eV) and normalized to the same absorption jump at the photon energy of 760 eV. Figures 1 and 2 show NEXAFS spectra in the photon-energy range of 678–710 eV. To our knowledge the high-resolution F 1s spectra of the majority of the binary TM fluorides under study are presented for the first time. Previously only the spectra from some difluorides of 3d atoms [3] and from ScF_3 [4] were measured although with essentially lower resolution. Evidently, the obtained spectra differ very strongly both from the F 1s spectrum of K_2TiF_6 containing covalent molecular anions TiF_6^{2-} and along the series of the 3d-metal fluorides (with increasing number of TM 3d electrons: TiF_4-⋯-ZnF_2). Nevertheless, one can distinguish two spectral ranges, whose structural features are similar for all the spectra, including that of covalent TiF_6^{2-}. The first range contains narrow resonances *a*, *a*′, *b*, and *b*′ located below the F 1s absorption edge (∼690 eV). The second range is dominated by the broader absorption bands *c*, *d*, and *e* that are located slightly above the edge and significantly overlap with each other.

Since for all fluorides under study an octahedral, or nearly octahedral, coordination of the 3d atoms by fluorine is typical,

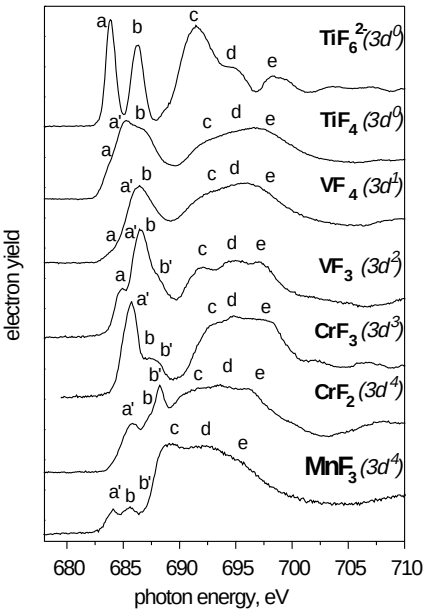

Fig. 1. High-resolution F 1s absorption spectra of 3d-metal fluorides K_2TiF_6, TiF_4, VF_4, VF_3, CrF_3, CrF_2, and MnF_3. The spectra were normalized to the same absorption jump at the photon energy of 760 eV.

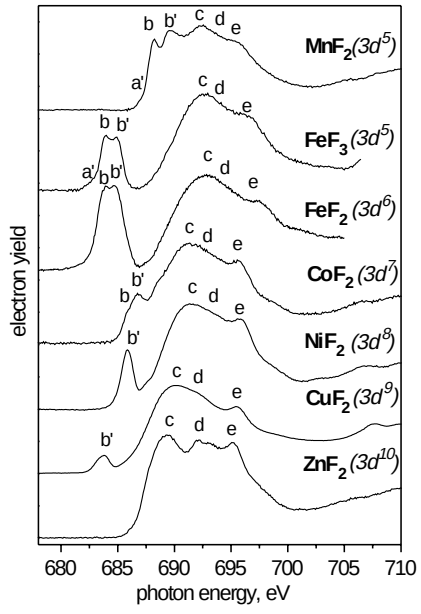

Fig. 2. High-resolution F 1s absorption spectra of 3d-metal fluorides MnF_2, FeF_3, FeF_2, CoF_2, NiF_2, CuF_2, and ZnF_2. The spectra were normalized to the same absorption jump at the photon energy of 760 eV.

these crystals are commonly considered as three-dimensional arrays of interlinked perfect or distorted MF_6 octahedra [5]. In this case, possible covalent bonding between the 3d atom M and surrounding fluorine atoms in ionic crystals can, evidently, take place within the octahedron due to the mixing of the valence M 3d, 4s, 4p and F 2p electron states. In order to follow how this hybridization of the valence states can be reflected in the F 1s absorption spectra of binary TM fluorides, first we discuss the origin of the absorption features in the spectra of the covalent molecular TiF_6^{2-} anion in solid K_2TiF_6.

In Fig. 3 we compare the F 1s NEXAFS spectra for the following isostructural covalent systems: the gas-phase SF_6 molecule and the solid-state molecular anions PF_6^- and TiF_6^{2-} representing isolated regular octahedra [5]. The absorption

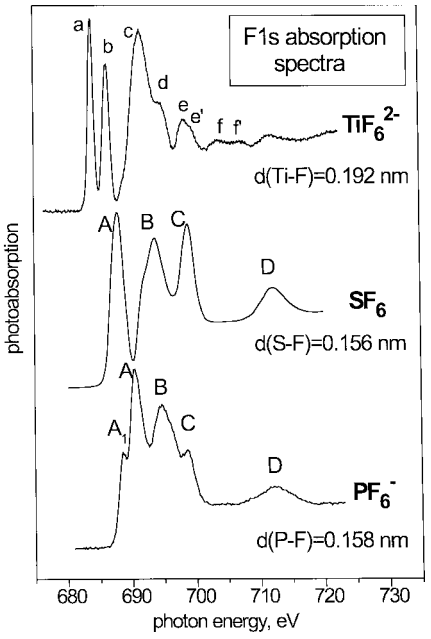

Fig. 3. Near-edge fine structure of the F 1s absorption spectra for covalent anions TiF_6^{2-} and PF_6^- in solid K_2TiF_6 and KPF_6 as well as for gas-phase molecule SF_6.

spectrum of SF_6 exhibits well-developed structures A-D, which result from the transitions of the F 1s electrons into unoccupied molecular orbitals (MOs) of a_{1g}, t_{1u}, t_{2g}, and e_g symmetry [6–9]. Bands C and D appear in the continuum significantly above the absorption edge resulting from the transitions to MOs t_{2g} and e_g. These MOs are formed due to covalent mixing of the S 3d states and the F 2p states, so that the corresponding peaks can be observed in the absorption spectra of both sulfur and fluorine at almost the same energy positions above the vacuum level. The latter is also true for the covalent molecular anion PF_6^- in solid KPF_6 showing absorption spectra similar to those of SF_6 [10].

Whereas the F 1s NEXAFS spectra of SF_6 and PF_6^- are similar to each other, they differ considerably from the spectrum of TiF_6^{2-}. Indeed, resonances C and D vanish from the continuum, two very narrow and intense absorption peaks *a* and *b* arise in the low-energy spectral range and the onset of the F 1s absorption becomes shifted by several eV to low energies. It is remarkable that the energy half widths of peaks *a* and *b* (∼1 eV) in the spectrum of solid K_2TiF_6 are significantly smaller than the half width of the lowest-energy peak A (2.3 eV) in the spectrum of gaseous SF_6 molecule. By comparison between absorption structures in the F 1s and the Ti 2p spectra it can be easily shown that the low-energy peaks *a* and *b* are related to electron transitions into the unoccupied Ti $3dt_{2g}$ and $3de_g$ states hybridized with the F 2p electron states [10]. Thus, the Ti 3d states in the TiF_6^{2-} anion can be probed by the F 1s NEXAFS. In going from SF_6 and PF_6^- to TiF_6^{2-} one can clearly observe (*i*) a large (∼15 eV) low-energy shift of the absorption bands related to the 3d states of the central atom (bands C and D for SF_6 and PF_6^- and peaks *a* and *b* for TiF_6^{2-}) and (*ii*) a considerable decrease in their energy half width (Fig. 3). These spectral changes result definitely from the collapse and the subsequent increase of localization of the 3d states of the central atom in going from the atoms at the end of the second row to the atoms of the first transition series [11].

Based on the local and space-oriented character of the covalent bonds and taking into account the results of our comparative

consideration for F 1s spectra of TiF_6^{2-}, TiO_2, KF, and TiF_4 [10], we believe that it is possible to consider the octahedral quasi-molecule MF_6 formed by the 3d atom and surrounding fluorine atoms as the main building block of the crystal not only in rather covalent 3d systems, but also in the case of ionic TM fluorides.

The similarity in overall lineshape and energy position for the NEXAFS in the spectra of the ionic fluorides and the covalent molecular anion TiF_6^{2-} allows us to assign the structures observed in both cases to the unoccupied electron states with the mixed TM 3d – F 2p character resulting from the significant covalent bonding between the valence electrons of the metal and fluorine atoms. However, in going from the TiF_6^{2-} anion to the binary fluorides and further along the series TiF_4- $\cdots$ -ZnF_2 the spectra in Figs. 1 and 2 exhibit remarkable changes in number and relative intensity of the resonances, as well as in their energy positions with respect to each other and to the onset of the F 1s continuum. These changes are likely caused by (*i*) a decrease in the number of unoccupied TM 3d states, (*ii*) an exchange interaction between the 3d electrons in partially filled shells, (*iii*) changes in size of MF_6 and the character of its distortion, and (*iv*) a different impact of the remaining part of the crystal on the quasi-molecule MF_6 that may particularly influence the coupling between these structural units.

Nevertheless, we can make some assumptions about the origin of these low-energy structural features. Taking into account the results of our comparative quasi-molecular analysis of the XAS spectra of TiF_6^{2-}, TiO_2, and KF [10], we can assume first of all that the coupling between the octahedra MF_6 in the TM fluorides affects only slightly the lineshape of the fluorine spectra. Calculations of the electronic structure for oxides of the 3d atoms [12] show that accounting for the exchange interaction between the 3d electrons leads to additional splitting of the $3dt_{2g}$ and $3de_g$ electron states of MO_6 into $t_{2g}\uparrow$, $e_g\uparrow$ and $t_{2g}\downarrow$, and $e_g\downarrow$ components related to the two possible spin orientations in both states: up ($\uparrow$) or down ($\downarrow$), respectively. Evidently, a similar situation must hold for MF_6 in the TM fluorides. It is also clear that the ordering of these split 3d components depends on the ratio between the magnitudes of the crystal-field and the exchange splitting. More detailed discussion [10] allows us to suppose that the crystal-field splitting for the fluorides under study is larger than the exchange splitting and, as a consequence, the ordering of the 3d components is $t_{2g}\uparrow$, $t_{2g}\downarrow$, $e_g\uparrow$, and $e_g\downarrow$.

Based on the formal valence, we assume that the titanium atom (with $3d^24s^2$ valence electrons) actually has the same electronic configuration of the Ti^{4+} ion in the molecular anion TiF_6^{2-} and in solid TiF_4, which contains no 3d electrons at all. In this case, the 3d – 3d exchange interaction is absent and peaks *a* and *b* in the spectrum of TiF_6^{2-} can be related to the electron transitions into the spin degenerate $3dt_{2g}$ and $3de_g$ states. The changes in the low-energy absorption structure in going from TiF_6^{2-} to TiF_4 result from the considerable tetragonal distortion of the octahedra in TiF_4 [5], which causes a splitting of the $3dt_{2g}$ and $3de_g$ bands each into two components and a merge of the low-energy absorption bands into one broad band *a*-*a*′-*b*.

In contrast to that, in other binary (V, Cr, etc.) fluorides these states are additionally split due to the exchange interaction between the 3d electrons, which occupy the $t_{2g}\uparrow$, $t_{2g}\downarrow$, $e_g\uparrow$, and $e_g\downarrow$ states successively according to their statistical weights: 3 and 2 for the t_{2g} and e_g components, respectively. In the case of VF_4 one available 3d electron partly occupies the lowest $3dt_{2g}\uparrow$ band, which may be additionally split into two components owing to the considerable distortion of the VF_6 octahedron (as in TiF_4). As a consequence, one broad band *a*-*a*′-*b* is observed at the low-energy onset of the F 1s absorption spectrum. The formal valence configuration $3d^2$ for the vanadium ion V^{3+} in VF_3 with the nearly perfect VF_6 octahedra indicates that the corresponding F 1s absorption spectrum may also exhibit all four 3d components, since the lowest $t_{2g}\uparrow$ state remains not fully occupied. Due to the ideal octahedral shape of VF_6 the absorption spectrum of VF_3 is characterized by better resolved structures as compared to the VF_4 and TiF_4 spectra. The overall lineshape of its low-energy structures *a*-*a*′-*b*′ does not rule out the possibility of existence of an additional unresolved component *b* in the range of the broad peak *a*′. In the case of CrF_3, CrF_2, MnF_3, MnF_2, and FeF_3 the lowest $t_{2g}\uparrow$ state is already completely occupied, so that only three low-energy features *a*′, *b*, and *b*′ (related to the transitions to the $t_{2g}\downarrow$, $e_g\uparrow$, and $e_g\downarrow$ states) are observed in the spectra.

Similarly, only two transitions to the $e_g\uparrow$ and $e_g\downarrow$ states are found in the spectra of FeF_2 and CoF_2, since the $t_{2g}\downarrow$ state in these compounds is filled. For NiF_2 and CuF_2 only the last absorption peak *b*′ is observed in the low-energy part of the F 1s spectra, since only one electron state $e_g\downarrow$ remains unfilled. In the spectrum of ZnF_2 the low-energy structure is absent because all 3d electron states are fully occupied.

In conclusion, the basic results of our study provide a strong experimental evidence for importance of covalent mixing in the formation of unoccupied electron states in crystalline 3d-TM fluorides. The F 1s absorption spectra are found to be very promising in probing unoccupied 3d states of the TM atoms in these compounds.

Abstract

The electronic and structural properties of Ru oxides were investigated by utilizing X-ray absorption spectroscopy (XAS). We estimate the valence of Ru in perovskite ruthenium oxides by XAS measurements. XAS measurements were carried out at room temperature around Ru K-edge. The valence of Ru in A_2(A = Ba, Sr)LnRuO$_6$ and A(A = Ca, Ba, Sr)RuO$_3$ was 4+. The valence of Ru in Ln$_3$RuO$_7$ was 5+. The valence of Ru in PbRuO$_3$ showed an intermediate value between 4+ and 5+. We calculated XAS spectra around the Ru K-edge by FEFF 8.0. Theoretical calculation reproduced the experimental spectra. We analyzed XAS spectra and obtained information of local structure. The bond length between Ru and O was consistent with the results of neutron diffraction.

1. Introduction

The perovskite-type oxides have the general formula ABO_3, in which A represents a large electropositive cation and B represents a small transition metal ion. The perovskite structure can be described as a framework of corner-shared BO_6 octahedra which contain A cations at 12-coordinate sites. Recent studies of ruthenium oxides with the formula ABO_3 have shown a wide variety of electrical and magnetic properties such as unconventional superconductivity, and ferromagnetism accompanied by spin glass behavior [1]–[3]. Double perovskite-type oxides have the formula $A_2B'BO_6$, in which the primes indicate the different ions in different oxidation states, and in some cases, the cations at the B sites, B' and B'', regularly order, i.e., 1 : 1 arrangement of B' and B'' ions has been observed over the six-coordinate B-sites. Since the B cations generally determine the physical properties of perovskites, different kinds of B' and B'' ions should show a variety of the physical properties of double perovskites. We have been interested in the properties of the perovskites containing tetra- or pentavalent ruthenium ions. The electronic structure of $Ru^{4+(5+)}$ is [Kr]$4d^{4(3)}$ ([Kr] = krypton core). Such highly oxidized cations from the second transition series sometimes show quite unusual magnetic behaviour. In the compounds A_2BRuO$_6$ (where A is alkaline-earth metal and B is a lanthanide (Ln) and a 3d transition metal (TM)), ruthenium ions are in the tetravalent state in the case of B = 3d TM and in the pentavalent state in the case of B = Ln. In the case of B = 3d TM, these compounds sometimes show ferromagnetic order [7]. In the case of B = Ln, these compounds show long range magnetic ordering at low temperature. For example, Sr_2YRuO_6 [4] and Sr_2LuRuO_6 [5] are antiferromagnetic below 26 and 30 K, respectively, and Sr_2ErRuO_6 [6] shows antiferromagnetic ordering involving both Ru^{5+} and Er^{3+} at 40 K. However, previous work is limited to the compounds in which the paramagnetic ions are only Ru^{5+} ions, except for Sr_2ErRuO_6. But direct measurements of Ru ion valence in A_2BRuO$_6$ and A(A = Sr, Ca, Ba, and Pb)RuO$_3$ have not been carried out before. Especially, the valence of Ru ions in $Pb_2Ru_2O_6$ could not be determined. In this study, we estimate directly the valence of ruthenium ions in the perovskites. We investigated the electronic and structural propertries of these Ru compounds by means of X-ray absorption spectroscopy (XAS) measurements.

2. Experimental

Polycrystalline samples of A(A = Sr, Ca, Ba, and Pb)RuO$_3$ and A(A = Sr, Ba, Ca, and La)$_2B$(B = La, Eu, Mn, and Ni)RuO$_6$ were prepared by the conventional solid state reaction as noted in Ref. [8 and 9]. These products were shown to be perovskite-like single phase materials by powder X-ray diffraction. The XAS spectra of the Ru K-edge for Ru oxides were obtained at the beamline BL39XU and BL01B1 of SPring-8, Japan. The beamline was composed of a double-crystal monochormator equipped with a Si 111 crystal and a Si mirror for eliminating higher harmonics. The XAS spectra were recorded under transmission mode. The X-ray intensity was monitored using ionization chambers filled with N_2 gas before and after observing samples. For the XAS measurements, powdered samples were uniformly spread on Scotch tape and then the thickness of samples were adjusted so that the edge jump was 1. All the XAS data were obtained at room temperature. The energy resolution was about 2 eV around the Ru K-edge. In order to investigate the electronic properties and local structure of Ru oxides, we carried out calculations of XAS spectra by utilizing the code FEFF 8.0 [10].

3. Results and Discussion

Figure 1 shows normalized XANES spectra of A(A = Ca, Sr, Ba)RuO$_3$ and $Pb_2Ru_2O_{6.5}$ around the Ru K-edge. The Ru K-edge correponds to transition from 1s to 5p. From bottom to top, six curves show CaRuO$_3$, SrRuO$_3$, BaRuO$_3$, $Pb_2Ru_2O_{6.5}$ and Eu_3RuO_7 respectively. The valence of Ru ions in Eu_3RuO_7 is known to be pentavalent. These spectra were composed of two peaks denoted A and B. According to Ref. [11 and 12], the two peaks of A and B correspond to $5p_x$ and $5p_{y(z)}$ respectively. This result means that RuO$_6$ octahedra are distorted and the apical Ru-O bond length is longer than the Ru-O bond length in the ab-plane. The spectral shape of these Ru compounds are very similar to each other. These results show that the

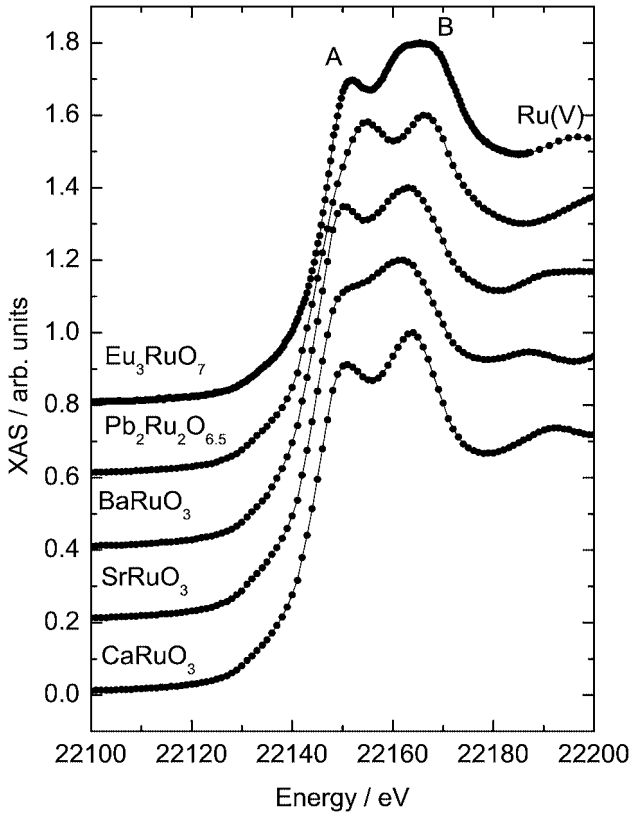

Fig. 1. XAS spectra in $A(A = \text{Ca, Sr, Ba})RuO_3$ and $Pb_2Ru_2O_{6.5}$ around the Ru K-edge.

compounds have the same local symmetry around the Ru ion. But the absorption edge in $Pb_2Ru_2O_{6.5}$ shifted to higher photon energy by 2 eV compared with the other compounds. This means that the valence of Ru ions in $Pb_2Ru_2O_{6.5}$ is higher than that of the other compounds and could be pentavalent. Therefore, we propose that the valence of Pb ions is nearly divalent.

Figure 2 shows normalized XANES spectra of $A_2B(B =$ Ni, Mn, Eu, La)RuO_6 around the Ru K-edge. From bottom to top, seven curves show Ca_2MnRuO_6, La_2NiRuO_6, Ba_2EuRuO_6, Ba_2LaRuO_6, Sr_2EuRuO_6 and Eu_3RuO_7. These spectra were composed of two peaks denoted A and B. The spectra are very similar. The width of peak B in the case of $B =$ Ln is broader than in the case of $B =$ 3d TM. But the absorption edge of La_2NiRuO_6 shifted to lower photon energy by 2 eV compared with the other compounds and is close to the absorption edge of $SrRuO_3$. This means that the valence of Ru ions in La_2NiRuO_6 is lower than for the other compounds and could be tetravalent [13].

In order to investigate the local strucutre and the electronic states of Ru ions in $A(A =$ Ca, Sr, Ba)RuO_3, we calculate the Ru K-XAS spectra by means of FEFF 8.0 [10]. The atomic position and space group were obtained in previous papers [14], [15]. We used that the space group of $BaRuO_3$ is $R\bar{3}m$ and that of $CaRuO_3$ is Pnma and that of $SrRuO_3$ is $Pm\bar{3}$ and Pnma. Figure 3 shows theoretical and experimental spectra around the Ru K-edge of Ru oxides. The solid lines represent theoretical spectra and solid circles represent experimental spectra. For $SrRuO_3$, the solid line shows (I)$Pm\bar{3}$ and the broken line shows (II)Pnma. The bottom panel shows $SrRuO_3$ and the upper panel shows $CaRuO_3$. For both compounds, theoretical spectra reproduced experimental spectra very well.

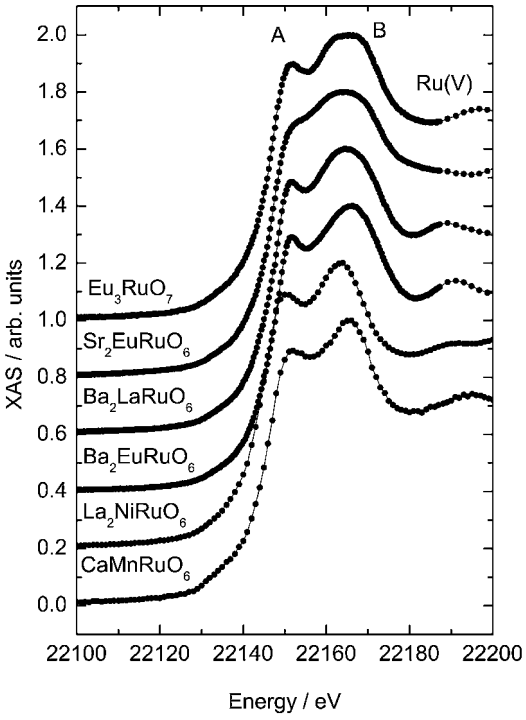

Fig. 2. XAS spectra in Ca_2MnRuO_6, La_2NiRuO_6, Ba_2EuRuO_6, Ba_2LaRuO_6, Sr_2EuRuO_6 and Eu_3RuO_7 around the Ru K-edge.

Especially, for $SrRuO_3$, theoretical spectra were calculated for two different models of the crystal structure in order to confirm the structure of $SrRuO_3$. In the case of Pnma, the theoretical spectral shape of XAS reproduced the experimental one. The intensity ratio of the peaks A and B was almost the same

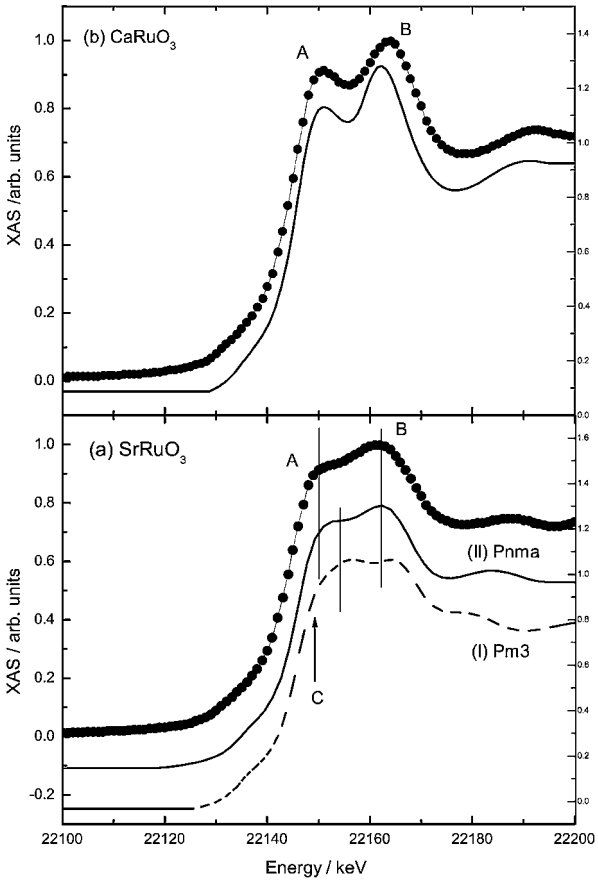

Fig. 3. Theoretical and experimental XAS spectra in $A(A =$ Ca, Sr)RuO_3 around the Ru K-edge.

between experimental and theoretical spectra. In the case of $Pm\bar{3}$, the difference between peaks *A* and *B* in theoretical XAS is closer than the difference of experimental one. The shoulder C was found. In this calculation, the spectrum of Pnma is reproduced better than that of $Pm\bar{3}$. Therefore, we conclude that the crystal structure of $SrRuO_3$ is Pnma and that the bond length between Ru and O, which were estimated by means of XAS measurements, is consistent with the results of neutron diffraction [16].

4. Summary

In summary, we measured XANES spectra around the Ru K-edges for Ru oxides at BL39XU and BL01B1 of SPring-8, Japan. We estimate the valence of eight Ru compounds. The valence of Ru ion in $Pb_2Ru_2O_{6.5}$ and Ca_2RuMnO_6 are close to pentavalent. The valence of Ru ions in Ba_2EuRuO_6, Ba_2LaRuO_6 and Sr_2EuRuO_6 are pentavalent. The other compounds are tetravalent. In order to investigate the local strucutre and the electronic states of Ru ions in $A(A = \text{Ca, Sr, Ba})RuO_3$, we calculate the Ru K-XAS spectra by means of FEFF 8.0. We conclude that the crystal structure of $SrRuO_3$ was Pnma [16].

Abstract

The local order around K for $K(CF_3SO_3)$ doped Siloxane-Poly(propyleneoxide) hybrids at different doping concentration was investigated by X-ray absorption spectroscopy (EXAFS and XANES) at the potassium K-edge. The results indicate that the use of HCl as hydrolytic catalyst for gelation induces the precipitation of KCl. The ionic conductivity is strongly related to the presence of oxygen atoms as first neighbours around potassium and to the amount of KCl precipitate.

1. Introduction

The search for new efficient solid polymer electrolytes is one of the clues for the development of various electrochemical devices such as rechargeable batteries, sensors, data storage or electrochromic displays [1]. These new advanced materials should combine good ionic conductivity, thermal and electrochemical stabilities, reasonable mechanical properties, and processing abilities, but also, optical transparency could be required for some of the cited applications [2]. The need for such a combination of properties explains the recent development of ion-conducting hybrids systems in which alkali salts are dissolved inside an organic-inorganic matrix. Such materials (also called Ormolytes – ORganically MOdified electroLYTEs) can be obtained by the sol-gel route by mixing and/or grafting together polyether chains with an inorganic network [3]. Then, these materials combine the solvent behavior of the polymer component (generally poly(ethyleneoxide) (PEO, $-(CH_2CH_2O)_n-$) or poly (propyleneoxide) (PPO, $-(CH_2CHCH_3O)_n-$) and the mechanical properties of a network grafted by silica nodules (SiO_2). The versatility of the "chimie douce" synthetic route allows to tailor the properties of the final materials by the choice of the starting component and the synthetic conditions. Then, strong effects of the catalyst which is used during the hydrolysis and condensation steps are well established, allowing to control the microsegregation of the two phases and the tuning of the thermo-mechanical properties of the organic component [4]. Less is known about the influence of the catalyst on the ionic conduction properties of the ormolytes.

Recently we have reported that in siloxane-PPO ormolytes doped with different potassium salts ($KClO_4$, KI, KCF_3SO_3 and KNO_2) [5], potassium ions are present in several forms: some of them are dissolved inside the PPO matrix because of the interactions with the ether-type oxygens, while the low solubility of these salts leads also to crystalline or amorphous KX(X = ClO_4, I and NO_2) precipitates. Besides of the low solubility of the salts inside the polymeric matrix, the use of HCl as catalyst for the gelation of the hybrid precursor induces the formation of a KCl phase. The set of results so-obtained have suggested that the ionic conductivity is correlated to the presence of oxygen atoms as first neighbours around potassium. Nevertheless, the existence of several sites for most of the samples studied in [5] did not make easy the correlation between ionic conductivity and the local order around the cation. To go further in this way, two families of almost equivalent materials are studied herein, differing only by the amount of HCl catalyst. Large variations of the ionic conductivity are observed and related to the study of the local order around the potassium salt by X-ray absorption spectroscopy (EXAFS and XANES) at the K K-edge.

2. Experimental

2.1. *Sample preparation*

The preparation of potassium-doped siloxane-PPO hybrid sols and gels has already been described [5]. Equimolar amounts of 3-isocyanatopropyltriethoxysilane (IsoTrEOS) and O,O′Bis(2-aminopropyl(polypropyleneoxide) were stirred together in tetrahydrofuran (THF) under reflux for 15 hours. THF was evaporated and a hybrid precursor $_3$(EtO)Si-(PPO)-Si(OEt)$_3$ was obtained. This process was adopted for PPO polymers with molecular weight (M_W) of 2000 and 4000 g/mol (labelled as PPO2000 and PPO4000). 0.5 g of the precursor was mixed with 0.6-mL of ethanol containing HCl at 0.001 M and 0.128 M for routes A and B, respectively. The amount of HCl in route B being two orders of magnitude higher than that in route A, we will speak about a non-catalysed route for route A and a catalysed one for route B. Then 0.15 mL of KCF_3SO_3 aqueous solution was added leading to ratios $[H_2O]/[Si] = 21.9$ and 38.4 for PPO2000 and PPO4000, respectively. The potassium amount so-added was defined as a function of the number of the ether-type oxygen of PPO chains (O): $R = [O]/[K] = 4$, 15, 20, 30 and 50. Monolithic pieces with thickness of 0.5 mm were obtained after slow drying under vacuum at 80 °C for 24 h.

2.2. *Conductivity measurements*

Ionic conductivity measurements were performed at room temperature (RT) with a SOLARTRON SI1260 apparatus in the range of 1 Hz to 10 MHz, with an applied tension of 300 mV.

2.3. *XAS measurements and data analysis*

XAS measurements were carried out at LURE (Orsay, France) on the D44 station installed on the DCI storage ring (1.85 GeV and 300 mA). Potassium K edge (3609 eV) data were recorded in transmission mode at RT using ionization chambers filled with He/Ne and a Ge(111) (Si(111)) double crystal monochromator for EXAFS (XANES). Harmonics rejection was done by using two mirrors cut-off. As-prepared rubbery samples were measured under primary vacuum leading to typical absorption jumps ranging from 0.05 to 0.5.

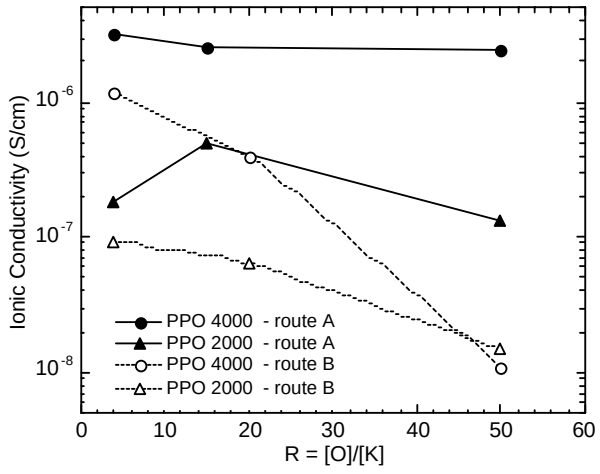

Fig. 1. Ionic conductivity of the different ormolytes as a function of R.

The EXAFS and XANES normalization were performed as previously described in [5]. Structural parameters were determined by a least square fitting procedure using experimental phase and amplitude functions extracted from KF and KCl. The transferability of the fluor electronic functions extracted from the rocksalt structure of KF to simulate oxygen contribution around potassium was checked onto $KClO_4$. Electronic phase and amplitude functions for carbon atoms were extracted from the McKale tables [6].

3. Results

The ionic conductivities measured for the different samples as a function of the molar ratio R are shown in Figure 1. These hybrids exhibit tunable ionic conductivities at RT ranging between $3 \cdot 10^{-6}$ and 10^{-8} S cm^{-1} depending on M_W and R. The ionic conductivity increases with the potassium content, but whatever M_W, the ionic conductivities of ormolytes prepared without HCl (route A) are higher than the values measured on the samples prepared with HCl (route B) by a factor 10 or 100.

Figure 2 presents XANES spectra of the corresponding ormolytes. On one hand, the XANES spectra of ormolytes prepared without HCl are superimposable for all samples. So only the spectrum recorded for route A ormolytes with the lower potassium content is presented in Fig. 2. On the other hand, the shapes of the XANES spectra of hybrids prepared with HCl are very dependent to the doping concentration. As the amount of KCF_3SO_3 decreases, the spectrum becomes more structured with resonances in phase with those observed on the XANES spectrum of KCl. In fact as demonstrated in the insert of Figure 2, a spectrum with a shape similar to the one observed for the K doped siloxane PPO2000 ormolyte with $R = 50$ is obtained from a linear combination of the XANES spectra of KCl and of route A ormolyte, in the ratio $\approx 1:1$.

Figure 3a and b reports $k\chi(k)$ EXAFS spectra and corresponding Fast Fourier Transforms (FFT) of the different samples. Due to the similarity of XANES spectra of the ormolytes prepared by route A only the PPO2000 sample with $R = 15$ has been presented. The first intense peak is related to the oxygen first shell of coordination whereas the second can be related to a chlorine or carbon contribution or both depending on the routes and dopant content. The structural parameters obtained by a least-square fitting procedure are gathered in Table I for ormolytes

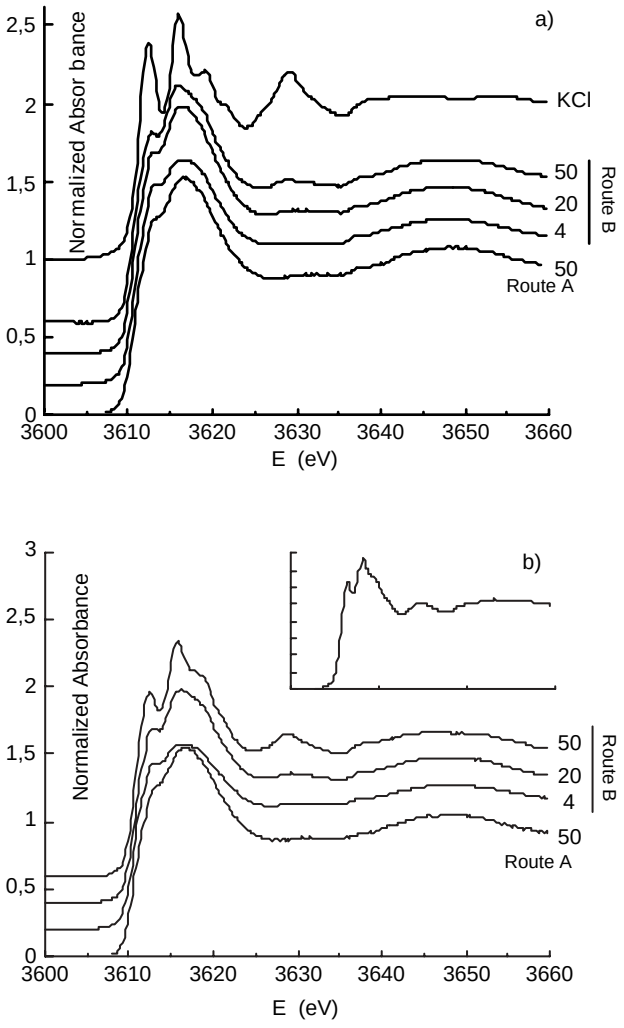

Fig. 2. Potassium K-edge XANES spectra of a) PPO4000- and b) PPO2000-based ormolytes. The XANES spectrum of KCl is given for comparison in a) whereas the insert in b) is the 1 : 1 linear combination of the XANES spectrum of KCl and of the typical XANES spectrum of route A ormolytes.

prepared with PPO2000. They are in agreement with the XANES analysis.

4. Discussion

4.1. *Local order around potassium for ormolytes of route A*

Irrespective to the KCF_3SO_3 content, the local order of potassium doping PPO2000 and PPO4000 ormolytes prepared by route A is identical. A potassium ion is coordinated by 6.6 ± 0.7 oxygens located at 2.77 ± 0.02 Å. The large Debye-Waller factor (0.16 Å) accounts for a large distribution of distances as reported for crystalline polymer-salt complexes PEO_4:KSCN [7] and PEO:KCF_3SO_3 [8]. Indeed in the PEO based-systems the average K-O distance was found at 2.85 Å with bond distances ranging from 2.49 to 3.09 Å. Note also that the coordination number of potassium determined by EXAFS is also in good agreement with the 7-fold coordinence reported for potassium in these published crystallographic structures. A common characteristic of PEO salt complexes [7, 8] is that anions participate in the coordination sphere of potassium together with ether-type oxygens of the polymer and the proportion in the number of anions and ether-type oxygens in the first coordination sphere depends on the proportion of salt in the complexes. In the case of siloxane-PPO hybrids doped by potassium salts, we have strong experimental evidence

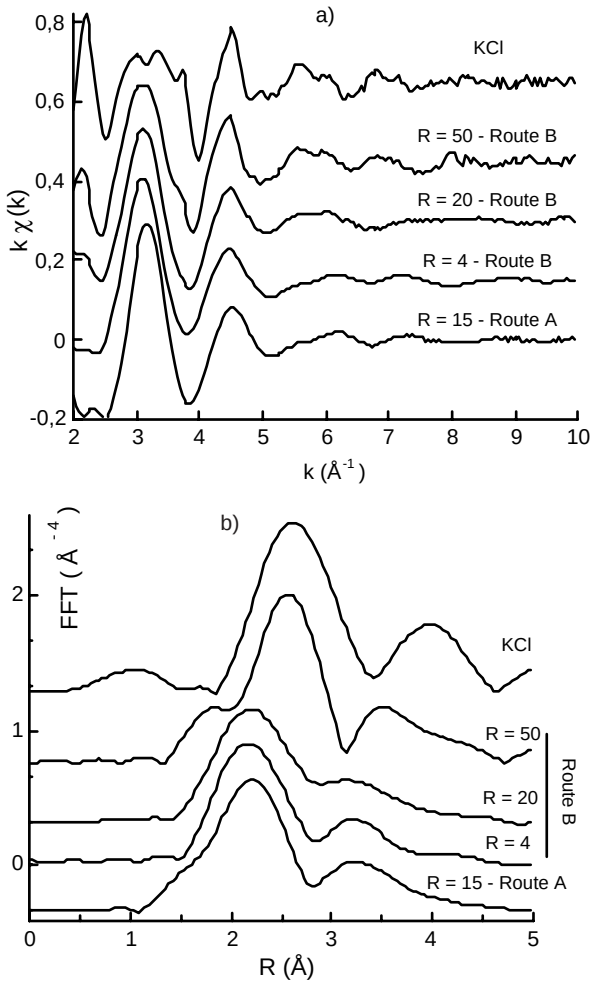

Fig. 3. a) Potassium K-edge $k\,.\,\chi(k)$ EXAFS spectra of the different PPO2000-based ormolytes and b) FFT of the $k^3\,.\,\chi(k)$, using a Kaiser apodization window from 2.7 to 9.3 Å^{-1} with $\tau = 4$. The spectrum of KCl is given for comparison.

that potassium is only coordinated by ether-type oxygens since the local order around potassium is the same using KSCN, KI or KCF_3SO_3 salts to prepare PPO2000 hybrids [9]. The anion is totally dissociated from the potassium atom, in agreement with some preliminary Raman experiments obtained with the potassium triflate salt [9]. This result allows us to unambiguously attribute the second peak of the FFT of ormolytes prepared by route A to a carbon contribution of the polymer backbone. The average number of carbon atoms, 6.4 ± 0.6, is equal to the average oxygen coordination number and the average distance is equal to 3.28 ± 0.02 Å. As for the K-O bond distance, the K-C correlation distance is shorter in the siloxane-PPO ormolytes than the average distance found for PEO_4:KSCN [7] (3.53 Å). Possible explanations should be the amorphous character of the polymer backbone in the PPO samples and the different conformation of the PEO and PPO skeletons.

Table I. *Results of curve-fitting analysis of potassium K-edge EXAFS spectra of the different PPO2000-based ormolytes. The inverse Fourier transforms were carried out from 1.30 to 3.60 Å, except for the route B sample with $R = 50$ for which the window was 1.40 to 3.05 Å. Uncertainty of the last digits is given in parentheses. The residual ρ factor is defined as:*
$\rho = [\Sigma(k^3\chi_{\mathrm{exp}}(k) - k^3\chi_{\mathrm{theo}}(k))^2/\Sigma(k^3\chi_{\mathrm{exp}}(k))^2]^{1/2}$

PPO2000-based ormolytes	Shell	N	R (Å)	σ (Å)	ρ (%)
Route A	K-O	6.6 (7)	2.77 (2)	0.16 (3)	0.14
R = 15	K-C	6.4 (6)	3.26 (2)	0.14 (3)	
Route B	K-O	6.2 (6)	2.79 (2)	0.16 (3)	0.14
R = 4	K-C	4.7 (5)	3.29 (2)	0.14 (3)	
Route B	K-O	5.4 (5)	2.79 (2)	0.15 (3)	0.19
R = 20	K-C	6.8 (7)	3.25 (2)	0.15 (3)	
Route B	K-O	4.2 (4)	2.81 (2)	0.16 (3)	0.50
R = 50	K-Cl	4.1 (4)	3.14 (2)	0.17 (3)	

4.2. *Local order around potassium for ormolytes of route B*

Potassium atoms are embedded for these ormolytes into two phases: a crystalline KCl phase and the phase in which potassium is in interaction with ether oxygens. The proportion of both phases is dependent on the doping level. This result has already been reported for iron(III) doped siloxane-PEO ormolytes prepared in presence of HCl [10]. Due to the constant amount of HCl introduced in the synthesis, the formation of KCl phase in the sample is a dominant phenomenon at low potassium concentration but decreases as the potassium amount increases. It is noteworthy that at equivalent doping level, the XANES spectra of PPO4000 ormolytes are less structured than PPO2000 ones suggesting that the KCl dissociation is more efficient for longer polymeric chains.

4.3. *Ionic conductivity and local order around potassium*

It is commonly accepted that in these materials ionic conductivity is obtained within the amorphous phase of the material via a liquid-type migration of the cations assisted by segmental motions of polymeric chains. A mechanism of charge hopping between adjacent sites having equivalent coordination symmetries is generally proposed and the ionic conductivity depends both on the number and the nature of the charge carriers [11]. Our structural results are in agreement with this viewpoint. Indeed for ormolytes prepared by route A, the local order around potassium is the same for all doping level and characteristic of potassium in interaction with ether-type oxygens of polymers. Ormolytes prepared with PPO4000 have better ionic conductivity than PPO2000 ormolytes: this is due to a better mobility of the longest chains ($n = 68$ (CH_2CHCH_3O) units) compared to the shortest ones ($n = 34$). The observed increase of ionic conductivity with R for route A PPO4000 ormolytes is due to an increase of the number of charge carriers. For route A PPO2000 ormolytes, we assume that the observed decrease of ionic conductivity for $R = 4$ results from the formation of O-K^+-O crosslinks leading to the decrease of chains mobility as it was reported for $LiClO_4$ doped ormolytes [12]. Ormolytes prepared by route B have a lower ionic conductivity than ormolytes prepared by route A whatever their composition. This could be explained by the lower number of charge carriers. Interestingly, route B PPO2000 ormolytes do not present the maximum of ionic conductivity with the doping level in the concentration range investigated. In fact, as a part of potassium atoms are embedded into KCl phase, we assume that the level in which O-K^+-O crosslinks are formed to strengthen the polymeric matrix is shifted to higher potassium concentration. This feature suggests that the KCl precipitate should play the role of plasticizer, as that reported for propylene carbonate in high molecular weight PEO-$LiCF_3SO_3$electrolytes [13]. To summary, it appears that the addition of HCl catalyst in the preparation is prejudicial for ionic

conduction at the lowest potassium concentrations ($R \geq 20$). For $R = 4$ the ionic conduction of ormolytes prepared by both routes is of the same order of magnitude.

5. Conclusion

This study describes some relationships between the ionic conductivity in ormolytes and the local order around the cation as measured by X-ray absorption. It evidences the strong influence of even small changes in the synthetic route and the need to control it severely to tune the properties of advanced materials.

Abstract

On the basis of the first successful determination of the solvation structure of 1-bromonaphthalene (BrNaph) in supercritical xenon (sc-Xe) fluid (BrNaph/sc-Xe), we measured bromine K-edge fluorescent XAFS of bromobenzene (BrBz) doped in supercritical xenon (BrBz/sc-Xe), in an attempt to study the detailed characteristics of the solvation structure in supercritical fluids. Observed spectra of BrBz/sc-Xe showed obviously different pattern from that of BrBz liquid and that of BrBz/Hexane in the near-edge region. The small peak at 13470 eV which appeared in the case of BrBz liquid was not observed in sc-Xe, and the broad peak around 13490 eV was deformed especially at the higher energy side. On the basis of these spectral changes, we tentatively concluded that the local structure in BrBz liquid was destroyed in sc-Xe and a new solvation structure was formed. Theoretical calculation is now being planned.

1. Introduction

Supercritical fluid is well known to be useful as a substitute of organic solvents to extract some specific organic materials in a variety of fields such as food industries and medical supplies [1, 2]. However, it is not clear what sort of solvation structure is responsible to the excellent solubility. Pioneer works [3, 4] have revealed from a macroscopic point of view that the excellent solubility originated from the cluster formation around the solute molecules. Many efforts were devoted to obtain the microscopic view of the solvation structure with spectroscopy [5, 6], neutron diffraction [7], and NMR [8] techniques. Recently, X-ray Absorption Fine Structure (XAFS) technique becomes to attract much attention because of the rapid advances in synchrotron radiation [9, 10].

The first successful measurement of XAFS spectra was reported by our group [11], in which XAFS spectra was observed by X-ray transmission mode for 1-bromonaphthalene (BrNaph) molecule doped in supercritical xenon (sc-Xe). In the case of BrNaph/sc-Xe, a new peak was observed in the near edge region of Br K-edge (13470 eV ∼ 13480 eV). This peak was not observed in the case of hexane solution (BrNaph/Hexane) and that of pure BrNaph liquid. Using the full multiple scattering calculation technique, K. Hayakawa *et al.* [12] succeeded at the first time to suggest a possible solvation structure of a molecule in supercritical fluid. According to their result, about six Xe atoms are surrounding a Br atom of BrNaph with distance of about 0.5 nm. The next step is to get information about the interaction between the Br and the benzene ring. Bromobenzene (BrBz) was selected in this work as the solute instead of BrNaph, because the size of BrBz is smaller than that of BrNaph. The reasons for choosing supercritical xenon as the solvent are as follows. (*i*) The critical temperature of xenon (289.73 K), the critical pressure (5.84 MPa) and the critical number density ($4.59 \cdot 10^{21}$ cm^{-3}) is relatively low. Thus, the handling is easy. (*ii*) Because of its large atomic number, the back-scattering cross section for photoelectron of Xe atom is large. (*iii*) Xenon is inert.

In this paper, we will report results of fluorescent XAFS measurement of BrBz/sc-Xe. Comparing the obtained results with those for BrBz/Hexane and for pure liquid of BrBz, we will discuss about possible solvation structure of BrBz/sc-Xe system.

2. Experiment procedure and results

The BrBz liquid was purchased from Aldrich Chemical Co. and used without further purification. Xenon gas was purchased from Tokyo Kasei Co. and purified by degassing and passing the molecular sieves column activated at 650 K.

A droplet of BrBz liquid was injected in a high-pressure cell which has a pair of beryllium windows with 3 mm thickness and 15 mm diameter. After the cell was evacuated, xenon was introduced into the cell from gas handling system which was described in detail elsewhere [10]. Density of Xe gas was determined by careful adjustment of pressure at room temperature. Values of pressure were converted into number densities according to data reported by A. Michels *et al.* [13]. In this experiment the Xe density was varied from zero to $8.7 \cdot 10^{21}$ cm^{-3}.

The XAFS measurement was performed at the beamline BL-12C of the Photon Factory (PF), Japan. In Fig. 1, we show the experimental setup schematically. Energy resolution of the Si(111) double crystal monochromator was better than 2 eV at $h\nu \approx 9$ keV, and the backlash of the main axis rotation was

0.0006 degree according to M. Nomura *et al.* [14]. The storage ring of PF was operated with the positron energy of 2.5 GeV and a stored current of 250 to 350 mA. The energy calibration was performed with the K-edge absorption of the Cu foil to be 8980.3 eV.

As shown in Fig. 1, in order to measure the XAFS signal of low concentration solute, we used the fluorescent XAFS technique. The Lytle detector [15] was used to detect the X-ray fluorescence. The Selenium filter was equipped to eliminate the scattering component of incident X-ray beams. In order to make the characteristic feature of sc-Xe clear, we also measured the spectra of BrBz vapor, pure BrBz liquid and BrBz doped in hexane liquid (BrBz/Hexane). The spectrum of BrBz/Hexane was measured in transmission mode.

Obtained spectra are summarized in Fig. 2; BrBz vapor (curve A), BrBz liquid (curve B) and BrBz/Hexane (curve C). Among a series of fluorescent XAFS spectra of BrBz/sc-Xe from low-density to high-density, typical two spectra at Xe = $0.7 \cdot 10^{21}$ cm^{-3} (curve D) and $8.7 \cdot 10^{21}$ cm^{-3} (curve E) are plotted in the figure. It should be noted that the curve D was obtained for just Xe gas under supercritical state and the curve E was obtained for the supercritical xenon.

As seen from Fig. 2, in the case of BrBz vapor, only one peak at 13473 eV was observed at the Br K-edge region. On the contrary, two peaks at 13470 eV and 13476 eV were observed for pure BrBz liquid. The 13470 eV peak shrank to a shoulder for BrBz/Hexane. In the $0.7 \cdot 10^{21}$ cm^{-3} xenon, the 13470 eV peak became smaller than that for BrBz/Hexane. Finally this peak disappeared in the case of sc-Xe ($8.7 \cdot 10^{21}$ cm^{-3}).

Onset energies of each spectrum were examined. The highest and the lowest onset energies were found for the case of BrBz vapor and for the case of pure BrBz liquid, respectively. In the case of the solvents with middle density, namely, for Xe gas, sc-Xe and hexane, onset energies were just between that for vapor and pure liquid. This tendency is natural in terms of the density effect of solvent.

Finally, we examined energy positions of the strong peak around 13475 eV. As seen from the magnified illustration shown in Fig. 3 and Fig. 4, the peak energy difference between pure BrBz liquid (peak: 13476 eV) and BrBz vapor (peak: 13473 eV) is larger than the energy resolution 2 eV of the monochromator and thus meaningful. On the contrary, the energy difference between Xe gas (peak: 13474.3 eV) and sc-Xe (peak: 13473.6 eV) is clearly smaller than the energy resolution of the monochromator and thus it is meaningless in the view of our experimental accuracy.

3. Discussion

In order to discuss about the solvation structure microscopically, we started from the pioneer work by H. Bertagnolli *et al.* [16]. They measured XAFS, X-ray and neutron diffraction and suggested the local order, in other word, solvation structure in BrBz liquid. Although they did not analyze, a small peak is observed in their XAFS spectrum (Fig. 1 of their paper), which is believed to be the 13470 eV peak shown our Fig. 2, 3 and Fig. 4. Using Fig. 3 of our paper, we will try to discuss the nature of the 13470 eV peak. In Fig. 3 and 4, magnitude of the vertical axis was normalized to the same order.

As seen from Fig. 3 and as mentioned above, the small peak observed at 13470 eV in pure BrBz liquid become to be only a small shoulder in BrBz/Hexane. Because this peak was not observed in vapor spectrum (curve C in Fig. 3), it is natural that this peak is originated from the local structure between a BrBz molecule and other BrBz molecules, which was described by H. Bertagnolli *et al.* [16]. The small shoulder in BrBz/Hexane may means that a BrBz molecule is still surrounded by other BrBz molecules to remain the $(BrBz)_n$ cluster partially. In vapor state, BrBz molecules may be separated each other and just isolated; thus, there was no 13470 eV peak in vapor.

Using Fig. 4, we will examine the solvation effect of sc-Xe. As seen from the figure, in Xe gas and in sc-Xe, 13470 eV peak disappeared, which means that the local structure in pure BrBz liquid was destroyed. It should be noted that for the sc-Xe ($8.7 \cdot 10^{21}$ cm^{-3}) the broad peak around 13490 eV was deformed especially at the higher energy side. This deformation imply that

the BrBz-$(Xe)_n$ cluster may be produced in sc-Xe. The tendency of spectral change is different from the case of BrNaph/sc-Xe, in which a new peak appeared in the lower energy side of the largest peak. This difference between BrBz/sc-Xe and BrNaph/sc-Xe may be due to different surrounding structure of xenon. On the basis of this difference in two similar molecules doped in same solvent Xe, we tentatively concluded that a new structure formed in BrBz/sc-Xe, which should be different from the solvation structure of BrNaph/sc-Xe.

Theoretical calculation with the full multiple scattering theory is now being planned together with theoretical scientists.

4. Conclusions

The fluorescent XAFS spectra were measured for BrBz vapor, pure BrBz liquid, BrBz dissolved in low-density Xe ($0.7 \cdot 10^{21}\,\mathrm{cm}^{-3}$) and in supercritical Xe ($8.7 \cdot 10^{21}\,\mathrm{cm}^{-3}$), as well as the transmission XAFS spectra of BrBz doped in Hexane. On the basis of careful comparison of these spectra, we tentatively concluded that the $(BrBz)_n$ structure in the pure BrBz liquid was completely destroyed in sc-Xe and a new structure BrBz-$(Xe)_n$ might be formed in sc-Xe. Theoretical calculation is being planned.

Abstract

We have investigated the initial stages of growth and relaxation of ZnO grown on $\{11\bar{2}0\}$ (**a**-sapphire) films ranging from 2.5 to 100 nm in thickness. A significant feature of this process is the change in symmetry in going from the two-fold symmetry of the **a**-sapphire surface to the six-fold symmetry of ZnO. As-grown films were investigated by atomic force microscopy (AFM), high-resolution (X-ray diffraction, and polarized XAFS. AFM measurements indicated planar growth even from the earliest stages of epitaxy reflective of the long surface diffusion length of Zn. High-resolution X-ray diffraction measurements demonstrated resolution-limited (0002) rocking curves for films up to 30 nm thick (early growth) upon which the onset of diffuse scattering was observed, eventually coming to completely dominate for films thicker than 100 nm (late-growth). Polarized XANES and EXAFS measurements were performed on the Zn edge to elucidate structural changes from early to late-growth. Analysis of EXAFS data indicated an anisotropic accomodation of misfit with large in-plane bond rotations and with only a slight outward relaxation of the ZnO lattice along the [0001] direction. Electrical measurements indicate that the electron concentration in this initial layer is degenerate.

Recent research into wide bandgap materials for photoelectronic applications has focused on III-V materials, in particular GaN. Another class of materials, the II-VI oxide-based semiconductors also holds great promise for optoelectronics applications. In particular, the II-VI oxide semiconductor ZnO is a harbinger for such applications with its direct bandgap of 3.7 eV and large excitonic binding energy of 60 meV. The most significant problems facing the practical use of ZnO remains the reduction of residual carrier defect-related carrier concentration and p-type doping. It has been recently demonstrated that it is possible to eliminate the 30° rotation twins observed in epitaxial ZnO films grown on (0001) sapphire substrates by growing on the $(11\bar{2}0)$ face of sapphire despite the apparent symmetry mismatch between the (6-fold) epilayer and the (2-fold) substrate [1]. These rotation twins most likely are a consequence of the large mismatch strain present between the ZnO epilayer ($\mathbf{a} = 0.3250$ nm, $\mathbf{c} = 0.5213$ nm) and the underlying (0001) sapphire ($\mathbf{a} = 0.4754$ nm, $\mathbf{c} = 1.299$ nm) substrate.

To further optimize the growth process with the ultimate goal of yet further reducing the defect-related residual carrier concentration, we have studied the relaxation process for thin films of ZnO grown on **a**-sapphire. The as-grown films were characterized using a combination of *in-situ* RHEED, X-ray pole figure analysis, HRXRD, AFM, and polarized XAFS.

Samples were grown on $(1\bar{1}20)$ sapphire substrates after the substrates were degreased with organic solvents and thermally cleaned *in-situ* at a temperature of 600 °C. ZnO layers were then grown using a thermal Zn source (7N) and a RF (300 W) oxygen (6N) source. Details of the chamber and growth process have been published elsewhere [2].

All samples were grown using a substrate temperature of 350 °C. Diffraction measurements made *in-situ* using RHEED showed that the films were c-oriented with the in-plane epilayer/substrate orientation $\langle 11\bar{2}0\rangle \| [0001]$. Films of differing thickness were made by stopping growth after 15, 30, 45, 60, 120, 600, and 3600 seconds. X-ray reflection was used to confirm that the thickness of these samples was approximately 3, 5, 8, 10, 20, 100, and 600 nm, respectively. As stated earlier for films less than ∼10 nm thick, the RHEED patterns, while being single-domain epitaxial, were diffuse. The patterns became streaky after about 10 nm with a 3×3 streaky reconstruction pattern becoming visible after ∼20 nm.

The HRXRD measurements utilized a Philips MRD goniometer with a 15° asymmetric Bartels Ge (220) monochromator and a triple-reflection Ge (220) analyzer. The ω and 2θ axes of the goniometer were fitted with optical encoders resulting in a quoted absolute positioning error of 10^{-4} degrees for ω and θ. Experiments on near-perfect Si wafers indicated that the lateral coherence of the source was on the order of ∼2 μm.

XAFS measurements were taken using the Zn Kα-edge at the Photon Factory at KEK in Tsukuba, Japan using line BL-12c. Measurements were taken at glancing angle in fluorescence mode using a liquid nitrogen cooled Ge detector array with both horizontal (incident beam polarization along the in-plane direction of the sample) and vertical (incident beam polarization along the c-axis of the sample) polarizations. The samples were at room temperature.

Fig. 1 (left) shows a reciprocal space area map for a (30 s) ∼5 nm thick ZnO epilayer near the ZnO (0002) reciprocal lattice point (RLP). In the figure, a resolution limited (∼0.003°) streak is visible with no intensity present outside the central streak. For these measurements the zero of ω was calibrated using the sapphire $(11\bar{2}0)$ reflection. The slight tilt observable along the RLP diffraction streak reflects the substrate miscut; the normal

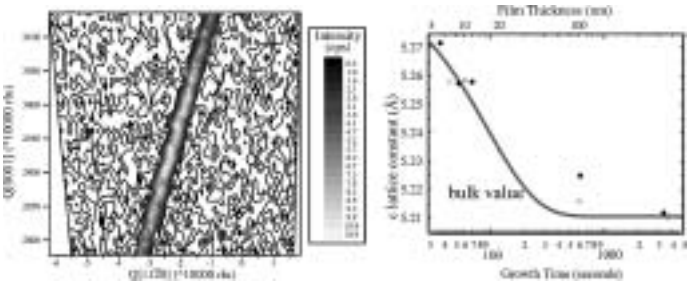

Fig. 1. (left) Triple axis X-ray reciprocal space map near the ZnO (0002) reflection for a ZnO film grown on approximately 5 nm thick (right). Thickness dependence of c-lattice constant values determined from reciprocal space mapping.

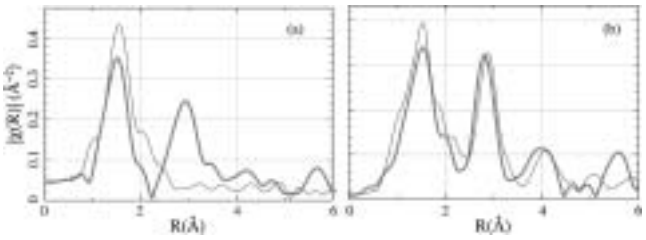

Fig. 2. Real space Fourier transform $|\chi(R)|$ for a 5 nm thick film taken in vertical (thick line) and horizontal (thin line) polarizations. The transforms were taken over the range from 3 to 12 inverse Ångstroms.

to the surface corresponding to the elongation direction of the RLP. A similar diffraction pattern was observed for 8 nm and 10 nm thick films with a slight narrowing of the diffraction streaks along the Q_z direction parallel to the substrate normal due to increased film thickness. No diffuse scattering was visible outside the central RLP streak and the transverse component was again resolution limited. In contrast, for a 20 nm thick (120 s) film, the reciprocal space map (not shown) indicated the presence of diffuse scattering in addition to the strong central streak indicating the likely presence of dislocations with a screw component were formed.

As can be discerned from the Fig. 1 (right) as film thickness decreases, the value of the c-lattice constant as determined from the center of the (0002) RLP increases. The strong intensity of the (0002) RLP is indicative of the presence of long-range order along the c-axis.

Fig. 2 shows real-space Fourier transforms of $|\chi(R)|$ for the same 5 nm thick film shown in Fig. 1 (left). From the figure, it is clear that the second shell is strongly attenuated when the incident beam polarization is in-plane (thin line), but, in contrast, is still very strong for the case in which the incident beam polarization in aligned along the c-axis. This result is consistent with large in-plane bond angle distortions. These distortions have only a minor effect on the atomic ordering along the c-axis direction as is clearly shown by the strong diffraction present in Fig. 1. In contrast, for the 10 nm thick film as can be seen in Fig. 2 (right), the strong anisotropy is no longer present.

To further elucidate the thickness trend, the experimental $|\chi(R)|$ were fitted to a model using the packages *Artemis* and *Ifeffit* [3] in which the values of the a and c lattice constants were allowed to vary independently with the appropriate changes in path lengths calculated geometrically. The scattering paths for the simulation were obtained using feff8 [4] using the ideal wurtzite structure and the appropriate polarization cards. As can be seen in Fig. 3,

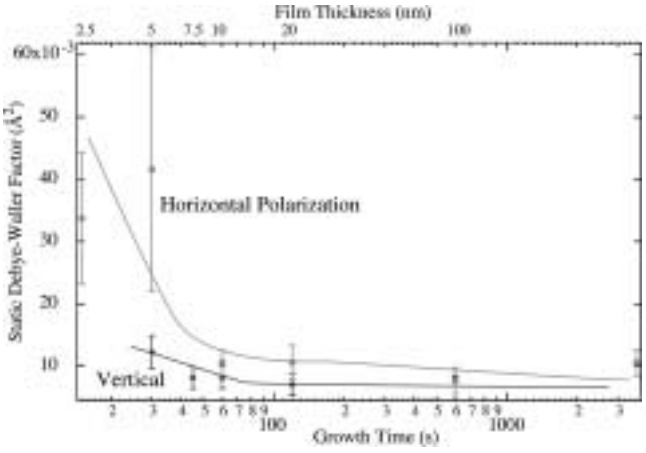

Fig. 3. Static two-center Debye-Waller disorder parameters as a function of film thickness.

there is virtually no change in the second shell static disorder with thickness for the case of vertical polarization. For the case of horizontal polarization in which bond angle disorder is probed in-plane, there is in contrast, a sharp increase in disorder for films $\leq$5 nm thick.

In conclusion, we have undertaken preliminary observations of the film relaxation processes occurring in the heteroepitaxial growth of ZnO on **a**-sapphire. From HRXRD and polarized EXAFS measurements, it is clear that there is strong anisotropy in the relaxation process with large in-plane bond distortions accommodating the different symmetry of the underlying sapphire surface. Concomitant with appearance of diffuse scattering in the 0002 reciprocal space maps, the in-plane distortion is greatly reduced and film quality improves markedly. This is suggestive of the generation of misfit dislocations which act to relieve the interfacial stress associated with growth on sapphire. Glancing incidence HRXRD suggest that initially random in-plane bond distortions reorganize into domains for thicker films as evidenced by omega peak half-widths for reciprocal lattice vectors nearly in-plane.

Abstract

In SiO_2-GeO_2 glasses submitted to high pressure conditions, germanium atoms undergo a coordination change from four to six on a pressure-range depending on the composition. In the transition region, the possibility of having a mixture of tetrahedra and octahedra for Ge instead of the intermediate fivefold coordination state has been studied. Through comparison of the informations extracted from XANES and EXAFS, the model of a mixture of IV and VI coordination states, with a possible small amount of fivefold coordinated Ge appearing on the compression, is favoured.

1. Introduction

In oxide glasses as in crystals, the major pressure-induced structural transformation is the coordination change of the network former, from the fourfold to the sixfold coordination state. However, the transformation process should be different in glasses with respect to crystals, because of the configurational variety of the former. Such a transformation has been recently investigated in a series of SiO_2-GeO_2 glasses, by *in situ* high pressure X-ray Absorption Spectroscopy (XAS) measurements at the Ge K-edge [1]. These experiments have put in evidence the existence of an intermediate phase on a large pressure range, stemming from the disruption of the low-pressure tetrahedral framework, and conducting to the high-pressure phase based on octahedral units. Two possibilities can be envisaged: either the intermediate structure consists of a mixture of the fourfold and sixfold Ge coordination states, or it involves an intermediate fivefold coordinated unit. These two alternatives refer to different underlying thermodynamic natures for the transformation, which can be of first order or continuous, respectively.

This proceeding focuses on the problem of determining mixtures of coordinences from the XAS spectra at the Ge K-edge. To this purpose, the XANES spectra have been decomposed in components representative of the low-pressure and high-pressure states. The analysis suggests a mixture of fourfold and sixfold coordinated units, with a possible small amount of the fivefold coordination state formed during the compression. However, limitations of this qualitative approach are outlined.

2. Experimental

$_x SiO_{2\ (1-x)} GeO_2$ glasses with $x = 30, 50, 65$ and 80 were obtained through a sol-gel process followed by heat-treatment of the gels. Compositions measured by microprobe analysis correspond to the nominal ones within 2 mol%. The details of the sample preparation are described elsewhere [1]. The XAS experiments were performed at the D11 beamline of the Laboratoire pour l'Utilisation du Rayonnement Electromagnétique (LURE, Orsay, France), using synchrotron radiation emitted by the DCI storage ring. The experimental dispersive set-up has been explained in [2]. A Si(111) curved monochromator selects the energy-range of the incident white beam and focuses the Bragg-reflected photons on the sample through a diamond anvil cell in which the sample is loaded, with silicone oil as a pressure transmitting medium. An accessible energy range of about 420 eV was obtained at the Ge K-edge. The pressure range explored was typically 0–25 GPa.

The XAS spectra were normalized in absorbance using Victoreen and spline functions. The k^3-XAFS signal was Fourier transformed using a Kaiser window with $\tau = 2.5$ and a k range of about 4 to 10 $Å^{-1}$. The E_0 value and the k-range for the Fourier transform (FT) were maintained constant over all the spectra of a pressure cycle. The FT-filtered oscillations corresponding to the Ge-O peak were fitted using phase and amplitude parameters extracted from reference spectra.

3. Results

Three reference spectra at the Ge K-edge are shown in the top of Fig. 1: GeO_2 of quartz structure (q-GeO_2) and vitreous GeO_2 (v-GeO_2), both based on corner-connected GeO_4 tetrahedra, and GeO_2 of rutile structure (r-GeO_2) in which Ge is in a sixfold coordinated state. q-GeO_2 XANES spectrum shows three features beyond the white line: the C feature, at about +21.2 eV above the absorption threshold and assigned to scattering inside the tetrahedron, and the lower-energy features A ($\sim$ +10 eV) and B ($\sim$+13 eV) corresponding to interactions extending beyond the tetrahedron. By comparison, v-GeO_2 XANES spectrum presents a C feature at the same energy, and only one broad resonance at $\sim$+11.5 eV in place of the A and B peaks. This is consistent with a structure of corner connected tetrahedra as in q-GeO_2, but with disorder beyond the first shell due to a distribution of the intertetrahedral angles. The r-GeO_2 XANES spectrum is characterized by a white line of higher intensity and subsequent features at +16.5 (B′) and +26 eV (C′). The edge crest is shifted by about 1 eV and appears broader with respect to that in q-GeO_2. Finally, the XANES spectra of the SiO_2-GeO_2 glasses show a C feature as in q- and v-GeO_2, but the resonance at +11.5 eV does not appear, indicating a higher degree of disorder on the medium-range scale, of both structural and chemical nature and induced by the SiO_2-GeO_2 mixing.

With increasing pressure up to about 25 GPa, the XANES shape of the SiO_2-GeO_2 glasses evolves toward a XANES shape similar to that of Ge in r-GeO_2 (center of Fig. 1, sample with 30 mol% SiO_2): the relative intensity of the edge crest increases, while the C feature progressively vanishes, consistently with the break-down of the tetrahedra. At high pressure, a very smoothed resonance appears at about +28 eV above the absorption threshold, which may correspond to the C′ resonance in r-GeO_2. The +2 eV shift may be related to a compression effect, according

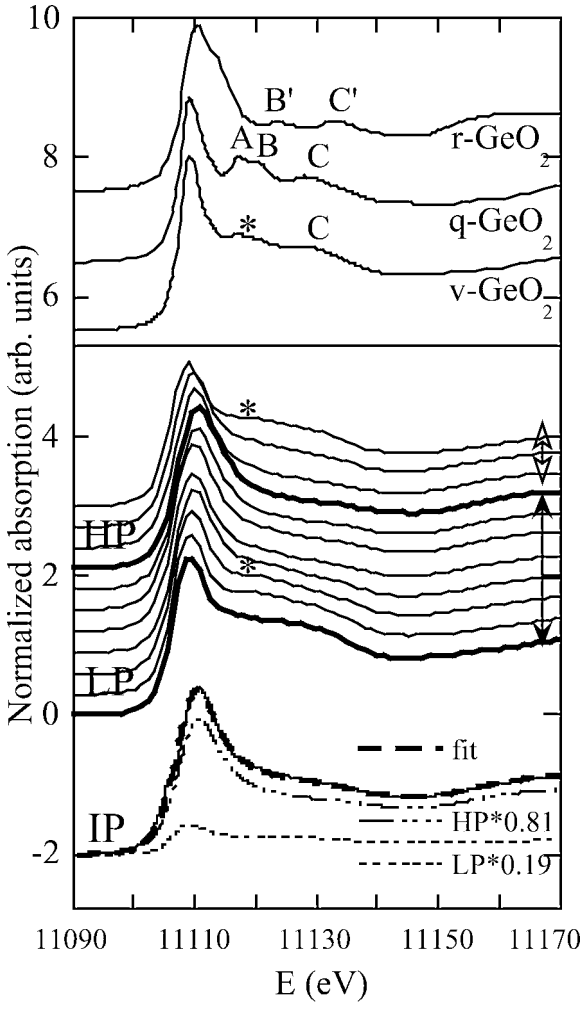

Fig. 1. Top: Ge K-edge XANES in rutile GeO_2 (r-GeO_2), quartz GeO_2 (q-GeO_2) and vitreous GeO_2 (v-GeO_2). Centre: Ge K-edge XANES in a SiO_2-GeO_2 glass with 30 mol% SiO_2, at different pressures: on compression at 0.7; 5.0; 9.9; 13.2; 15.7; 18.8; 22.0; 26.8 GPa from bottom to top (black double arrow) and on decompression at 8.8; 5.1; 0 GPa (white double arrow). Bottom: Example of a XANES decomposition of a spectrum (IP) in terms of low pressure (LP) and high pressure (HP) components.

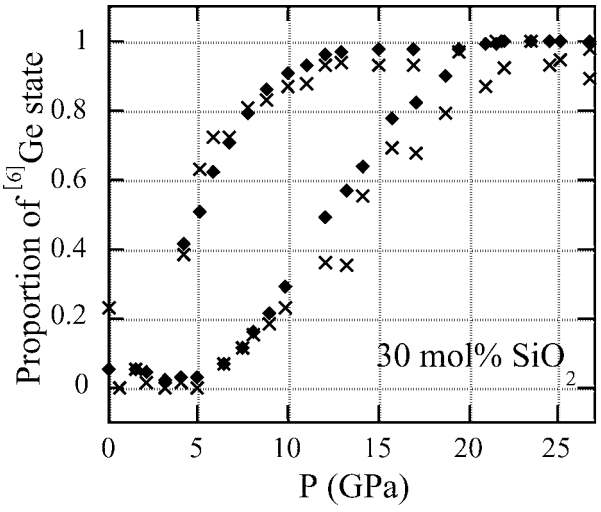

Fig. 2. Proportion of [6]Ge state derived from XANES linear decomposition (full diamonds) and double-shell fitting of EXAFS (crosses).

to the $1/r^2$ dependence invoked for the energy of multiple scattering resonances [3]. Moreover, the edge crest broadens and shifts by about +1 eV. Therefore, the XANES spectrum at high pressure (26.8 GPa for this sample) is assigned to Ge in mainly sixfold coordination state. The mean Ge-O distance of 1.81 Å, extracted from the EXAFS on the same measurement, corroborates this assignment [1]. Finally, in the limited pressure-range during the compression, then on decompression, we observe the growing of a smoothed resonance similar to that in v-GeO_2 (it is marked by a * in Fig. 1). This is related to changes on the medium-range scale, whose origin is difficult to ascribe without an analysis based on structural models.

A spectrum at intermediate pressure (17.1 GPa) is reproduced on the bottom of Fig. 1. This spectrum is refered to as IP, while the low-pressure and high-pressure spectra are respectively noted LP and HP and indicated as bold lines in the center of Fig. 1. These latter spectra are chosen as references for [4]Ge and [6]Ge respectively. Considering that the IP spectra result from a mixture of both [4]Ge and [6]Ge, we have decomposed the IP XANES spectra as a linear combination of the LP and HP XANES spectra, by use of a least-squares fitting procedure. The result of the fit is depicted on the bottom of Fig. 1 along with the weighted LP and HP components. Two hypotheses are made in this procedure. Firstly, the absence of the fivefold coordination state is assumed. Indeed, such a contribution can hardly be established from the XANES spectra, because the shape of the XANES of [5]Ge is not known and may be close to that of [4]Ge + [6]Ge. Secondly, we suppose that the [4]Ge and the [6]Ge sites remain unaltered under pressure, so that they give identical XANES signals, whatever the pressure.

The linear combination fits very well the shape of the IP XANES spectra at each intermediate pressure (Fig. 2). Only the resonance (*) appearing on the first stage of the compression could not be reproduced, confirming its assignment to pressure-induced changes on the medium-range scale. Further confirmation of this decomposition is obtained from the EXAFS signal, which has been fitted using two shells of oxygen neighbours, as explained elsewhere [1]. In Fig. 2 are compared the proportions of [4]Ge and [6]Ge obtained by XANES decomposition and double-shell-EXAFS fitting. The agreement is very good for both the compression and decompression measurements. The discrepancy of 10% at high pressure represents the total uncertainty over both procedures.

4. Discussion and conclusion

In situ high pressure XAFS experiments have been carried out on GeO_2-SiO_2 glasses at the Ge K-edge, in a dispersive mode using a diamond anvil cell. The XANES spectra can be adequately modelled using a linear combination of the 4-fold and 6-fold coordination states for Ge. On compression and on decompression, the XAS spectra thus reflect the coexistence of the fourfold and sixfold coordination states, without the presence of a significant amount of other intermediate species (possible amount is less than 10%).

The different behaviours on compression and on decompression may be due to different extension of the metastability field of each coordination state. The metastability of the sixfold coordinence on pressure release is likely to be important, because the GeO_6 octahedron is energetically favoured (r-GeO_2 is the most stable phase in ambient conditions). At the metastability limit [6]Ge may revert back to [4]Ge in an abrupt way, precluding any observation of an intermediate state. The reversibility of the transformation suggests that some memory of the initial glass is

maintained in this ambient-temperature process, preventing from the retention of an octahedral network.

The presence of $^{[5]}$Ge can not be completely excluded in this study, without knowing the shape of the $^{[5]}$Ge XANES. Ge in fivefold coordination has been reported in crystalline potassium germanate [5], which should be used for XAS measurements. We note that in alkali germanate glasses of low alkali compositions, the occurrence of $^{[5]}$Ge is also controversial, partly because of the small amount of $^{[5]}$Ge possibly involved (about 15% [6]), and because the differences expected between the $^{[4]}$Ge, $^{[5]}$Ge and $^{[6]}$Ge species in the radial distribution functions and spectroscopic signals are weak. Another important question is the pressure-dependence of the Ge K-edge XANES of $^{[4]}$Ge or $^{[6]}$Ge site, owing to the compression of the site itself and the changes in medium-range ordering. Simulations and XANES calculations are needed to assess the influence of the isotropic medium-range order of such glasses on the XANES signal. Finally, a principal component analysis (PCA) of both the XANES and EXAFS signals is in progress to determine independent components in the series of spectra and possibly rule out the presence of intermediate species in the transformation [7].

Acknowledgments

We are grateful to Guillaume Morin (LMCP) for providing the least-squares fitting procedure adapted to XANES spectra. Pascal Munsch (LURE) and Daniel Neuville (IPGP) are gratefully thanked for their help in loading the DAC and during the data acquisition. Laurence Galoisy and Delphine Cabaret (LMCP) are acknowledged for fruitful discussions.

Abstract

Soft X-ray excited optical luminescence (XEOL) of silica glasses was studied with respect to the excitation X-ray energy (near the Si K-edge) and irradiation time. The luminescence spectra showed emission bands at 3.1 eV and 2.7 eV, assigned to $B_{2\beta}$ and $B_{2\alpha}$ oxygen deficient centers in silica glasses, and the luminescence yields of these bands changed drastically before and above the Si K-edge. Si K-edge photoluminescence yield (PLY) spectrum of the band at 3.1 eV was similar to Si K-edge XANES spectrum recorded in the photocurrent mode for the same silica sample, except for the negative edge jump in the PLY spectrum.

The time evolutions of the band intensity at 3.1 eV were also investigated under the excitation by soft X-ray below and above Si K-edge. The band intensity in both cases decreased slightly with the irradiation. These results indicate that a part of $B_{2\beta}$ centers in the silica glass probably changed to other types of oxygen deficiencies by the electron excitation effect. In the early stage of the irradiation, a rapid increase in the intensity of the 3.1 eV band was also observed, indicating that soft X-ray irradiation produced luminescence sites such as $B_{2\beta}$ centers.

1. Introduction

Radiation effects on silica glasses are one of the main concerns for their application as optical windows, insulators and optical fibers in fusion and fission environments [1]. Although the radiation damage of silica in nuclear environments has been widely studied, the detailed damaging process and damaged structure has not been fully understood. That is mainly because the effect of ionizing radiation, which is very important in optical materials like silica, is mixed up with the displacement effect.

The present work is our trial to observe soft X-ray radiation effects on silica. Since the energy region of soft X-rays covers the K-edges of silicon and oxygen, it is possible to study the dynamic and specific radiation effect of silica under the preferential excitation of these inner-shell electrons. In this study, we have measured the luminescence from silica glasses under soft X-ray irradiation near the Si K-edge, and discussed the origin and the variation of the luminescence sites.

2. Experimental

The samples used in this work were unirradiated low-OH and high-OH fused silica glasses (T-2030 and T-1030, produced by Toshiba Ceramics, Japan) and high-OH fused silica glass after irradiation in a nuclear reactor. The diameter and thickness of each sample was 13 mm and 2 mm, respectively. The measurement of luminescence of these silica glasses induced by soft X-ray irradiation (1.8–1.9 keV) was carried out on the beam line 7A at UVSOR, Institute for Molecular Science with a stored current of 100–200 mA. The luminescence was focused by a lens in the UHV chamber to the monochromator (CP-200, JOBIN YVON) and detected by a multi-channel analyser (OMA III, EG&G PRINCETON APPLIED RESEARCH). The photon energy (E) from ca. 4 eV to 1.5 eV was measured because the photon detecting efficiency in the region $E < 1.5$ eV and $E > 4$ eV were reduced drastically. The luminescence yield spectrum was also measured using a photomultiplier (Hamamatsu Photonics R955).

3. Results and discussion

3.1. *X-ray excited optical luminescence (XEOL)*

Fig. 1 shows observed luminescence spectra from various types of silica glasses under soft X-rays near Si K-edge (1848 eV). The low-OH fused silica glass (T-2030) showed an intense emission band at around 3.1 eV (Fig. 1(a)), while no distinct

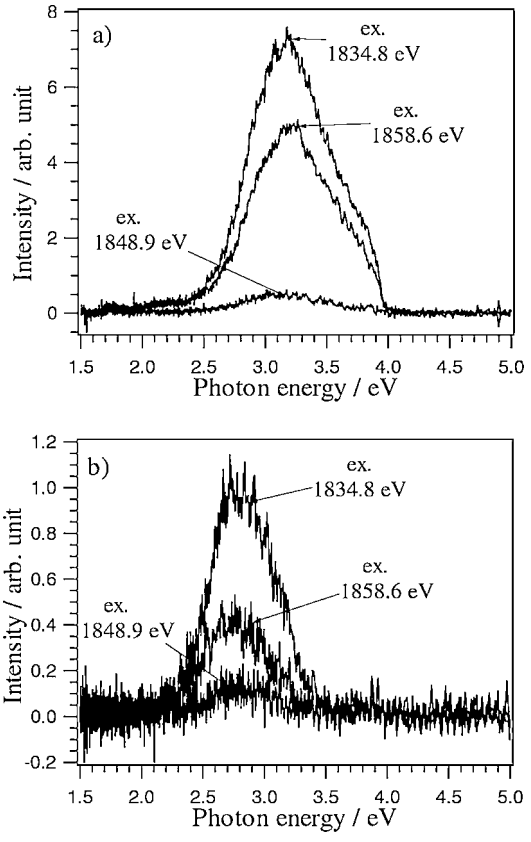

Fig. 1. Optical luminescence spectra of silica glasses excited by soft X-rays with energy of 1834.8 eV, 1848.9 eV and 1858.6 eV. (a) Low-OH fused silica glass. (b) High-OH fused silica glass after neutron irradiation.

*e-mail: yoshida@cirse.nagoya-u.ac.jp

emission band was observed for the high-OH fused silica glass (T-1030) (not shown here). However, after neutron irradiation in a nuclear reactor, the latter silica glass showed an emission band at 2.7 eV and not at 3.1 eV. Similar luminescence spectra have been measured for silica glasses under in-reactor or UV irradation [2, 3], and we have concluded that the origin of the present XEOL is likely due to electron excitation of oxygen deficiencies in silica glasses by soft X-rays. Based on the photon energy of the emission bands, the 3.1 eV band should be related to the intrinsic $B_{2\beta}$ center in the low-OH silica glass (T-2030), while 2.7 eV band to $B_{2\alpha}$ center produced in silica glasses (T-1030) by the atomic displacement effect of neutron irradiation [4]. In this short paper, we focused on the luminescence at 3.1 eV attributed to $B_{2\beta}$ center.

3.2. *The photoluminescence yield (PLY) spectrum of the 3.1 eV band*

It is noteworthy that the intensities of the 3.1 and 2.7 eV emission bands change with the excitation energy of soft X-rays (Fig. 1). We measured a photoluminescence yield (PLY) spectrum of the 3.1 eV band which is shown in Fig. 2(a) together with a Si K-edge XANES spectrum (Fig. 2(b)) recorded in the photocurrent mode for the same fused silica glass. One can clearly see that both PLY and XANES spectra are similar, although the former jump negatively whereas the latter positively at Si K-edge. The outline of the phenomenological theory for the shape of the PLY spectrum has been proposed previously [5, 6] and is due to the competitive absorption of sites being responsible for the luminescence and those being not. Since in both cases the total absorption condition applies, the key factors that decide the direction of the edge jump are relative luminescence yield of the absorption events above and below the edge. By applying this theory to the present case, above Si K-edge, the transition of Si 1s electron to 3p orbital and/or continuum state occurs and simultaneously the relative luminescence yield reduces; therefore, the PLY spectrum may show negative and similar feature to the XANES spectrum. This is also the reason why the intensities of the 3.1 eV emission band change with the soft X-ray excitation energy in Fig. 1.

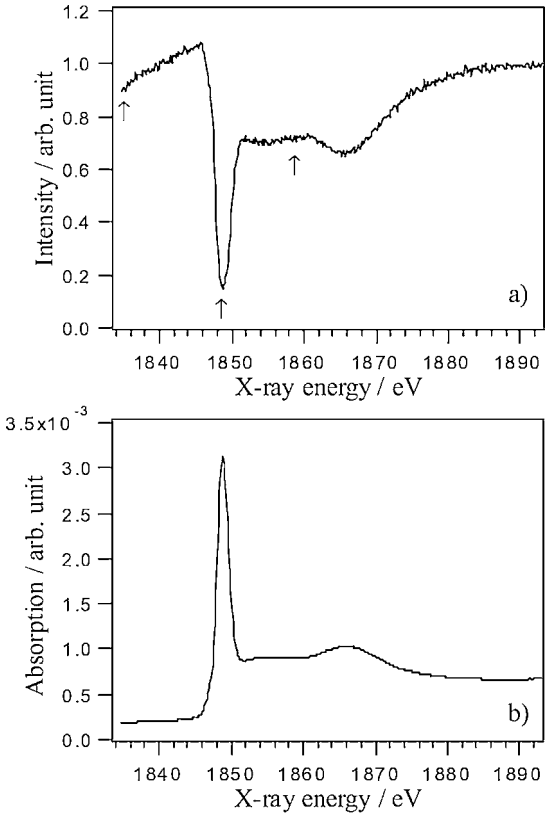

Fig. 2. Comparison between a) the luminescence yield spectrum of the 3.1 eV band and b) Si K-edge XANES spectrum of a fused silica glass.

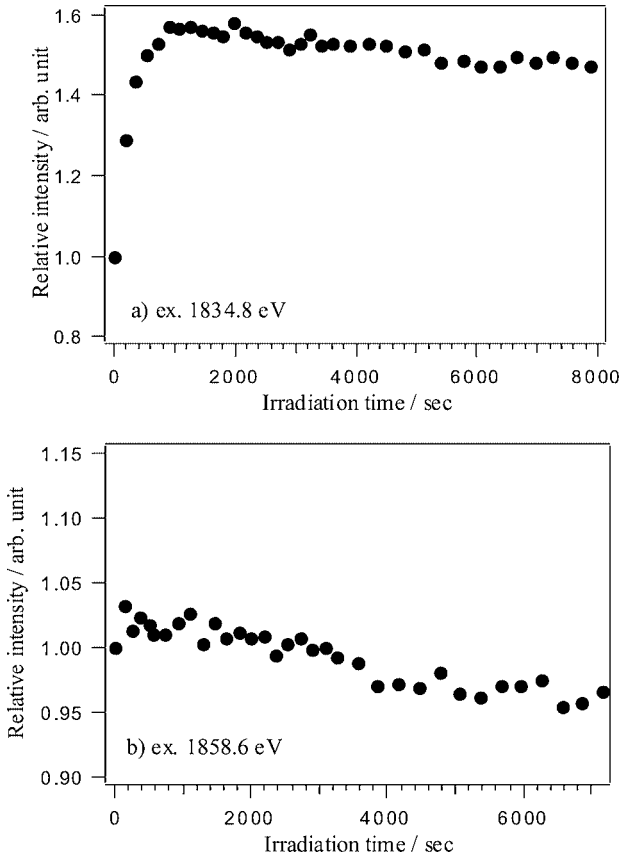

Fig. 3. Variation of the relative intensity of the band at 3.1 eV with the irradiation time. Excitation X-ray energies are a) 1834.8 eV (below Si K-edge) and b) 1858.6 eV (above Si K-edge), respectively.

3.3. *Time evolution of the intensity of XEOL*

We have investigated the long term change of 3.1 eV XEOL intensity with the irradiation time of soft X-rays. Fig. 3 shows the variation of the band intensity at 3.1 eV due to $B_{2\beta}$ center under the excitation by X-rays with energy of 1834.8 eV (below Si K-edge) and 1858.6 eV (above Si K-edge). The intensities were normalized by the intensity at the beginning of the soft X-ray irradiation. Except the very early stage of the irradiation, the relative intensity in both cases decreased slightly with the irradiation time. Ishii *et al.* and Skuja [7, 8] have reported that the $B_{2\beta}$ centers in silica are easily changed to E′ centers by electron excitation under the UV laser irradiation. In addition, the transformation of $B_{2\beta}$ centers to E′ centers had been observed in our separate γ-ray irradiation experiment for silica glasses [3]. Therefore, we have concluded that some of the $B_{2\beta}$ centers probably changed to other types of oxygen deficiencies such as E′ centers by electron excitation effect, but the $B_{2\beta}$ centers were fundamentally stable against the present irradiation condition. This result may be partially due to the weak intensity of X-ray from the synchrotron in this energy region.

On the other hand, in the very early stage of the irradiation, the increase of the 3.1 eV band intensity is appreciable (Fig. 3(a)). This result may indicate that soft X-ray irradiation produced luminescence sites such as $B_{2\beta}$ centers. The increasing rate was quite different with excitation X-ray energies at 1834.8 eV and 1858.6 eV. In the present stage, the origin of the difference of the initial increasing rate are not clear. However, such a dynamic phenomenon was observed for the first time, so far as we know, and the present results clearly indicate that the *in-situ* observation is a potential technique to study the dynamic radiation effects of soft X-ray on silica.

Abstract

The adsorption site of sodium atoms deposited onto a clean TiO_2(110) surface has been determined by EXAFS. The best result is obtained for an 'in-between' site where the sodium is bound to two bridging oxygen atoms at 2.25 Å and one in-plane one at 2.40 Å, in full agreement with DFT calculations. At higher coverage the site becomes a hollow site where Na is equidistant to the three oxygen atoms at 2.30 Å.

1. Introduction

Among the numerous metal/oxide interfaces, deposit of alkali metals on titanium-dioxide play a special role since these atoms induce specific properties of the interface [1], and their atomic or electronic structure is far from fully understood. In this paper we have carried out X-ray absorption spectroscopy measurements (XAFS) on low and high sodium coverages at the sodium K-edge and we compare our experimental results on the local environment of the sodium atoms with the most recent theoretical models [2].

2. Experimental and data analysis

The preparation method of the TiO_2(110) surface is nowadays very well documented. Successive phases of cleaning by 500 eV Ar^+ ions, followed by annealing in UHV at 600 °C using electron bombardment have been used. The surface has then been checked by Auger spectroscopy, which does not show any contamination by carbon or calcium. This procedure has been applied to two samples, which both present a sharp (1×1) LEED pattern but differ by the orientation of the [001] bonding oxygen rows which have been set parallel or normal to the photon electric field.

XAS experiments have been done on the SA32 beam line at LURE-Super-ACO. For sodium K-edge spectra, the line is equipped with a beryl (10$\underline{1}$0) double-crystal monochromator, allowing an energy resolution of about 0.5 eV at 1 keV. The incident flux is monitored by the total electron yield (TEY) from a 2 µm polyethylene film covered by 700 Å of titanium. The absorption signal is also measured by TEY inside the UHV chamber. The vacuum level has been kept always, even during the Na evaporation, in the low 10^{-10} Torr range.

The Fourier transform of the kX(k) XAFS data uses an Hanning window spanning from 2.3 to 7.5 $Å^{-1}$. Structural parameters are then obtained by a fitting procedure using the FEFFIT [3] code, the phase shift parameters being *ab-initio* calculated by FEFF7 [4] and tested on the crystallized model compound Na_2SiO_3 [5]. It is worth to point out here that we have to fit two independant polarization experiments with the same structural environment.

3. Results

3.1. *Low sodium coverages*

We have at first deposited an almost equal small amount of sodium on the two samples. The position of the edge is identical to that of pure sodium chloride, 3 eV higher than that of metallic sodium. This indicates that the sodium is nearly fully ionized when deposited onto the surface, a result in agreement with the theoretical calculations of the energetics of this system as well as photoemission results [1, 2].

The first step of the analysis consists in building a model cluster, shown in Fig. 1, from which the different phase shifts can be calculated by FEFF7. Sodium atoms have been located on the site that the theoretical results [2] consider to be the more stable. It is the so-called 'in between' site where the sodium is linked to two bridging oxygen at 2.25 Å and to one in-plane oxygen at 2.40 Å. Therefore all interatomic distances and apparent coordination numbers are defined. The fitting procedure then involves only the energy position of the edge and the Debye-Waller factors of each bond. The best results of the fits are given in Table I while Fig. 2 shows the corresponding theoretical and experimental Fourier transforms.

According to photoemission experiments [1] and also to theoretical calculations [2] on the stability of the sodium site, adsorption of sodium induces a derelaxation of the surface, then the model described in Table I assumes bulk-terminated positions for the titanium and oxygen atoms surrounding Na. During the fitting procedure, it appears that the result is definitely improved when one allows the last Na-O distance to vary, the final value being 3.6 Å instead of 3.8 Å. We believe that this discrepancy is

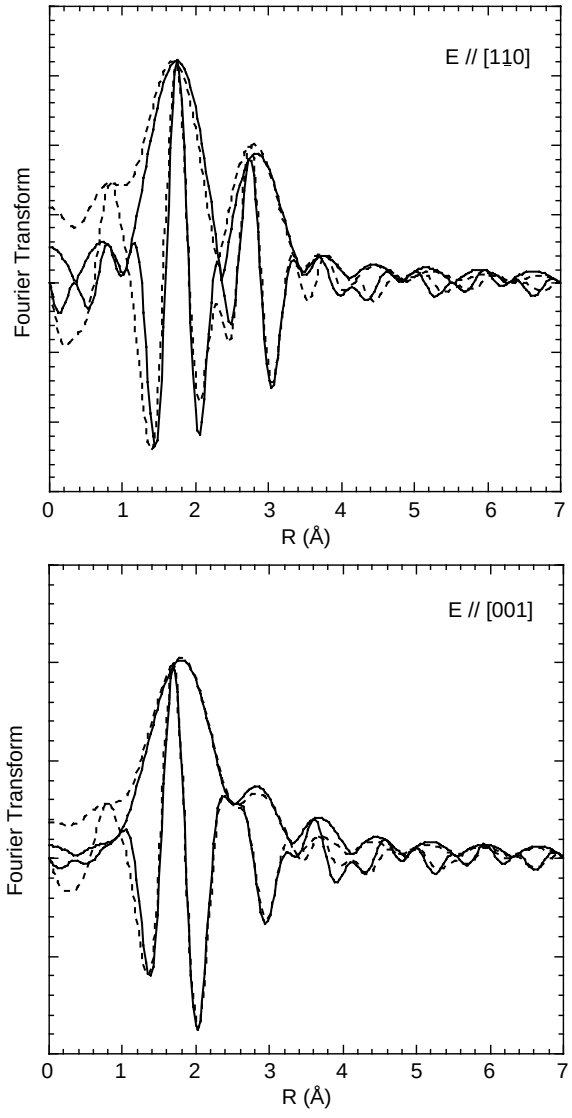

Fig. 2. Experimental (solid lines) and model (dashed lines) Fourier transforms for the two polarizations for a low sodium coverage described by Table I.

not real but corresponds to the limit of our modelling of the data, given the signal to noise ratio and the EXAFS energy domain available.

In both orientations, the introduction of sodium-sodium interactions, assumed for both the [1$\underline{1}$0] direction or the [001] one at distances corresponding to the occupancy of equivalent neigbouring sites, is destroyed by the fitting procedure which returns a very large Debye-Waller factor for the corresponding interatomic distance. This means that the sodium atoms should be isolated, in line with the presence after evaporation of still a definite (1 × 1) LEED pattern, although less sharp than that of the clean surface. According to the findings by Nerlov *et al*. [1], this means a coverage less than one monolayer.

The above results only prove that the site of the sodium determined by *ab-initio* density functional calculations is fully in agreement with EXAFS experiments. We then attempted to check if other published structural solutions could also be in agreement with our experimental results:

1- Albaret *et al*. [2] have also considered the 'adjacent' site, where the sodium is bound to one bridging oxygen and two planar ones. It presents a very short (2.09 Å) and two very long (2.56 Å) Na-O distances. This splitting is not compatible with the experimental results and the fitting procedure never reaches a reasonable value.

2- In most of the sodium compounds where sodium is bound to oxygen, the distance Na-O lies close to 2.30 Å which is close to the sum of the two ionic radii. We have therefore attempted to simulate our experimental data assuming for sodium an hollow site where the alkali atom is equally distant, at about 2.30 Å, from three oxygen atoms. Whatever is the site considered (either 'adjacent' or 'in-between') the fit is only obtained if some distances between the sodium and the surface atoms are allowed to vary in a way not really grounded physically.

3.2. *High sodium coverages*

The above samples have been first cleaned and then a long deposit of sodium has been made giving a relative jump at the edge about five times higher. Albaret *et al*. [2] have also modelled the relative stability of different adsorbate configurations at a coverage of half a monolayer: the alkali atoms are now in a nearly perfect 'in between' hollow site. Assuming that this site remains the same at full coverage, the fitting procedure returns the values listed in Table II. The changes, in both crystallographic directions, induced by the occupation of all possible equivalent sites by the sodium atoms are well described by the analysis of the EXAFS experimental results. Here again (see Table II) the fit is improved by a change of the more distant shells. Photoemission experiments [1] suggest the existence, at high sodium coverage, of metallic sodium which could form disordered metallic clusters. As a matter of fact, Fig. 3 compares the near edge spectra of the very low coverage analyzed in section 3.1 (curve a) to that of the high coverage (curve b). This last spectrum exhibits a pre-edge

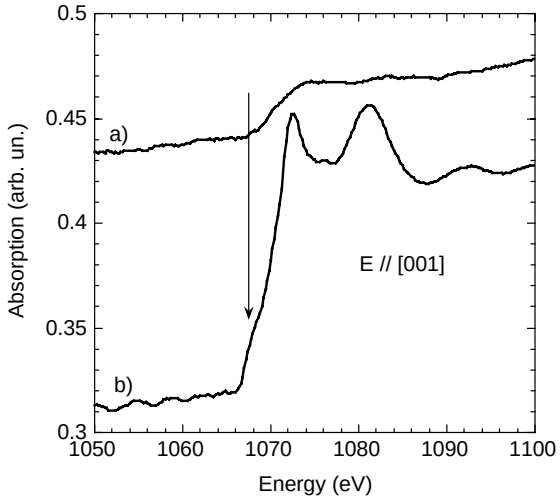

Fig. 3. Near edge structure of sodium for a low coverage (curve a) and for the high coverage (curve b). The amount of sodium is related to the relative jump at the edge and the arrow points to the position of a pre-edge feature which could be the signature of metallic sodium.

feature, around 3 eV below the main edge, attributed to sodium metal which, because of its very low Debye temperature, appears only in the edge jump.

4. Conclusions

A direct determination of the sodium adsorption site on a clean TiO_2(110) surface has been obtained by XAFS. The experimental results agree very well with density-functional calculations: at low coverages when sodium atoms do not interact the sodium locates on an 'in between' site with a distance to the bridging oxygens (2.25 Å) shorter than that with the in-plane one (2.40 Å). When the sodium amount increases to reach a full coverage, the Na-O distances become nearly equal, the presence of sodium neigbours is well evidenced in the experiments while the near edge spectra shows a signature from metallic sodium clusters on top of the surface.

Abstract

The position and shape of X-ray absorption discontinuities have been used to deduce structural and chemical bonding information on model compounds of thallium and its superconducting cuprates. The L X-ray absorption spectra were recorded on a Rigaku X-ray Spectrometer and monochromatized using a flat crystal of Si (1, 1, 1). The background subtraction was done using Victoreen function. The normalized absorption coefficient is plotted as a function of X-ray photon energy. It is observed that the XANES of L_I edge has fewer features as compared to those of L_{III} edge. The L_{II} edge spectra of thallium are similar to L_{III} edge spectra. The L_{III} absorption discontinuity of thallium splits into three components whereas no splitting is observed in L_I edges. Thallium L_{III} edge spectra show a single absorption peak for monovalent compounds whereas in trivalent compounds a weak peak followed by a shoulder on rising absorption which culminates into a strong absorption peak. The important difference between the spectra of monovalent and trivalent compounds is the shift in the inflexion point energy of L_{III} edges and a shift of the main absorption maximum. The X-ray absorption spectra of superconducting cuprates show similarities with the spectra of Tl_2O_3 suggesting the presence of Tl^{3+} ions in octahedral configuration in these cuprates.

1. Introduction

It is well known [1–5] that monovalent and trivalent thallium compounds have interesting chemistry as a consequence of 6s and 6p electrons present in the valence band. The nature of the bonding in these compounds varies widely. Covalent contributions to the bondings [6] in thallium (I) halides reach a maximum with thallous iodide, which has a double-layered orthorhombic structure [7]. A feature of fundamental importance which influences the structure and bonding in thallium compounds is that the 6s, 6p and 6p levels are sufficiently close and hybridization of these orbitals is energetically favorable in several thallium compounds. Hybridization alters the character of the otherwise pure and vacant 6p and 6d levels of monovalent and trivalent thallium in covalently bonded compounds. In the absence of hybridization, like in ionically bonded Tl^{1+} or Tl^{3+} compounds, the same 6p and 6d levels are subjected to strong crystal fields. The effects of the coordination sphere of ligands and the point group symmetry of the thallium atom lift the degeneracies of the p and d manifolds. This suggests that X-ray absorption spectroscopy is a very strong informative experimental approach to study the coordination geometry and bonding relation in thallium compounds. The near-edge features involve the transition from some core state to allowed lowest unoccupied empty states in the valence region of a given atomic center. XANES reveal the identity of the allowed transitions and also the mixing or splitting of the final state orbitals [8, 9]. Using known structural data, informative deductions on structure – bonding relations have been made. Both Tl L_I and Tl L_{III} edge XANES spectra have been used since they probe $2s \rightarrow 6p$ and $2s \rightarrow 6d$ transitions respectively. The study was extended to a new class of superconducting oxides containing thallium [10–15] to collect information on atomic environment and valence states of thallium ions.

2. Origin of Data

The analyzed data were collected in the in-house EXAFS laboratory. X-rays emitted from a conventional X-ray tube were monochromatized by a flat silicon (1,1,1) crystal and allowed to pass through the sample. The transmitted X-rays were then detected through a detector by moving the sample in and out of the X-ray beam. The voltage pulses produced were fed into a digital scalar and counted for a certain time, the number of counts per unit time is directly proportional to the number of photons entering into the detector. The ratio of counts of detector reading without the sample and with the sample gave I_0/I. The logarithms of this are proportional to the absorption coefficient μ. The I_0/I was then recorded as a function of the monochromator crystal position. The crystal was mounted on a goniometer driven by a step motor. The monochromator steps were proportional to the incident angle of the X-ray beam on the crystal face. The data analyzed was originally in the form of monochromator steps versus I_0/I.

3. Numerical Analysis

The L absorption of model thallium compounds and superconducting oxides containing thallium were normalized by fitting a linear function to the pre-edge data and fitting cubic splines to the XANES region of the data up to 100 eV, extrapolating both functions to zero energy i.e. the inflexion point energy, subtracting the pre-edge data function from each point in the experimental spectrum and dividing by the step height. This procedure results in a normalization of the data to the unit step height.

The profiles of absorption edges were obtained by averaging the results of a large number of spectra recorded in turn from each sample. The inflection point in the L_{III}-edge in Tl_2O_3 was taken as a reference point. Its energy was found to be 12665 eV.

4. Results and Discussions

The normalized L_{III} and L_I absorption spectra of model thallium compounds and superconducting oxides containing thallium are presented in Figs. 1–6. These normalized X-ray absorption spectra suggest that the XANES of L_I-edge have far fewer features as compared to those of L_{III} edge. The L_{II}-edge spectra of thallium were similar to L_{III}-edge spectra, therefore, the profiles of L_{II}-edge

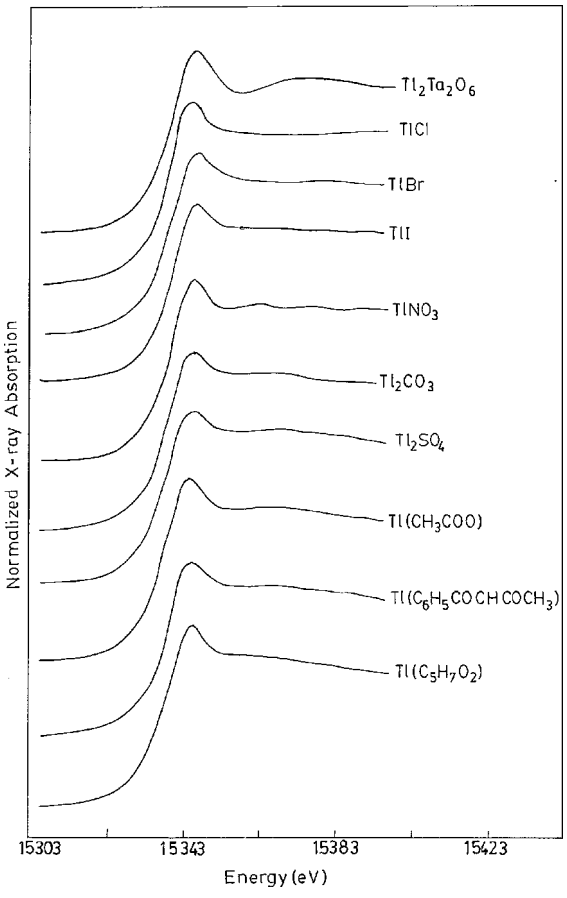

Fig. 4. Normalized Tl L_I absorption spectra of monovalent compounds.

are not presented. The L-absorption spectra of pure thallium metal could not be recorded as it is easily oxidized in air at normal temperature [2]. Figures 1–6 show that the L_{III} absorption discontinuity of thallium splits into three components whereas no splitting was observed in L_I-edge.

4.1. *Thallium L_{III}-edge Spectra*

Fig. 1 shows a single absorption peak for monovalent compounds whereas in the spectra in Fig. 2 for trivalent compounds a weak peak is followed by a shoulder on rising absorption which

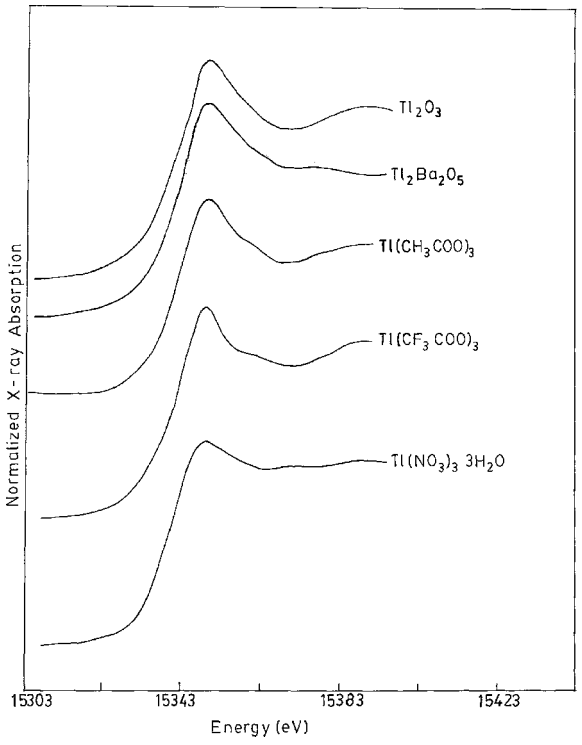

Fig. 5. Normalized Tl L_I absorption spectra of trivalent compounds.

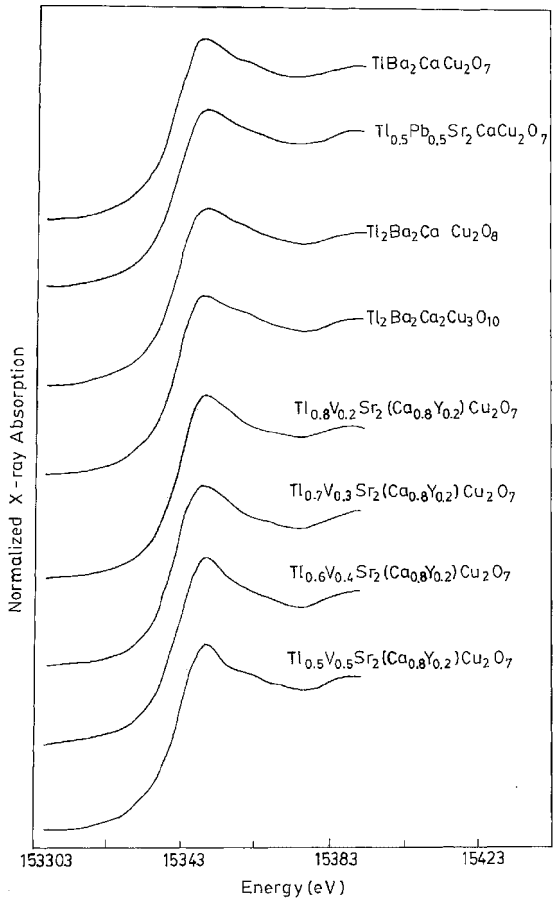

Fig. 6. Normalized Tl L_I absorption spectra of cuprates.

culminated into a strong absorption peak. The outer electronic configuration of monovalent thallium is: $6s^2\ 6p^0\ 6d^0$ hence the single absorption peak observed in the monovalent thallium compounds corresponds to the allowed transition of an $2p_{3/2}$ electron to 6p state which is admixed with 6d and 2s characters of metal and ligands respectively. In trivalent thallium compounds 6s, 6p and 6d states being completely vacant, a weak peak, the shoulder and the main absorption peak can be attributed to the transitions to hybridized states $2p_{3/2} \rightarrow 6s$, $2p_{3/2} \rightarrow 6p$, $2p_{3/2} \rightarrow 6d$ respectively. The transition $2p_{3/2} \rightarrow 6s$ becomes allowed by mixing of 6d character from metal and 2s character of ligating atom. In monovalent thallium compounds, no peak corresponding to the electronic transition, $2p_{3/2} \rightarrow 6s$ is observed. In fact, the transition probability for p to d transition is higher than that for p to s transition [16]. On the basis of these absorption spectra of thallium model compounds, the states concerning the valence states of thallium ions in well-characterized superconductors can be described. The overall profiles of these oxides shown in Fig. 3 are very similar to those of Tl_2O_3 and other trivalent thallium compounds. The L_{III}-edge peaks in these superconductors are slightly different from those observed for trivalent compounds as the octahedron of ligands around thallium ions is distorted. This distortion was studied by analyzing the EXAFS spectra of these compounds. The results obtained are in good agreement with those reported by Studer *et al.* [17–18] and Vijayakrishnan *et al.* [19]. Vijayakrshnan *et al.* [19] proposed the Tl^{1+} like state in cuprate superconducters suggesting the presence of a 6s state. The L_I-edge profiles have ruled out this possibility.

4.2. *Thallium L_I-edge Spectra*

The L_I-edge spectra for monovalent, trivalent and superconducting oxides were simple in all cases. Splitting of the edge was not observed. In the monovalent compounds the 6s orbital is occupied, but 6d is completely vacant. Therefore a main peak corresponding to $2s \rightarrow 6p$ transition was expected and since 6s is unavailable for transition to occur, no splitting of the L_I-edge was observed. In trivalent compounds, the 6s and 6p orbitals being vacant, a pre-edge peak corresponding to the forbidden transition $2s \rightarrow 6s$ was expected. However no such peak was observed. In these compounds, like monovalent compounds, only the main absorption peak corresponding to $2s \rightarrow 6p$ was observed.

The L_I-edge spectra of all the superconducting oxides were similar to Tl_2O_3 and other trivalent thallium compounds. The intensity of this peak is slightly less in superconducting oxides as compared to that in Tl_2O_3. Similar results were obtained by Studer *et al.* [17–18] in 1212, 2212, 1223 and 2223 superconducting oxides. Thus L_I XANES also leads to the conclusion that the thallium ions exist in +III state in superconducting oxides, i.e. the absence of electrons in the 6s levels.

5. Conclusions

1) The shoulder peak of trivalent compounds and the main absorption peak of monovalent compounds occur almost at the same energy positions in L_{III}-edge spectra. The only difference is the shift in the inflexion point energy of L_{III}-edges and a shift of the main absorption maximum.

2) The observations indicate the presence of octahedraly coordinated Tl^{3+} ions in the well-characterized superconducting oxides.

3) The X-ray absorption spectra of vanadium doped cuprates show similarity with the spectra of Tl_2O_3, thereby suggesting the presence of Tl^{3+} ions in octahedral configuration in these cuprates.

4) The only difference in the L_I-edge profiles of monovalent and trivalent thallium compounds is the shift of the inflexion point and the shift of the main absorption peak.

5) It was also observed in the L_I-edge profiles that the main absorption peaks were located at the same energy positions. The only difference was the intensity of the peak corresponding to 2s to 6p transition.

Acknowledgements

The authors warmly thank Professor Dr. P. R. Sarode (Goa University, India) for providing samples of superconducting cuprates and helpful discussions on the subject. The authors also warmly thank Dr. K. R. Priolkar (Goa University, India) for the help in recording the spectra and Mr. Joao Luiz Azevedo de Carvalho (University of Brasilia, Brazil) for preparing the figures in the print format.

Abstract

This study combining X-ray diffraction and X-ray absorption spectroscopy reveals the variation of the lattice parameters a and c and the atomic position parameter z(Sn) of tetragonal stannous oxide SnO under pressure up to 10 GPa. The observed strong elastic anisotropy of the SnO crystal can be attributed to its layered structure. The axial ratio c/a decreases from 1.27 to 1.16 whereas the position parameter z(Sn) increases from 0.237 to 0.269.

1. Introduction

Recently, stannous oxide (SnO) has received much attention due to its technological applications. Powders of SnO can be used as anode materials in lithium rechargeable batteries, as coating materials or as effective catalysts for several acid syntheses [1]. The oxidation and disproportionation process of SnO thin films enables the production of thin tin dioxide films, which are used as transparent electrodes in liquid crystal displays (LCDs) and solar-electrical energy conversion devices or as chemical sensors [2].

At ambient conditions tin oxide SnO has a tetragonal litharge-type structure with one free atomic positional parameter z for Sn. Above 1.5 GPa a transition to an orthorhombic phase has been reported [3, 4], but is also discussed controversially [5]. In order to get more insight into the high pressure behaviour of SnO we performed EXAFS and energy dispersive X-ray diffraction (EDXRD) experiments to receive the structural parameters a, c and z(Sn) and to prove the existence of the reported tetragonal to orthorhombic phase transition.

2. Experimental

The blue-black metallic shining sample material SnO obtained from Chempur (99.9%) was grounded for the EDXRD and EXAFS measurements. After grounding a pale-brown mat powder was obtained.

EDXRD measurements were carried out at beamline F3 of HASYLAB (DESY Hamburg) with white synchrotron radiation from a bending magnet with a critical energy of 16 keV. The diffracted beam is recorded by a nitrogen-cooled Ge-detector with an energy resolution of 360 eV at 20 keV. The diffraction angle Θ was chosen to 3.91° so that the fluorescence lines of Sn do not interfere with the important diffraction lines. The beam was collimated to $0.2 \times 0.2\,\mathrm{mm}^2$. A diamond anvil cell (DAC) with 1 mm flats was used for the EDXRD measurements with inconel as gasket material and liquid nitrogen as pressure transmitting medium. The sample diameter was 0.4 mm. The diffraction patterns were analysed with the computer programme EDXPowd [6]. The pressure was determined from the diffraction lines of gold [7], which was mixed into the sample.

EXAFS measurements at the Sn-K edge (29.2 keV) were performed at the HASYLAB beamline X1 using a Si(311) double crystal monochromator. The beam was collimated to $0.8 \times 0.8\,\mathrm{mm}^2$. A high pressure cell with boroncarbide (B_4C) as anvil material and copper as gasket material was used in this study [8]. The sample diameter was 1.3 mm. Polyethylene was used as pressure transmitting medium and silver powder as pressure marker, using the known pressure dependence of the Ag-Ag distance [9] derived from the EXAFS signal measured at the Ag-K edge (25.5 keV). EXAFS data reduction and analysis were performed using the software WinXAS 2.3 [10].

3. Results and Discussion

The litharge type structure of SnO consists of Sn-O-Sn layers with weak bindings between adjacent layers. Sn is square-pyramidal coordinated by oxygen with a Sn-O distance of 2.22 Å [11]. Our EDXRD analysis at ambient conditions reveals the lattice parameters $a = 3.800$ Å and $c = 4.836$ Å ($c/a = 1.272$) in good agreement with the values of c/a from 1.2687 to 1.2745 given in the literature [3, 11–14]. The position z of Sn above the O plane is given to $z = 0.2369$ [11]. An investigation concerning the pressure dependence of z(Sn) has not been published yet.

The high-pressure EDXRD study reveals the variation of the lattice parameters a and c. However, due to the strong preferred orientation of SnO in the high-pressure cell, the free atomic position parameter z(Sn) could not be determined from the diffraction intensities. The EDXRD study revealed no phase transition up to 11 GPa. At pressures above 5 GPa the diffraction lines (hkl) with $h \neq k$ became broadened (Fig. 1). The broadening is less than 2% at 11 GPa for the (200) reflection, where [4] reports a line splitting of more than 7% for that reflection in the orthorhombic phase at 9 GPa. Because [4] used LiF as pressure transmitting medium we performed control experiments with other pressure transmitting media, MgO, NaCl and mineral oil, known for their nonhydrostatic performance, which revealed also line broadening of 5% and more for the (200) reflection. Hence, we attribute this line broadenings to tensil stress conditions in the high pressure cell. It seems that SnO is very sensitive to tensil stress as has already been assumed by [5].

The pressure variation of the lattice parameters a and c of the tetragonal phase is shown in Fig. 2 as well as the decrease of the volume V. A fit of the Birch equation of state to the p-V

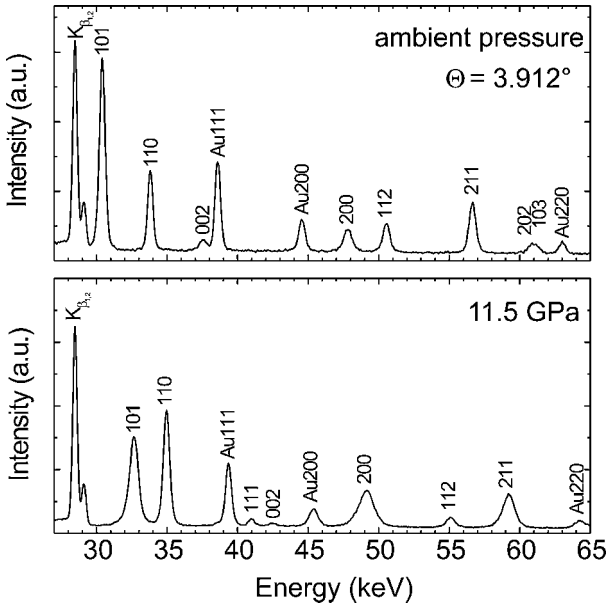

Fig. 1. EDXRD spectra of SnO at ambient pressure (top) and 11.5 GPa (bottom). Diffraction lines (*hkl*) with $h \neq k$ are broadened with pressure, the (200) reflex stronger than the (101) and (211) reflexes.

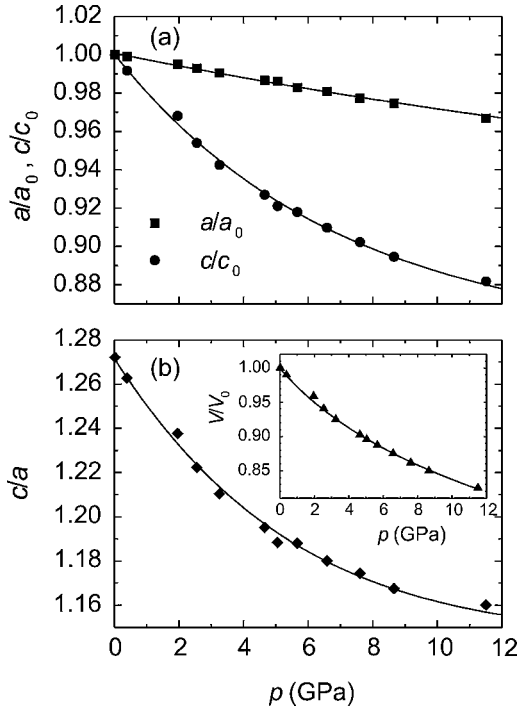

Fig. 2. (a) Normalized lattice parameters a and c. (b) Pressure dependence of c/a. The inset shows the normalized unit cell volume fitted with a Birch equation of state.

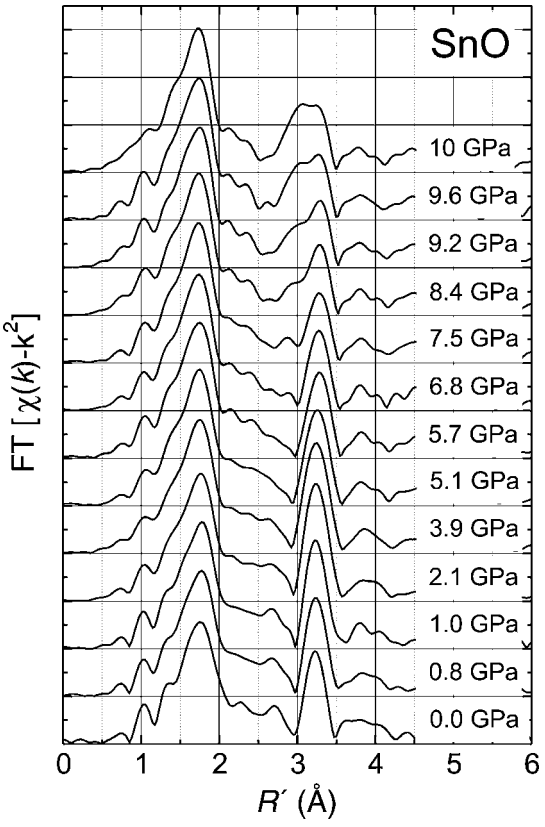

Fig. 3. Fourier transformation of the pressure dependent EXAFS signal. The Sn-O distance was obtained from a fit to the peak around $R' = 1.8$ Å.

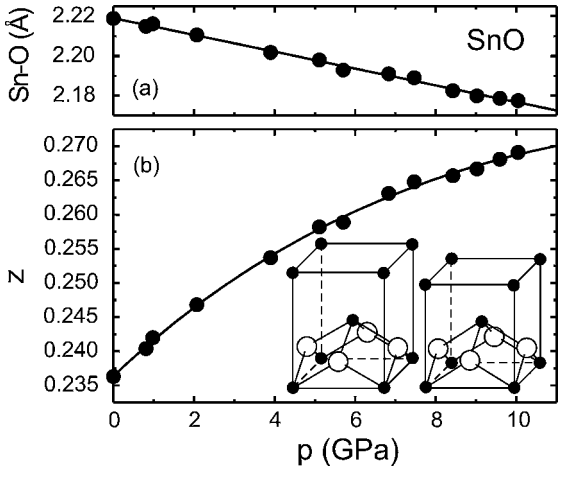

Fig. 4. (a) Pressure dependence of the Sn-O distance determind from EXAFS and (b) pressure dependence of the position parameter z(Sn) in SnO, determined from EXAFS and EDXRD studies. The inset shows the unit cell of tetragonal SnO at 0 GPa (left) and 10 GPa (right). Large spheres are O atoms; small spheres are Sn atoms.

data of SnO provides a bulk modulus $K_0 = 33.5(11)$ GPa and a first derivative of $K_0' = 6.1(5)$.

The variation of the z(Sn) parameter is determined from the X-ray absorption spectra providing the Sn-O distance and using in addition the lattice parameters from the EDXRD experiments, as done previously by [15]. Fig. 3 shows the Fourier transforms of the normalized X-ray absorption spectra at the Sn-K edge for SnO at different pressures up to 10 GPa. The analysis of the nearest neighbour distances (Sn-O) in the range form $R' = 0.85$ to 2.5 Å yield the distance R and the 2nd cumulant σ^2. The nearest neighbour distance decreases from 2.219 Å at ambient pressure to 2.178 Å at 10 GPa and the 2nd cumulant decreases from $5.3 \cdot 10^{-3}$ Å^2 to $4.3 \cdot 10^{-3}$ Å^2. The apparent change in the second neighbours peak around $R' = 3.2$ Å in Fig. 3 at pressures above 8 GPa is due to the approach of the adjacent Sn layers and has not been evaluated here because it involves three different Sn shells.

From the pressure dependence of the Sn-O distance and the lattice parameters a and c one can calculate the position parameter z(Sn). As seen from the EXAFS experiment the compressibility of the Sn-O bonding is quite small which means that this bonding is rather strong. From purely geometrical considerations one can

see that the strong compression of the c-axis together with a negligible variation of the Sn-O distance causes an increase of z with increasing pressure. When the Sn-O-Sn layers come closer with pressure the repulsion increases and the increase of z(Sn) flattens under increasing pressure (Fig. 4).

Abstract

The electronic structure of Mn/ZnO system has been invesigated by synchrotron radiation photoemission. Manganese vacuum deposition was done at room temperature onto a ZnO(0001) single crystal for coverage $\Theta_{Mn} \leq 4$ ML. Photoemission spectra taken near the Mn3p–Mn3d absorption edge after each deposition step show resonant enhancement of Mn3d states within 10 eV of the Fermi edge. The experimentally deduced partial Mn3d density of states for $\Theta \geq 1.2$ ML shows at least three features: a major Mn3d structure at 3.8–4.5 eV below the Fermi edge, a valence structure at lower binding energy (1–3 eV) and a broad satelite in the 5.5–9 eV range. The branching ratio of satellite/main structure increases with depostion from 0.33 for 0.4 ML to 0.65 for 4 ML. After annealing up to 500 °C the satellite/main ratio decreases to 0.43 indicating a high degree of hybridization between the Mn3d states and valence band of ZnO. After annealing no manganese cap layer was found at the crystal surfaces as was confirmed by the lack of metallic Fermi edge in photoemission spectra and by scanning Auger spectroscopy experiment. The photoemission Mn3p core level spectra taken after annealing consist of two components separated by about 4 eV, which shows that at least two manganese states are observed in the Mn–ZnO interface region.

1. Introduction

The wide bandgap semiconductor ZnO doped with one of the 3d Transition Metals (TM) is a promising material for short wavelength magneto-optical applications [1], especially for transparent magnets. Manganese and cobalt are the most interesting TM admixtures for ZnO because their solubility in the ZnO matrix is significantly higher than other TMs. In addition, theoretical calculations point out that a ferromagnetic state of ZnMnO is expected even at room temperature [2].

Manganese ions are usually incorporated *in situ* during ZnO flux growth [3], combinatorial lase molecular-beam epitaxy method [4] or pulsed-laser deposition [5]. In the experiment presented here we used the method of Mn diffusion into the ZnO matrix after heating up to 500 °C of Mn/ZnO interface with 4 ML of manganese deposited onto the ZnO(0001) surface. We investigated the experimental Mn3d partial density of states in order to determine interactions between this magnetic electron shell and valence band of the ZnO single crystal.

2. Experimental conditions

The single ZnO wurzite crystal was grown in the Insitute of Physics, Polish Academy of Sciences by chemical vapor transport using chlorine as transporting agent. The orientation of the crystal was determined by X-ray diffraction. A clean (0001) surface of ZnO monocrystal was prepared in an ultra-high vacuum system ($p \approx 4 \cdot 10^{-10}$ Torr) using argon ion bombardment ($U = 600$ V, $t = 40$ min) and annealing to 300 °C. The experiment was performed at BL41 beamline at the MAX I storage ring in Lund, Sweden. Angle-resolved photoemission spectra were recorded with the overall energy resolution of 200 meV at photon energy of 50 eV. Mn was deposited in the III-Mn-V MBE system vacuum connected to the photoemission chamber. During Mn deposition all the sources other then Mn were cooled down to low temperatures. The Mn coverage of the ZnO surface was estimated from precise calibrations of Mn flux used for III-Mn-V MBE growth [6]. We sequentially deposited small amounts (from 0.2 to 4 ML) of manganese on a clean ZnO(0001) surface under ultra-high vacuum and, via photoemission spectra, we follow changes in the valence band of Mn/ZnO system and in the experimental Mn3d partial density of states. After deposition of 4 ML of manganese the Mn/ZnO system was heated up to 500 °C in order to promote diffusion of manganese atoms.

The photoemission spectra were taken at room temperature, normalized to the photon flux and the secondary electron background has been subtracted. The binding energy scale is referred to the Fermi level of a thick manganese film.

3. Results and discussion

Energy Distribution Curves (EDC's) were taken after each step of deposition at various photon energies between 30 and 110 eV. We have investigated the Mn contribution in the valence band region by resonant-photoemission spectroscopy at the Mn3p-Mn3d absorption threshold. At resonance the Mn3p electron is excited into the empty part of the Mn3d states. This excited state decays via autoionization in which the Mn3d electron drops down to fill the Mn3p hole and its energy is transferred to another Mn3d electron that is ejected into the continuum:

$$\mathrm{Mn3p^6 3d^5} + h\nu \rightarrow \mathrm{Mn3p^5 3d^6} \rightarrow \mathrm{Mn3p^6 3d^4} + \mathrm{e}.$$

The final state of the process is the same like in direct photoemission from the Mn3d shell:

$$\mathrm{Mn3p^6 3d^5} + h\nu \rightarrow \mathrm{Mn3p^6 3d^4} + \mathrm{e}.$$

The interference between the two channels of photoemission leads to the increase in the photoemission intensity as the photon energy is swept through the 3p-3d threshold. The asymmetric Fano line shape characterizes the intensity variations.

In Fig. 1 we show the set of normal photoemission spectra of Mn/ZnO interface measured at the maximum of Mn3p-3d resonance ($h\nu = 51$ eV). All the spectra in Fig. 1 were

*email: ela@lanl.gov

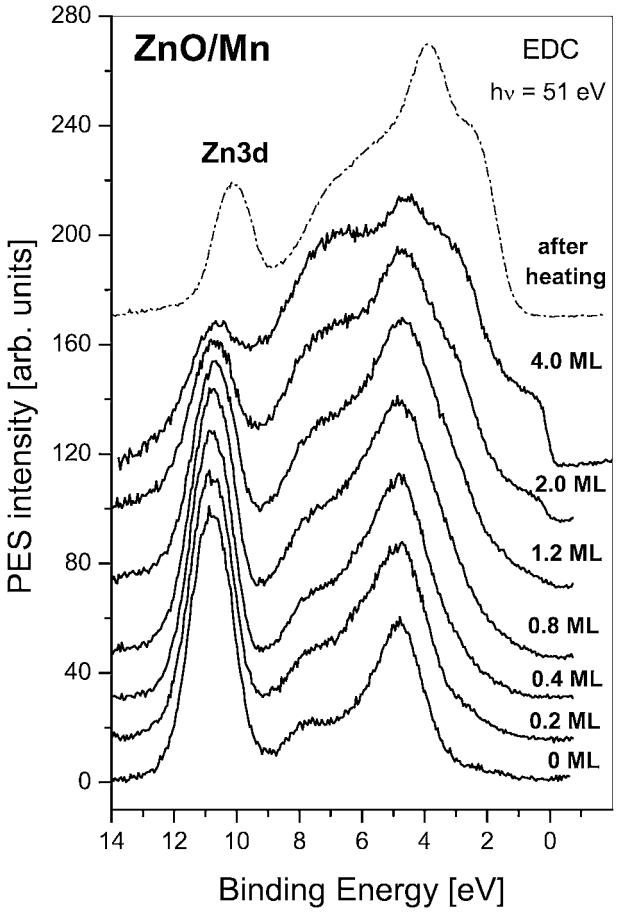

Fig. 1. EDC's for Mn/ZnO(100) system measured after each step of deposition for $h\nu = 51$ eV (maximum of Mn3p-3d resonance). The spectra intensities were normalized to 100 in their maximum.

normalized to constant height to emphasize line-shape changes. The bottom spectrum shows clean ZnO(0001) valence band and Zn3d emission taken before Mn deposition. The spectrum was shifted by 0.12 eV towards higher binding energies in order to compensate the binding energy shift due to a Shottky barrier formation. Contribution from the ZnO substrate is visible at around 4.8 eV up to the 4 Mn ML depositions. For $\Theta = 4$ ML the position of this highest valence band peak is shifted about 0.3 eV towards lower binding energy which results from contribution of the manganese emission in this binding energy region. The manganese contribution is also observed between 6.5 and 8 eV starting from coverage of 1.2 ML. For $\Theta = 2$ ML a metallic shoulder at the Fermi edge is created. This means that part of manganese atoms do not diffuse into the interface region and remains at the crystal surface. For $\Theta = 4$ ML the metallic shoulder is three times higher than for $\Theta = 2$ ML. The structure between 6.5–8 eV is more pronounced and we can see a new shoulder created at around 3.2 eV.

The upper curve in Fig. 1 (dashed line) was taken after 18 hours of annealing in 500 °C in the MBE chamber. After annealing the metallic shoulder at the Fermi edge has disappeared and the rest of photoemission spectra is shifted towards lower binding energies. The Zn3d core level after annealing is located at 10.1 eV, which is 0.6 eV lower than for clean ZnO single crystal. The main structure of the valence band is now situated at 3.8 eV below the Fermi level and the spectra in 9 eV of the Fermi edge is very similar to the Mn3d contribution in another II-VI based ternary compounds reported in the papers published before [7–10]. The Zn3d core level photoemission peak is sharp and its full width at half maximum (FWHM) is exactly the same as in single ZnO and equals 1.6 eV. The sharpness of the peak indicates that manganese does not lead to the disorder in the ZnO cation sublattice.

The scanning Auger microprobe measurements were taken for Mn/ZnO system after annealing. Auger spectra from the surface were measured during ion etching of a small spot of the crystal. There was no Mn capping layer and Zn was abundant at the surface. The Mn/Zn ratio measured on the surface was 0.43. During etching the oxygen concnetration was constant and Zn gradually replaced Mn. The transition region width had an extension of about 20 Å with gradually lower Mn concentration.

The experimental Mn3d partial density of states is presented in Fig. 2. The method exploits an asymmetrical lineshape of the photoemission intensity near the resonant Mn3p-Mn3d threshold. Below the maximum of the resonance ($h\nu = 51$ eV in the experiment) one can observe a minimum where the photoemission from Mn3d shell can be neglected ($h\nu = 47$ eV). The contribution of the Mn3d states to the valence band can be obtained from

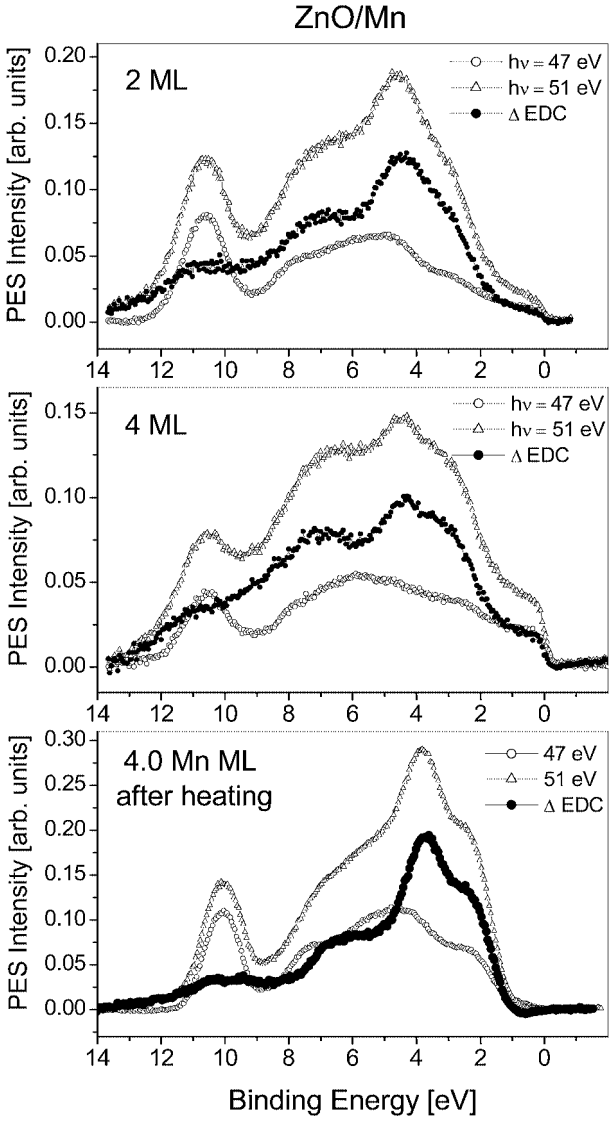

Fig. 2. The set of difference ΔEDC spectra (resonance-antiresonance) obtained for $\Theta = 2$ and 4 ML, and after annealing of Mn/ZnO system. Open triangles show resonant spectra ($h\nu = 51$ eV), open circles antiresonant spectra ($h\nu = 47$ eV) and solid circles calculated ΔEDC spectra.

difference between EDC spectra taken on and off resonance. The results of the procedure for $\Theta = 2$ and 4 ML, and after annealing are presented in Fig. 2.

The ΔEDC = EDC(51 eV)-EDC(47 eV) spectra consists of three structures typically found in II-VI ternary compounds with manganese [7–10]. The main structure is situated at 3.8–4.5 eV, valence structure at 0–3 eV and a broad satellite between 5.5 and 9 eV below the Fermi edge. For $\Theta = 2$ and 4 ML the low energy shoulder of the main peak contains two contributions: a metallic shoulder located at the Fermi edge and structure around 3 eV below.

Electronic structure calculations are available for $Cd_{1-x}Mn_xTe$ [11, 12] ternary compound. They are also used to interpret the Mn-derived structures of other Mn-substituted II-VI compounds. The main peak in the overall structure of the Mn3d partial density of states represents part of the Mn3d electrons only weakly influenced by hybridization. The valence structure presumably originates from the Mn3d states hybridized with the valence band. The satellite structure is not related to the partial density of Mn3d states, but represents a shake-up-like satellite of the main Mn3d peak, which is not described in the one-electron picture.

The binding energy of the main Mn3d structure of Mn/ZnO system is 4.4 eV and 4.38 eV for $\Theta = 2$ and 4 ML, respectively, and 3.8 eV below the Fermi edge after annealing. The intensity of satellite/main peak ratio changes from 0.33 for $\Theta = 0.4$ ML to 0.89 for $\Theta = 4$ ML and drops to 0.43 after annealing. The relative satellite/main intensity of the Mn3d peak in ZnMnY (Y = S, Se, Te) compounds was regarded in dependence of V_{pd} hybridization parameter [7]. The 0.43 value obtained for ZnMnO alloy follow the trend toward higher hybridization as we move up in the Periodic Table, which was found in ZnY compounds (Table I).

According to the results obtained for ZnMnY (Y = S, Se, Te) ternary compounds V_{pd}, a parameter describing the amount of the Mn3d-anion p hybridization, increases with decrease of satellite/main branching ratio. Therefore for Mn/ZnO system we may expect hybridization effect comparable to ZnMnS compound and higher than in the case of ZnMnSe or ZnMnTe. It is also higher than the hybridization effect in the widely investigated $Ga_{1-x}Mn_xAs$ compounds [13].

It is worth to mention that the experimental Mn3d partial density of states presented here follows very well the trend found the chalogenide-based semiconductors [7]. The similarity is much better than in the case of $Zn_{1-x}Mn_xO$ thin films obtained by pulsed-laser deposition [14].

Table I. *The energy of the main Mn3d peak and branching ratio of the satellite to the main structure in Zn-VI ternary alloys with Mn. The data of ZnY (Y = Te, Se, S) are taken from ref. [7].*

	E_{main}	satellite/ main ratio
$Zn_{0.68}Mn_{0.32}Te$	3.8 eV*	1.05
$Zn_{0.81}Mn_{0.19}Se$	3.7 eV*	0.90
$Zn_{0.81}Mn_{0.19}S$	3.5 eV*	0.4
Mn/ZnO after annealing	3.0 eV*	0.43

*The binding energy is given in respect to the valence band edge.

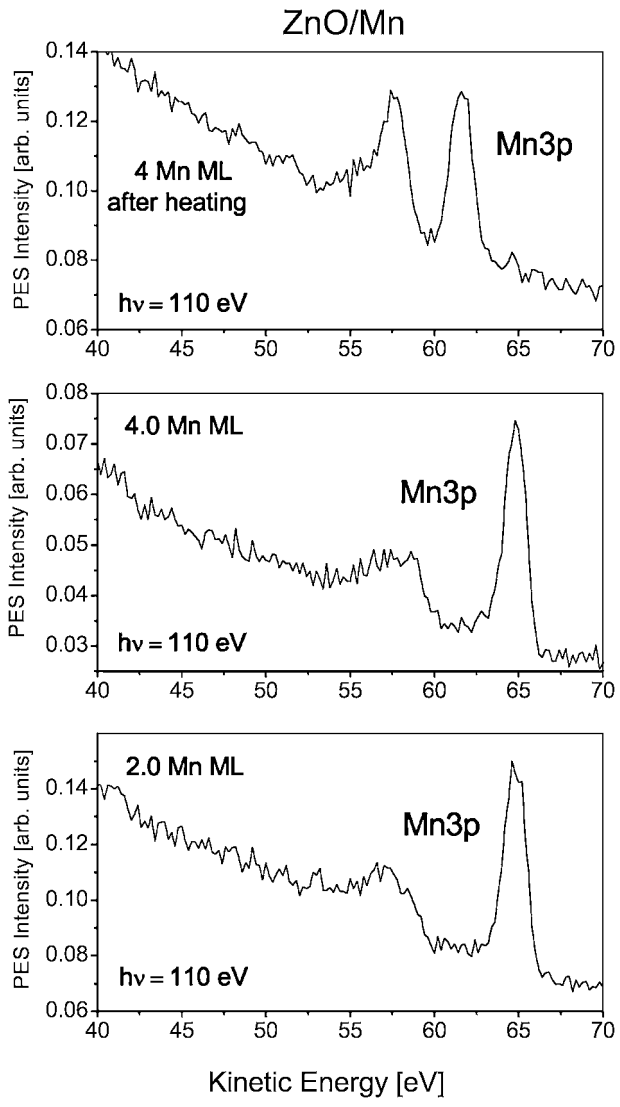

Fig. 3. Mn3p core EDC's measured with photon energy of 110 eV. Spectra show two Mn3p components chemically shifted by about 4 eV.

In Fig. 3 we show the photoemission spectra of Mn3p core level measured at $h\nu = 110$ eV after deposition of 2 and 4 Mn ML, and after annealing. EDC's show two Mn3p features observed at kinetic energies 57.5 eV and 64.9 eV before annealing and 57.7 eV and 61.7 eV after this process. The intensity of the structure observed at lower kinetic energy increases after annealing and presumably it consists of two photoemission peaks. This is the evidence that we have at least two manganese states in the Mn-ZnO interface retion.

4. Conclusions

In conclusion, we have measured Mn/ZnO(0001) system by synchrotron radiation photoemission. After deposition of 4 ML of manganese on clean ZnO(0001) surface and annealing up to 500 °C the metallic shoulder at the Fermi edge disappeared and no Mn capping layer has been found at the surface. The intensity of satellite/main peak in the experimental Mn3d partial density of states was determined as 0.43. This is evidence that the hybridization effect in $Zn_{1-x}Mn_xO$ surface alloy is comparable to $Zn_{1-x}Mn_xS$ and much higher than in $Zn_{1-x}Mn_xSe$, $Zn_{1-x}Mn_xTe$ and $Ga_{1-x}Mn_xAs$ semimagnetic compounds.

Abstract

The luminescence of a prototype gold(I) compound, PPh_3AuCl, which is a building block compound for many light emitting organo-gold complexes and polymers, has been studied by the X-ray excited optical luminescence (XEOL) technique in conjunction with the X-ray Absorption Fine Structures (XAFS) at the C and P K-edge as well as the Au $M_{5,4}$-edges. We present the site and excitation channel specificity of XEOL and its chemical implications.

1. Introduction

Since Dori *et al*. [1] reported the luminescence of the gold(I) complex, $[(PPh_3)_3AuCl]$, a variety of mono- and multinuclear gold(I) complexes as well as gold(I) polymers and oligomers has been synthesized. These materials often show interesting photophysical and photochemical properties [2–5]. For example, a number of symmetrical binuclear gold(I) complexes with various diphosphine or diacetylides ligands exhibit strong luminescence in both solution and solid state [2–4]. The luminescence is generally assigned as phosphorescence from the metal-centered or metal-to-ligand charge transfer excited states. Along with small molecules (eg. Alq_3, $q = 8$ hydroxyquinoline, and $Ru(bipy)_3^{2+}$, bipy = bipyridene) [6, 7] and organic polymer light emitters (eg. poly-phenylene vinylene and derivatives) [8], gold containing complexes have potential applications in organic light emitting diodes (OLED). OLED are based on layers of thin organic films that are the hole-injection/transport, emissive and the electron injection/transport layers sandwiched by two electrodes. Upon applying an appropriate voltage to the cell, the injected positive (holes) and negative (electrons) charges recombine in the emissive layer to produce light (electroluminescence).

The present study aims to investigate the optical properties of the representative mononuclear gold(I) complex, PPh_3AuCl, (Au is linearly bonded to P and Cl through σ and π interactions) using the X-ray Excited Optical Luminescence (XEOL) technique, which has shown promising applications in the characterization of thin films, organometallic compounds, as well as polymers [6–8]. Larson, *et al*. reported the optical and optically detected magnetic resonance (ODMR) studies of the excited states of PPh_3AuCl and found weak high energy (3.9 eV and 3.4 eV) emissions, which were attributed to the phenyl-localized $\pi\pi^*$ state [9] as well as low energy emissions at ∼2.3–2.7 eV (charge transfer phosphorescence). XEOL with synchrotron light as an excitation source is an X-ray in, optical photons out technique [6–8]. An excitation of a core electron with tunable X-rays to the LUMO and beyond is the primary photoabsorption process, which is followed by the decay of the core hole. These processes lead to the production of photoelectrons, Auger electrons, fluorescence photons, and the associated secondary processes, which result in the formation of thermalized holes and electrons, respectively, in the valence band/HOMO and the conduction band/LUMO. The radiative recombination of holes and electrons produces luminescence. The de-excitation of an exciton, an excimer or exciplex can also lead to luminescence. The XEOL technique involving core level excitation can be site- and excitation-channel specific when the excitation energy is tuned across the absorption edge of the element of which the local electronic structure is effectively coupled to the luminescence channel [6–8].

2. Experimental

The compound was prepared by standard methods from reagent-grade materials [10]. The specimens were prepared as a fine powder film on an indium foil. The Near Edge X-ray Absorption Fine Structures (NEXAFS) at the C and P K-edges and Au $M_{5,4}$-edges were recorded at the Spherical Grating Monochromator (SGM) beamline (bending magnet) and the Double Cystal Monochromator (DCM) beamline, respectively, of the Canadian Synchrotron Radiation Facility (CSRF) at the Synchrotron Radiation Center, University of Wisconsin-Madison. The NEXAFS were monitored simultaneously by total electron yield (TEY), fluorescence yield (FLY) and photoluminescence yield (PLY) collecting all the optical photons (zero order) as well as partial yields at a selected emission channel. At the SGM, the monochromatic soft X-ray beam has an energy resolution of ∼0.3 eV at the carbon K-edge of ∼286 eV with a slit size of 100 μm × 100 μm. The energy resolution at the DCM is ∼0.8 eV with InSb (111) crystals in these experiments. It should be noted that the TEY spectrum resembles that of the absorption while the PLY is sensitive to the chemical environment of the absorbing atom and the excitation channel that may or may not couple to the luminescence chromophore effectively, leading to site and excitation channel specificity [6–8]. The optical photons were collected with a J-YH100 monochromator. All spectra were normalized with the intensity of the incident beam.

3. Results and Discussion

Fig. 1 (a) shows the normalized XEOL of the gold(I) compounds obtained with various excitation energies across the C, P K-edge and Au $M_{5,4}$-edge. It should be noted that the emission profiles remained the same regardless of the excitation energy across the edges although the intensity was noticeably different depending on the excitation energy. The XEOL exhibits well-defined structures with luminescence peaks at 455 nm (2.72 eV), 486 nm (2.55 eV), and 533 nm (2.33 eV). This is in good agreement with the emission spectra at room temperature for the phosphine

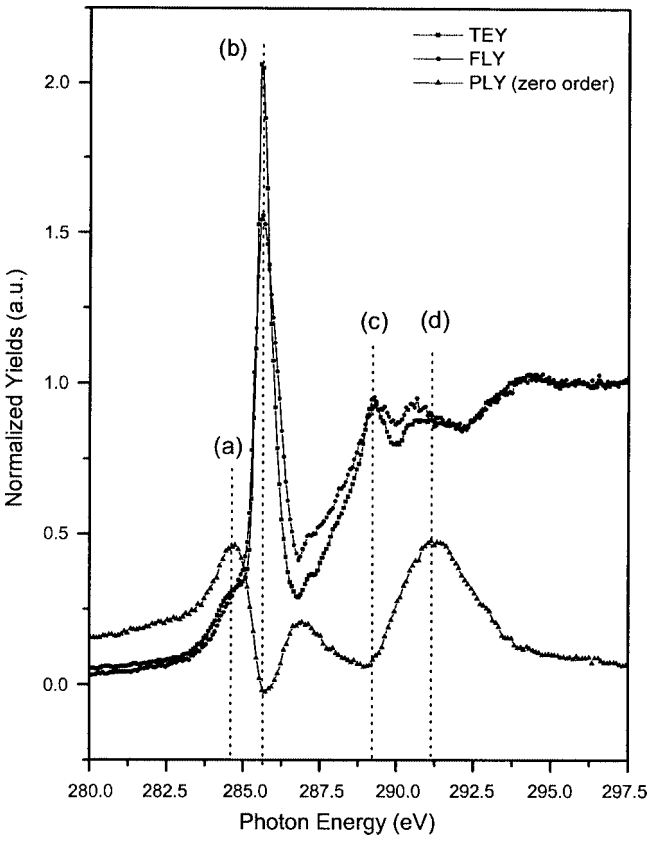

Fig. 2. The normalized yields of PPh_3AuCl at the C K-edge in TEY, FY, PLY (zero order) modes.

complexes, following pulsed laser excitation at 337 nm reported by Larson *et al*. [9]. One would expect higher intensity from the higher excitation energies, however, the luminescence intensities were higher across the C K-edge than the P K-edge and the Au $M_{5,4}$-edge. However, as noted in the experimental section, two different beamlines have been utilized, a comparison cannot be quantified without the absolute flux. Qualitatively, however, this may be due to a higher absorption cross-section at the C K-edge. A closer examination of the XEOL spectra at the P K-edge and Au $M_{5,4}$-edge reveals that the relative intensities of the three peaks are slightly different between the edges as shown in Fig. 1(b). Upon normalizing of all the spectra at the strongest peak at 486 nm, it becomes apparent that the intensity of the peak at the higher wavelength (533 nm) increases at the expense of the peak at the lower wavelength (455 nm), as the excitation energies decrease from the Au $M_{5,4}$-edge to the P K-edge. An emission at the shorter wavelengths (385 nm ∼ 3.22 eV) becomes noticeable. This situation can be understood in terms of the increase in the population of the more energetic states.

Fig. 2 shows the C K-edge NEXAFS of PPh_3AuCl in TEY and FLY as well as zero order PLY. NEXAFS measures the photoabsorption cross-section for the excitation of tightly bound core electrons to LUMO and LUMO +1 orbital, etc. and is recorded by scanning the incident X-ray photon energy across an absorption edge. It provides informations about the local structure and bonding of the absorbing atom [11]. For unsaturated organic molecules such as aromatics, the C K-edge typically exhibits two types of main transitions. The intense and narrow feature at low energy (∼285–286 eV) represents a C 1s → π^* (bound state) transition, whilst the broad transition at higher energy (∼290–292 eV) represents a C 1s → σ^* (quasi bound state involving carbon-carbon interaction) transition. There are also weak resonances in between associated with C 1s → σ^* transition of the C-H bond. It is apparent that there are two peaks in π^* transition regions, an intense and sharp peak at ∼286 eV (peak (b)) and a weak broad shoulder (peak (a)) at slightly lower energy region. These absorption peaks can be attributed to C 1s to π^* transitions of nonequivalent carbons on the phenyl rings. It should be noted that the specimen was a reasonably thin and uniform film as indicated by the exact profiles of TEY (surface sensitive) and FLY (bulk sensitive).

The phosphorus K-edge absorption spectrum collected in the TEY mode is shown in Fig. 3, together with the photoluminescence yields. Two sharp peaks are apparent, which represent the two main transitions as in the case of the C K-edge, a P 1s → π^* transition at the lower energy region and a 1s → σ^* transition at a slightly higher energy. Similar to the C K-edge, the TEY and FLY are identical, indicating a thin and uniform film. The TEY at the Au $M_{5,4}$-edge is displayed in Fig. 4, which only shows a weak edge jump. This is not unexpected since the Au $M_{5,4}$-edge jump (d – p transition) has a low cross-section and a large lifetime broadening.

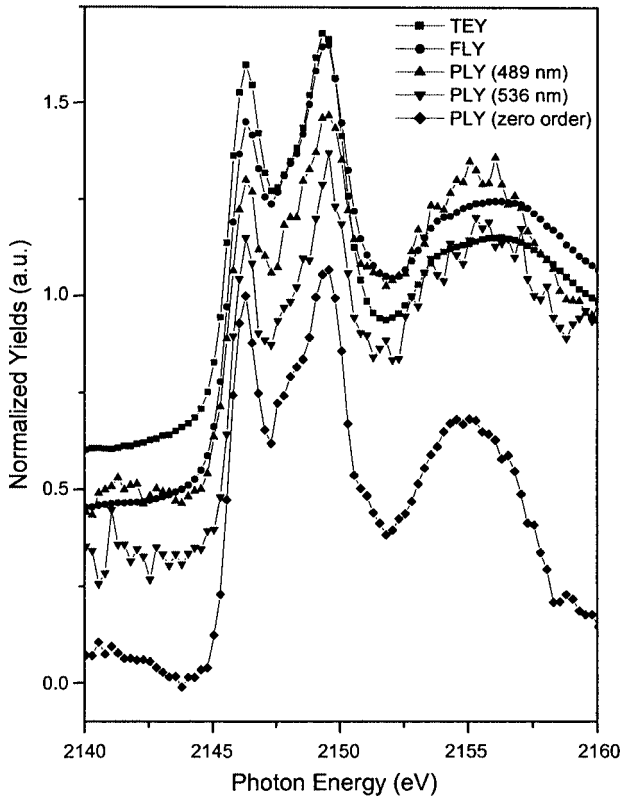

Fig. 3. The normalized yields of PPh_3AuCl at the P K-edge in TEY, FY, PLY (zero order and partial yields) modes.

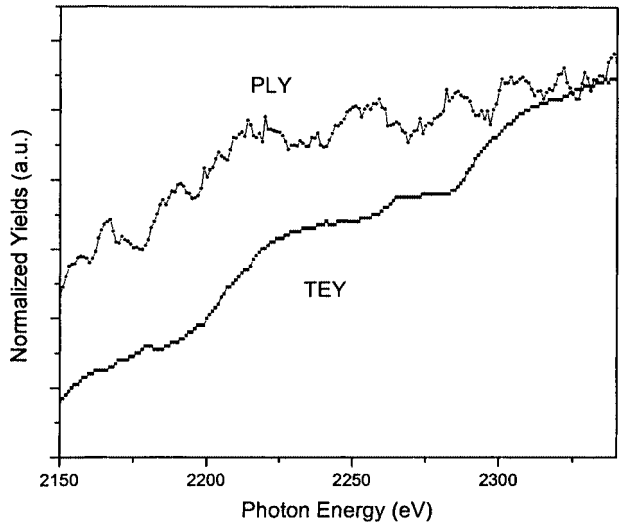

Fig. 4. TEY and PLY (zero order) of PPh_3AuCl at the Au $M_{5,4}$-edge.

Returning to the C K-edge (Fig. 2), the most interesting feature is in the PLY in which all optical photons of the gold(I) complex are collected. A close examination of the TEY and the PLY of the PPh_3AuCl reveals that the first π^* resonance, peak (a), is enhanced in PLY relative to TEY, whilst the main π^* resonance, peak (b), is inverted in the PLY. The inversion can be explained as follows. First, the splitting in the π^* resonance occurs due to the nonequivalent carbon atoms in the phenyl rings and only those carbon atoms (most likely those bonded directly to P) that are associated with the transition are coupled effectively to the luminescence. Second, the inversion could be due to the total absorption phenomenon in which the strong π^* channel absorbs a major fraction of the incoming photons. If the luminescence quantum yield is less efficient than the absorption elsewhere, the PLY would invert. It is interesting to note that the transition from C 1s to σ^* quasi bound states at ~290 eV peak (d) shows a broad peak in the PLY. This observation is in contrast to a previous XEOL study of Ru(2,2'-bipy)$_3^{2+}$ in which the σ^* transition was significantly suppressed [7].

The total (zero order) and partial photoluminescence yields (PLY) at the P K-edge NEXAFS shown in Fig. 3 exhibit the same profile as the TEY and the FLY indicating that local excitations at the P K-edge is strongly coupled to the luminescent chromophore. Thus the emission can be assigned to the decay of an excited state having both P and Au character. This is also supported by the observation of an intense Au $L_{3,2}$-edge whiteline for PPh_3AuCl, indicating that the P-Au-Cl moiety has high densities of unoccupied states of Au d character. According to Larson *et al.* [9], the vibronic analysis of the emission in PPh_3AuCl was consistent with an assignment of a LMCT state, but the vibrational frequencies disagreed with Raman frequencies. They then attributed that a severely perturbed trap or an adventitious impurity was responsible for the emission in PPh_3AuCl. They concluded in a more recent study that the low energy emission is a phosphorescence of gold-based $\sigma^* \rightarrow \sigma$ parentage [12]. Based on the C, P K-edge, the Au $M_{5,4}$-edge PLY, and Au $L_{3,2}$-edge XANES, our results indicate that the excited state has considerable Au-P character.

4. Conclusions

We have reported experimental observations of soft X-ray induced luminescence of the PPh_3AuCl complex by exciting the system with photon energies tuned across the carbon, and the phosphorus K-edge as well as the gold $M_{5,4}$-edge. We find that the luminescence is dominantly at low energy and the origin of the luminescence is primarily from the P – Au σ^* to σ of primarily Au d character.

Abstract

X-ray absorption spectroscopy was used to study the local structure and chemical bonding of elemental phosphorus. Three allotropes of this element exist in the solid state. The most common of these is the amorphous red phosphorus. The other two are crystalline: white phosphorus and black phosphorus. In the gas phase tetrahedral P_4 molecules are stable up to ~800 °C. At higher temperatures P_2 molecules become dominant.

Theoretical P(1s) and P(2p) XAFS spectra of gaseous and solid state phosphorus were calculated by *ab initio* FEFF and GSCF3 methods. These were compared and the spectral features were related to structural and electronic properties of the different allotropes of elemental phosphorus. The calculation results were then used to explain the features observed in the experimental P(1s) and P(2p) spectra of red phosphorus that were measured using synchrotron radiation.

1. Introduction

Three structural allotropes of the element phosphorus exist in the solid state. Crystalline black-P is the most stable allotrope, a semiconducting material with an orthorhombic puckered layer structure [1]. Two high pressure phases exist: a semi-metallic rhombohedral form that is formed reversibly at 40–80 kbar, and a metallic simple-cubic phase, formed reversibly at 110 kbar. Crystalline white-P, the least stable allotrope, is composed of tetrahedral P_4 molecules. At room temperature it is in the β-phase, a plastic crystal [2, 3]. Its structure is similar to that of α-Mn with the P_4 molecules in the positions of the Mn atoms [2]. The low temperature α-phase, formed reversibly at −77 °C, has a structure comparable to γ-Pu [2]. The most common allotrope is red-P. Like white-P, it is composed of P_4 molecules. It is usually an amorphous solid, but a crystalline form with a very complex 3D network structure can be prepared [4]. Tetrahedral P_4 molecules are stable in the gas phase up to ~800 °C. At higher temperatures they decompose into P_2 molecules that have a shorter P-P bond length and, like N_2, a formal triple bond [4].

2. Calculations

The molecular geometry of gaseous P_2 and P_4 was optimised with GAMESS US [5]. The Huzinaga minimal basis set 533/53, expanded to 322121/3221, with one d polarisation function was employed. The resulting P-P single bond length for tetrahedral P_4 is 2.2095 Å, in good agreement with experimental values for the P-P single bond [2, 6]. The bond length of 1.8797 Å of linear P_2 is significantly shorter, as expected for a triple bond.

Theoretical P(1s) and P(2p) XANES spectra were calculated for the gas phase using the GSCF3 computer code [7, 8]. The atom positions for P_2 and P_4 correspond to the optimised geometry, and the same basis set was employed. However, in the calculation of the core-hole states, it was expanded to 2111111111/2111111 with one d-polarisation function for the excited P atom. To generate the spectra, Gaussian peaks are used with the peak area set equal to the calculated oscillator strength, and the peak width at half maximum (FWHM) was set to 0.1 eV and 1.0 eV for the P(2p) and P(1s) XANES, respectively.

The theoretical P(1s) EXAFS interference function $\chi(k)$ was calculated with the FEFF 7.0 computer code [9] for the P_4 molecule (optimised geometry) and for the crystalline phases of solid state P that exist at room temperature and atmospheric pressure. The experimental crystal lattice parameters and atom positions were used for black-P [1]. Individual P atoms were placed into the unit cell of the β-phase of white-P [2] using the optimised P_4 structure with the centre of the molecule at the fractional coordinates corresponding to the atom positions of α-Mn [10]. The calculations were done for radial distances up to 10 Å which correspond to clusters containing between 150 and 215 atoms. Only single scattering (SS) and triangular multiple scattering (MS) paths were included. The unit cell of white-P contains several symmetry unique P atoms (9 in the β-phase). The FEFF calculation was done for each of these as the central atom, and the overall $\chi(k)$ was then taken as a weighted average. This was not necessary for black-P, as there is only one symmetry unique atom in the unit cell. The Fourier Transform (FT) of the k^3 weighted $\chi(k)$ was obtained over the k-range from 2 to 15 $Å^{-1}$ using a 30% Gaussian window function.

3. Experiment

P(1s) and P(2p) XAFS spectra of red-P were measured at the double crystal monochromator (DCM) [11] and Grasshopper [12] beamlines of the Canadian Synchrotron Radiation Facility (CSRF), respectively. The spectra were measured simultaneously by total electron yield (TEY), using the photoelectron current, and by fluorescence yield (FY), using a multi-channel-plate detector. The incident photon beam was at normal incidence to the sample surface. Normalisation with respect to the photon flux (I_0) was achieved through simultaneous TEY measurement of a Ni mesh at the Grasshopper and a gas cell with ~1 torr N_2 at the DCM, both located upstream from the sample. The red-P was obtained commercially from Alfa Aesar (99% purity) and used without further purification.

The EXAFS was extracted from the P(1s) absorption spectrum using WINXAS [13]. The edge energy E_0 was set to 2143.6 eV, and the atomic absorption μ_0 was approximated by a cubic spline function with 9 sections over a range from 2 to 15 $Å^{-1}$. A weighing factor of k^3 was applied to the data. The FT of $k^3\chi(k)$ was obtained over the same k-range using a 30% Gaussian window function.

*e-mail address: ajurgens@uwo.ca

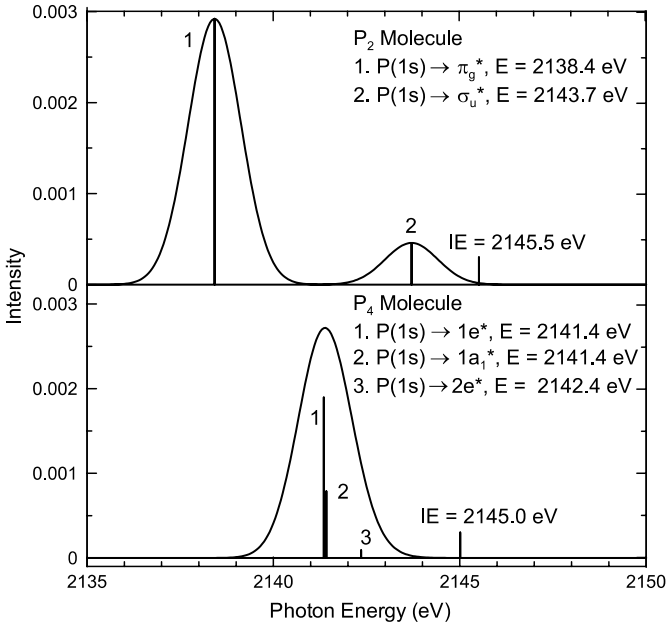

Fig. 1. The theoretical P(1s) XANES spectra of the P_2 (top) and P_4 (bottom) molecules.

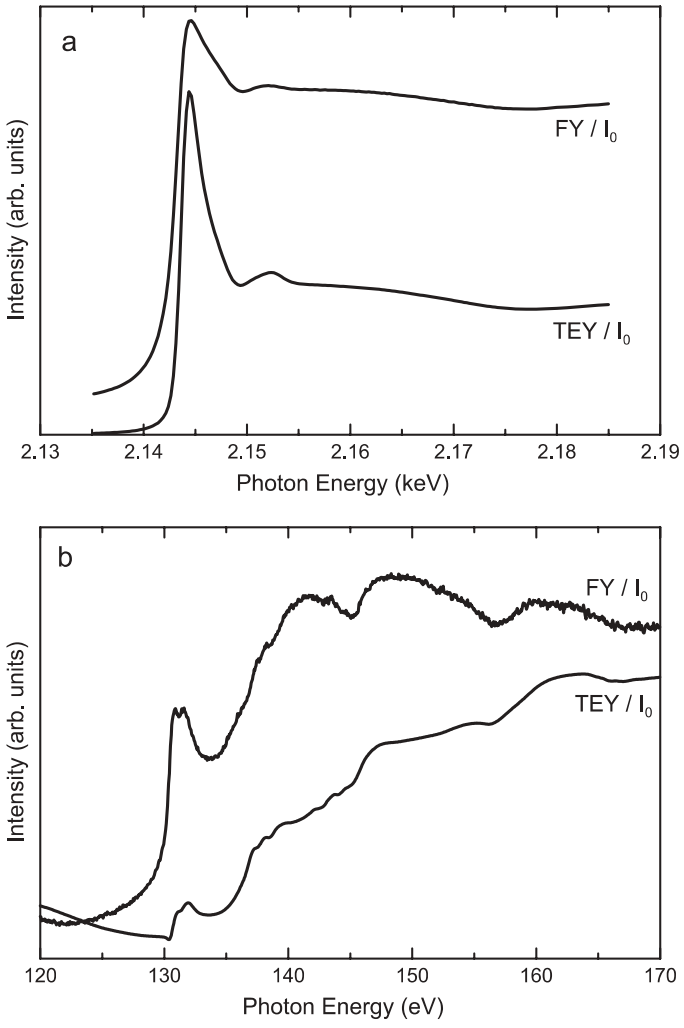

Fig. 2. The experimental (a) P(1s) and (b) P(2p) XANES spectra of red-P.

4. Results and Discussion

The theoretical P(1s) XANES spectrum of P_2 has two absorption peaks that result from the P(1s) $\rightarrow \pi_g^*$ and P(1s) $\rightarrow \sigma_u^*$ transitions (Fig. 1). There is only one feature in the XANES of P_4 that is at an energy intermediate to the peaks of P_2. It arises from the overlap of three unresolved absorption peaks (Fig. 1). The $1e^*$ and $1a_1^*$ orbitals of P_4 correspond to the π_g^* and σ_u^* of P_2, respectively. The orbital lobes of π_g^* are perpendicular to the P_2 bond axis, thus minimising repulsion. In the $1e^*$ of P_4 they lie more along the bond axes. They point towards each other, destabilising the orbital, and hence increasing the transition energy. The opposite effect occurs for the σ_u^*-$1a_1^*$ pair. The σ_u^* lies along the P_2 bond axis and is thus destabilised relative to the $1a_1^*$ of P_4. The $2e^*$ orbital of P_4, another P-P antibonding orbital, has no equivalent in P_2. A transition to the last antibonding orbital of P_4, $1a_2^*$, is not observed, because it is forbidden by symmetry constraints.

The main absorption peak in the experimental P(1s) XANES of red-P (Fig. 2a) occurs at 2144.4 eV, 5.5 eV below the ionisation edge [6]. It corresponds to the XANES feature of the P_4 molecule. The smaller height observed in the FY spectrum relative to TEY, suggests distortion due to self-absorption in the former. The second XANES peak at 2152.4 eV might be caused by a small amount of phosphate in the sample. It could also be a post-edge shape resonance of red-P.

The P(2p) XANES of P_2 has four features resulting from the spin-orbit pairs of the P(2p) $\rightarrow \pi_g^*$ and P(2p) $\rightarrow \sigma_u^*$ transitions. Due to the molecular field splitting of the P(2p) orbitals ($\Delta E = 0.085$ eV for the ionisation energy (IE) and $\Delta E = 0.23$ eV for the excited molecular states), they are partially resolved double peaks.

Convergence problems were encountered for the calculation of the P(2p) XANES of P_4. One solution, using the unrestricted Hartree-Fock method for the excited states, resulted in an increase of the calculated IE by ~10.5 eV. Furthermore, it reduced the molecular symmetry, splitting all e-orbital pairs ($2p_{x,y}$, $1e^*$ and $2e^*$). Hence, three P(2p) IE's were calculated with energy differences of 0.013 and 0.341 eV. Seven P(2p)-hole excited states with a transition energy below the IE were found, the six states with the electron in a P-P antibonding orbital, and one additional state with the electron in a P(3d) orbital. The P(2p) $\rightarrow 1a_1^*$ and P(2p) $\rightarrow 1e^*$ transitions occur between 6 and 7.5 eV below the IE, and the P(2p) $\rightarrow 2e^*$ and P(2p) $\rightarrow$ P(3d) transitions are between 1 and 2.5 eV below the IE. A P(2p) $\rightarrow 1a_2^*$ transition, 1.9 eV below the IE, is not observed. The most intense feature in the spectrum is the spin-orbit pair resulting from the P(2p) $\rightarrow 1e^*$ transition. Due to molecular field effects each of these peaks is split into three that are partially resolved.

The experimental P(2p) XANES spectrum of red-P (Fig. 2b) has one pre-edge feature peaking at 130.9 and 131.6 eV followed by several shape resonances in the ionisation continuum. The pre-edge peak corresponds to the most intense feature in the XANES of the P_4 molecule, the P(2p) $\rightarrow 1e^*$ transition, but only the spin-orbit splitting is barely resolved. The TEY spectrum is shifted by ~0.3 eV towards higher energy relative to the FY spectrum, probably due to sample charging effects.

The k^3-weighted FT of the P(1s) EXAFS interference function for the P_4 molecule has a single peak corresponding to the P-P single bond distance (Fig. 3). A negative phase shift causes the peak to appear at a lower R value then expected. The P_4 molecule is the main building block of white- and red-P, and the atoms in black-P also form three P-P single bonds. Thus this peak is observed in the P(1s) EXAFS of all forms of solid state P.

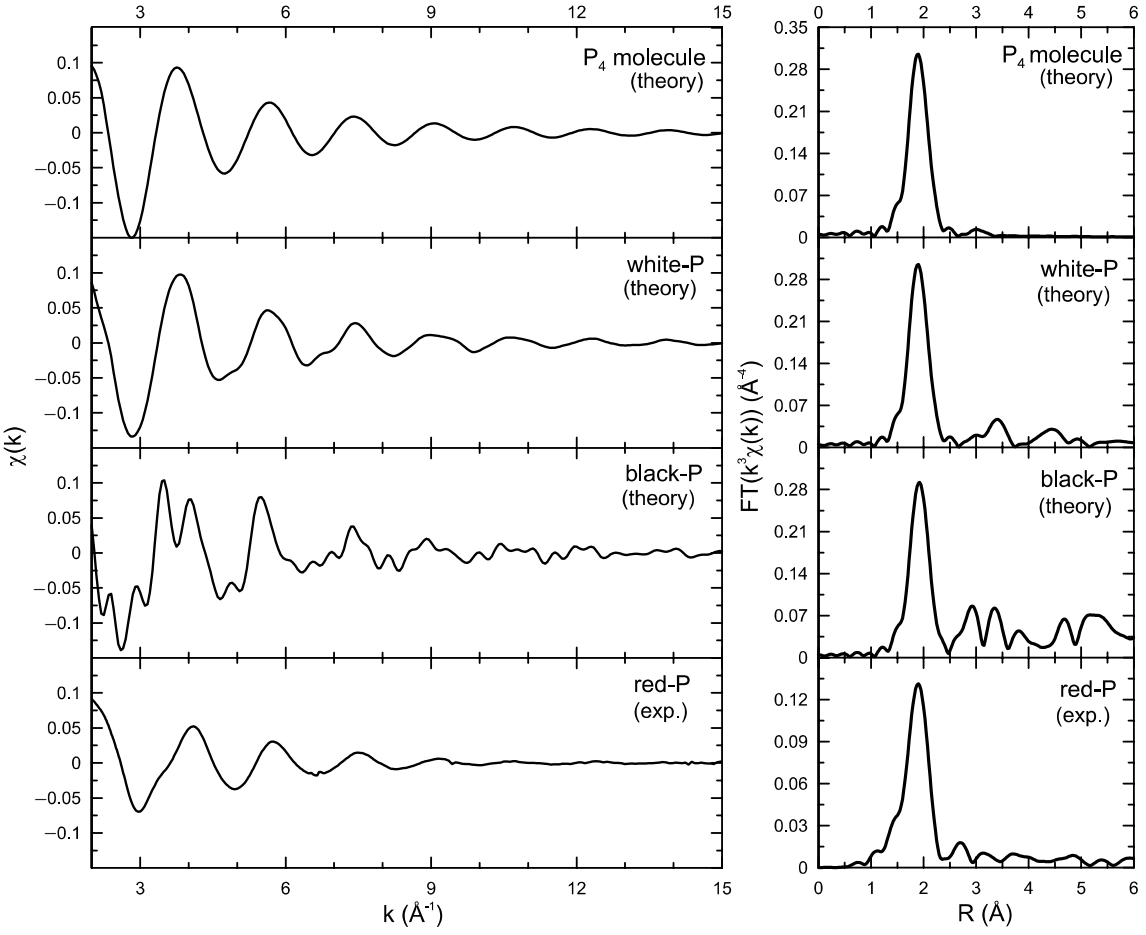

Fig. 3. The EXAFS interference function $\chi(k)$ and the magnitude of its k^3 weighted FT for the P_4 molecule (theory), white-P (theory), black-P (theory) and red-P (experiment).

For white-P the contribution from other shells is minor, because there are so many paths with slightly different radial distances that their scattering waves tend to be out of phase with each other, and thus cancel out. In the experimental $\chi(k)$ of the β-phase of white-P even less contribution from higher shells is expected, because this phase is a plastic crystal and the P_4 molecules can rotate about their centres [3]. In black-P there are significantly fewer scattering paths, so peaks are observed at larger R-values in the FT (Fig. 3). The second and third peaks result from the combination of six SS paths and four MS paths with scattering distances between 3.3 and 4.0 Å. These include scattering from second and third neighbours within the layer and two SS paths involving atoms in an adjacent layer.

As expected, only one dominant peak is observed in the FT of the $k^3\chi(k)$ that was extracted from the P(1s) TEY spectrum of red-P (Fig. 3). It was fitted using the FEFF paths calculated for the P_4 molecule (one SS path and one MS path). The coordination numbers were fixed, ΔE_0 was limited to one value, and R and σ^2 of the MS path were correlated to the corresponding value of the SS path. The results are shown in Fig. 4. The R-value of 2.212 Å obtained for the P-P single bond length is in good agreement with literature values [2, 6]. Attempts to fit the low-R shoulder using P-O scattering paths were unsuccessful, indicating that phosphate, if present, is a very minor impurity in the sample.

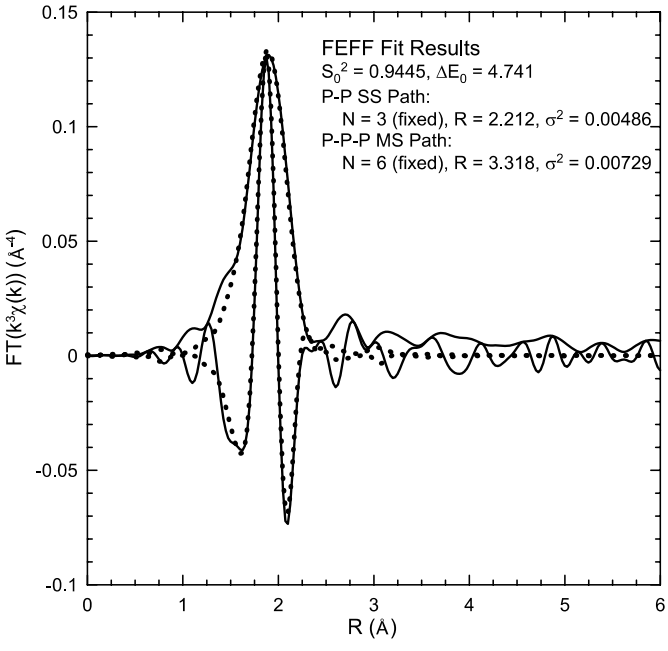

Fig. 4. The imaginary part and the magnitude of the experimental FT($k^3\chi(k)$) of red-P (solid lines), and the fit results using the theoretical $\chi(k)$ of the P_4 molecule (dotted lines).

Abstract

In this work, we analyze and correlate information obtained from XANES, EXAFS and NMR on a SiO_2 aggregate attacked by Alkali Silica Reaction (ASR). EXAFS and XANES results enable local order evaluation during the amorphization process within the aggregate. NMR results show the presence of amorphous and crystalline phases of silica during ASR attack. Besides, theoretical simulations of XANES spectra were performed and the atomic structure that generates the peak located 8 eV above the white-line (feature C in the text) was identified. The results lead us to deduce a change in the local order around silicon.

1. Introduction

The Alkali-Silica Reaction (ASR) is one of the main phenomena that damage the concrete in the world. Many studies were carried out in order to explain the ASR mechanism [1]. In recent studies we evaluated the damage caused by ASR in a flint aggregate by Environmental Scanning Electron Microscopy (ESEM) and X-ray Diffraction (XRD) [2, 3]. Both results support the formation of new phases, which precipitate in the aggregate.

A relationship between the concrete degradation and its structural behavior has been established [4]. Today, most authors agree with the idea that the beginning of the ASR is the rupture of the siloxane bonds Si-O-Si when the aggregate used in the concrete contains SiO_2 as in our study. Thus, any attempt to understand the ASR mechanism must consider the local changes around silicon and/or oxygen.

The studies performed by Dien Li *et al.* [5] showed the utility of the XANES technique to examine the amorphization process in crystalline SiO_2. Then we used, for the first time, X-ray absorption spectroscopy (XANES and EXAFS) to analyze the structural evolution of a flint aggregate. Nuclear magnetic resonance (NMR) results obtained on the flint aggregate submitted to ASR are also presented. Further, using FEFF8 [6], we show how to identify the origin of the XANES structures found in the spectra.

2. Materials and Methods

The aggregate used in this work is a natural SiO_2 flint from the north of France. It contains 99.1% SiO_2. X-ray diffraction shows that it is made of α-quartz phase with moganite traces. Sample preparation and the ASR procedure used have been previously described [3, 7].

In the ASR mechanism, the ions present in the concrete (such as OH^-, K^+ and Ca^{++}) can penetrate the poorly crystallized and porous parts of the aggregate [8]. The attack is initiated by hydroxyl ions, as indicated below

$$2SiO_2 + OH^- \Rightarrow SiO^-{}_{5/2} + SiO_{5/2}H \quad (1)$$

inducing the rupture of Si-O-Si bonds between two tetrahedrons SiO_2, called Q_4, and producing $SiO^-{}_{5/2}$ and $SiO_{5/2}H$, called Q_3 or silanols. The equation of the reaction could be written as: $2Q_4 + OH^- \Rightarrow SiO^-{}_{5/2} + Q_3$. The cations, which are abundant in the porous structure of the material, are attracted to the sites of negative charge and participate in the reaction. The calcium cations are likely to react with silica species to form calcium silicate hydrate [8].

The flint aggregate was powdered and the distribution of the average particle size showed two maxima, at 160 µm and 630 µm, before the reaction. 1 g of crushed flint was subjected to accelerated ASR at 80 °C with a mixture of 0.5 g of portlandite $Ca(OH)_2$ and 10 ml of potash solution KOH at 0.79 mol/l [3, 7]. The pH of the solution was 13.9. In this study we will present results from samples of flint aggregate after 30, 72 and 168 hours of ASR attack, respectively named 30 h, 72 h and 168 h. In order to probe the surrounding of silicon atoms in the sample, solid-state ^{29}Si magic angle spinning nuclear magnetic resonance (MAS-NMR) and both EXAFS and XANES spectra at the Si K-edge were collected.

MAS-NMR spectra were obtained using a Bruker MSL 300 spectrometer operating at 59.631 MHz with a 2.5 mm Bruker CP/MAS probe spinning at 4 kHz. Tetramethylsilane (TMS) was used as a reference for chemical shifts measurements. Spectra were recorded with a pulse angle of 30° and a recycle delay of 80 s. The number of scans was 2150 for each sample.

The XANES and EXAFS data were recorded using the SA32 beam-line of the Super-ACO ring at LURE, Orsay, France. The data were collected in the total electron yield (TEY) detection mode, using a 0.2 eV step for XANES and 1 eV step for EXAFS. The beam was monochromatized by a double-crystal monochromator, equipped with two InSb (111) single crystals, and calibrated on a c-Si sample (1839 eV at the Si K-edge threshold). The software "*EXAFS pour le Mac*" [9] was used to perform the initial data treatment and first shell simulations. A 6th degree polynomial function was used to reproduce the atomic absorption, and the signal was normalized using the Lengeler-Eisenberger method. A k^2 weighting and a Kaiser apodization window between approximately 2.8 and 11.3 $Å^{-1}$, with $\tau = 1.0$, were used to calculate the Fourier transform of the EXAFS signal shown here.

The FEFF8 code was used to simulate the XANES signal of α-quartz [10]. We used the Hedin-Lundqvist interaction potential

*e-mail: khouchaf@ensm-douai.fr

and determined the local interstitial atomic potential around the absorbing atom. In order to identify the multiple scattering paths (atomic structure) responsible for the generation of feature C (see Fig. 1), we first identified the size of the cluster necessary to reproduce this feature.

Subsequently, in order to identify the atoms that are involved in the multiple scattering process generating feature C, we generated several different sub-clusters. For each of these sub-clusters, we deleted only one different atom of the initial cluster (except the absorber atom) and performed a FMS calculation. If the deleted atom contributes to the generation of feature C, then this feature is weakened or disappears for this specific calculation. With this procedure, we were able to identify the only atoms that are involved in the multiple scattering process generating feature C.

3. Results

3.1. *Experimental*

Figure 1 shows the XANES spectra from samples 30 h, 72 h and 168 h compared to the flint before ASR attack. The main peaks are noted A, B, C, D and E. The positions of all peaks are the same for all samples: peaks A, C and E are located respectively at 1846.8 eV, 1854.4 eV and 1864.2 eV, corresponding to the value of the same peaks for α-quartz. The origin of the XANES peaks is only described in a general way in the literature [5, 11]. With the exposition to ASR, one can notice decreasing intensity and/or broadening of the features.

The EXAFS study enabled us to follow the evolution of the short-range order (SRO) around silicon under the effect of ASR. Figure 2 shows Fourier Transforms (FT) of the EXAFS signal from flint aggregate before and after 30, 72 and 168 hours of exposure to ASR. One can observe that the amplitude of the first shell (Si-O bonding) peak slightly increases during ASR attack, due to the equivalence of the Si-O distances in the SiO_2 tetrahedra after amorphization. However, silicon atoms are always surrounded by four oxygen atoms at a mean distance of 1.60 ± 0.02 Å. In addition, the amplitude of the peaks for the second and third neighbors decreases, due to the amorphization of the material.

The analysis of the EXAFS Fourier transforms shows that the SRO above the first shell around Si atoms is almost preserved during ASR attack, however the amplitude of the peaks for the second and third neighbors decreases, due to the amorphization of the material.

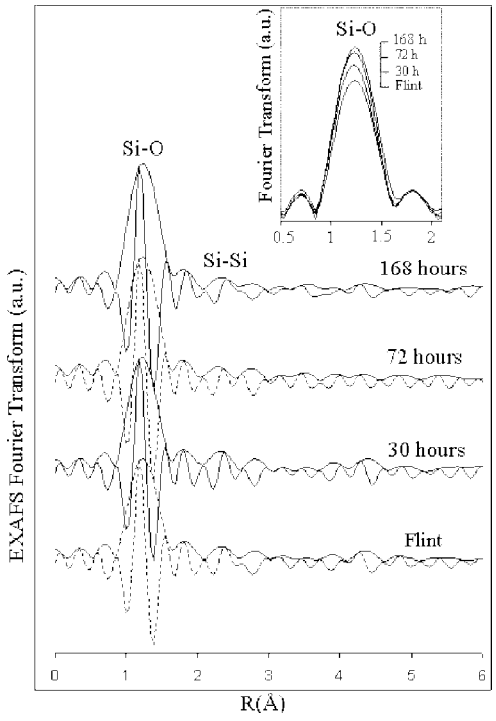

Fig. 2. EXAFS Fourier Transforms from flint aggregate before ASR attack, and after 30, 72 and 168 hours of exposition to ASR.

In figure 3 MAS-NMR ^{29}Si spectra from samples 30 h, 72 h and 168 h are compared to that of the flint aggregate before ASR attack. On the spectrum of the flint aggregate we can notice the presence of a sharp peak at −107 ppm, related to the presence of Q_4 (crystalline) sites, and another peak at −100 ppm, related to Q_3 sites [12]. After 72 hours of attack, one can observe an increase in the number of Q_3 sites in the aggregate. Moreover, a new peak appears around −110 ppm, also increasing its intensity with the time of attack, being attributed to poorly crystallized or amorphous silica [12].

3.2. *Calculation*

In agreement with other results [11], theoretical simulations of the XANES spectra show that feature C appears when a cluster having 53 atoms (diameter of 10.5 Å) is used.

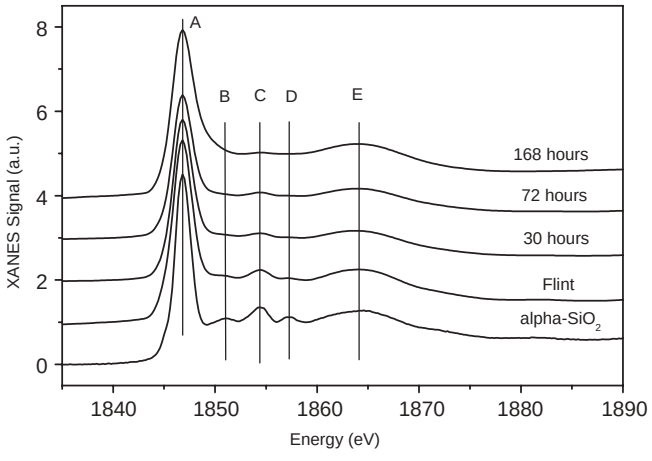

Fig. 1. XANES spectra of the samples 30 h, 72 h, 168 h, flint aggregate before ASR attack and α-SiO_2.

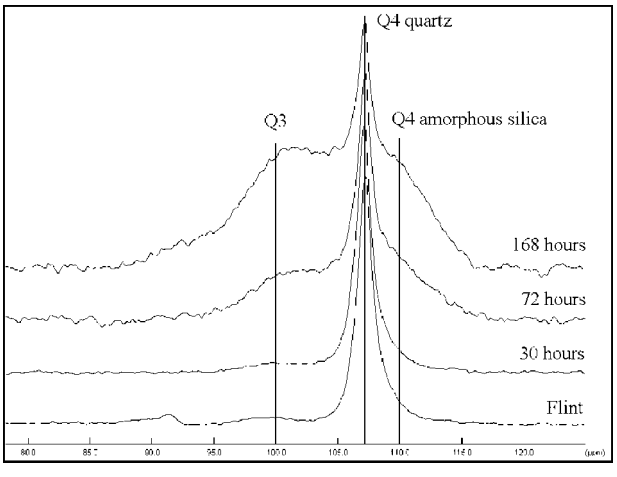

Fig. 3. MAS NMR ^{29}Si spectra of the samples submitted to ASR during 30h, 72h and 168h compared to flint aggregate before ASR.

Table I. *Position and distances from the central Si atom, set at the origin, for the six atoms that generate feature C (see Fig. 1) by multiple scattering in the α-SiO_2 structure.*

atom	shell	*x* (Å)	*y* (Å)	*z* (Å)	Distance (Å)
Si	6th	−2.27367	−3.93810	1.80168	4.86
Si	6th	−4.54733	0.00000	−1.80165	4.86
O	3rd	−2.90895	−2.96759	0.66283	4.20
O	3rd	−4.02448	−1.03543	−0.66283	4.20
O	7th	−1.15813	−4.84909	1.13883	5.10
O	7th	−4.77850	1.42152	−1.13883	5.10

Subsequently, we generated 52 sub-clusters. For each of these sub-clusters, we deleted one different atom of the initial cluster (except the absorber atom) and performed a FMS calculation. Finally, the absence of only 6 (4 O and 2 Si atoms) of the 52 atoms analyzed influenced the intensity of feature C during simulation. The positions of these six atoms are listed in Table I. These are the sole atoms that influence the generation of this XANES structure and, as one can see, their atomic positions are symmetric, as expected.

Figure 4 shows simulation of results for some sub-clusters (from sub-cluster without atom 33 to that without atom 46 of the FEFF input list of atoms) and compare them to the experimental spectra. In this figure, the original energy range of the theoretical spectra, obtained with the Hedin-Lundqvist interaction potential, was scaled to provide the coincidence of both A and E features in both theoretical and experimental spectra. However, the use of the Dirac-Hara interaction potential gives automatically a good energy scale but also a less realistic whiteline. Simulations without feature C were obtained for sub-clusters without atoms 39 and 40 of the FEFF input list, that is, the Si atoms in table I.

4. Discussion

The data collected by MAS-NMR show that the flint aggregate is not perfectly crystalline, confirming previous results [3]. As expected, the quantity of Q_3 sites increases with ASR attack. Simultaneously, a new peak located at −110 ppm, related to the presence of amorphous silica (amorphous Q_4 sites) [12], appears only after attack and also increases its intensity with duration of ASR.

These data show that the formation of a Q_3 site during ASR attack causes, simultaneously, the creation of amorphous Q_4 sites by deformation/relaxation of its direct neighborhood. Therefore, the presence of a crystalline phase within all samples shows that, at least, amorphous and crystalline phases coexist in the aggregate during ASR attack, corroborating previous results [13], in which flint aggregates attacked by ASR are heterogeneous, presenting what seems to be different phases.

In order to check this assumption and correlate the NMR data with the respective phases, it will be important to carry out experiments of micro-XAFS on each one of the different zones identified in our samples.

XANES results clearly show the effects of the structural deterioration during ASR attack (figure 1), confirming that this technique can give significant information about the amorphization process generated by ASR in the concrete.

The positions of the peaks in the XANES spectra are identical for all samples, and also identical to those for α-quartz, indicating that the crystalline phase of the samples has always the same basic structure. However, with the exposition to ASR, the decreasing intensity of peak C and broadening of features A and E are remarked, pointing out the amorphization of the material.

Since the first coordination sphere of Si is preserved with 4 oxygen atoms, the EXAFS data corroborates the fact that the agent of the ASR is the hydroxyl ion, as shown in equation (1). Also, the Fourier transforms of the EXAFS signal illustrate the evolution process of the SRO around silicon with ASR.

Theoretical simulations of the XANES spectra were also performed and the set of atoms responsible for the generation of feature C is identified, but the intensity of this peak is underestimated by FEFF8 code, despite our efforts to reduce the broadness of the spectra or to increase the intensity of the peak by changing the FEFF8 parameters. On the other hand, the size of the cluster necessary to generate the feature is in agreement with other similar works, as well as the position of the feature, corroborating our result. This feature disappears only when deleting one of the six atoms listed in table I. In addition, separating these atoms into two groups of 3 (1st, 3rd, 5th and 2nd, 4th, 6th in table I) one can see that both groups are symmetric by a 180° rotation. This result enables us to deduce that the origin of feature C in SiO_2 can be attributed to the MS of the photoelectron by the ensemble of atoms listed in table I.

Due to the fact that feature C is generated by the atomic structure inside a small cluster with a radius of 5.1 Å, it is clear that the initial structural order of the flint is deteriorated in sample 168 h, as confirmed by EXAFS. However, since the depths probed by NMR and EXAFS measured in TEY mode are different, NMR being more bulk sensitive, this result is not in opposition to the existence of a crystalline phase in the flint aggregate after ASR. It indicates that the surface of the aggregate is more damaged than the bulk.

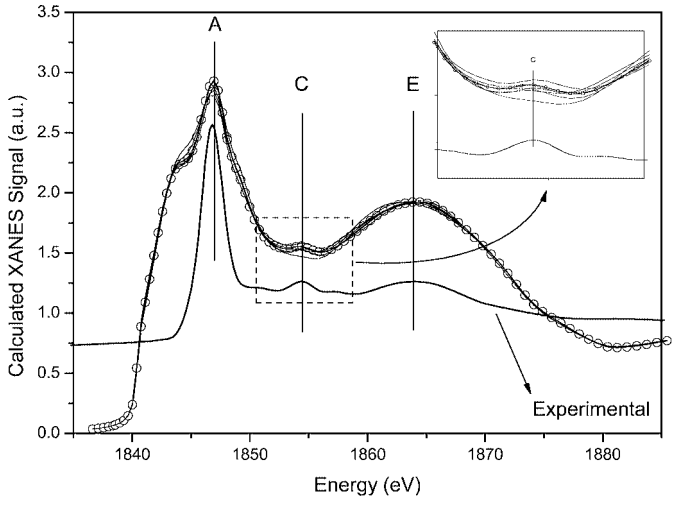

Fig. 4. Comparison between experimental and XANES simulation spectra for several sub-clusters, as explained in the text.

5. Conclusions

The XAFS results complement and agree with other studies performed by Dien Li *et al.* using model materials, providing extra information and helping us to better understand the mechanisms of the ASR in concrete. The NMR data give additional information about the ASR process, showing the coexistence of different

phases such as Q_3 rich zones, well-crystallized and amorphous zones within the aggregate. Additionally, we developed a method to identify the set of atoms that generates a specific structure in the XANES spectra. As an example, we identified the origin of feature C in the experimental spectra of α-quartz.

Abstract

Pressure-induced scheelite-to-wolframite structural phase transition in $SrWO_4$ was studied using two complementary techniques – X-ray absorption spectroscopy and X-ray diffraction (XRD). In situ XRD and W L_3-edge EXAFS measurements were performed using the synchrotron radiation. The experiments were done at room temperature in the pressure range from 0 to 30 GPa using the diamond anvil cell. The XRD results unambiguously show that $SrWO_4$ transforms from the tetragonal scheelite phase to the monoclinic wolframite-type phase at about 11.7 GPa. Locally this transition appears as a change of the tungsten ions coordination from regular tetrahedral to distorted octahedral. The analysis of the EXAFS data suggests that tungsten ions displace from the centres of the tetrahedra by about 0.04 Å and some nearest oxygen atoms relax by about 0.23 Å.

1. Introduction

Strontium tungstate $SrWO_4$ belongs to scheelite-type ABO_4 compounds which are commonly used as solid-state laser hosts when doped with rare-earth ions [1]. In scheelites [2], tungsten ions are surrounded by four equidistant oxygen atoms, forming regular tetrahedra, whereas the A^{2+} ions are located between WO_4 units and are eight-fold coordinated by oxygen atoms.

At high pressure, the scheelite structure transforms into the wolframite one, in which both tungsten and A^{2+} ions are expected to be six-fold coordinated by oxygen atoms. Pressure-induced scheelite-to-wolframite phase transition in ABO_4 compounds has been studied for many years [2]. It is associated with a displacement of B cations, leading to the change of their coordination from tetrahedral to distorted octahedral (Fig. 1).

Until now most works on the scheelite-to-wolframite phase transition have been performed by Raman spectroscopy and X-ray diffraction. In particular, the Raman studies of tungstates indicate that the transition occurs at 6.5 GPa for $BaWO_4$ [3], at 10 GPa for $CaWO_4$ [4] and at 11.5 GPa for $SrWO_4$ [4, 5].

In this work we present for the first time in situ X-ray absorption spectroscopy (XAS) and X-ray diffraction (XRD) measurements of the high-pressure phase transition in $SrWO_4$. A combination of two complementary structural methods allowed us to follow precisely pressure-induced modifications of the $SrWO_4$ structure and to probe directly the transformation of WO_4 tetrahedron to WO_6 octahedron. Note that this work is the first observation of the scheelite-to-wolframite phase transition from the local viewpoint.

2. Experimental details and data analysis

In-situ pressure-dependent (0–30 GPa) energy-dispersive XAS and XRD experiments were performed at D11 (XAS10) and DW11A (WDIS) beamlines using synchrotron radiation from the LURE DCI storage ring, operated at the energy 1.85 GeV and the current 230–300 mA. Polycrystalline $SrWO_4$ (99.9%) sample was commercial powder, obtained from Alfa Aesar. It was finely ground, and some quantity was placed together with few pieces of ruby into the standard diamond anvil cell. A water-ethanol-methanol mixture was used as a pressure-transmitting medium. Pressure was measured before and after pair of XAS and XRD experiments using the standard ruby fluorescence technique. The position of the cell was adjusted during each XAS experiment to improve the quality of the spectra, thus minimising the appearance of extra absorption peaks associated with Bragg reflections from the diamonds. The energy scale of the W L_3-edge XAS experiments was calibrated relative to the measurement of $SrWO_4$ powder in transmission mode on a conventional spectrometer (beamline D21 at LURE) with a double-crystal Si(311) monochromator. All experiments were done at room temperature.

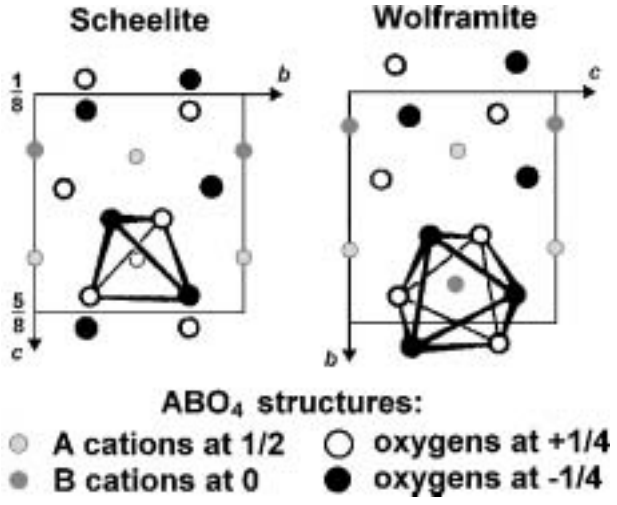

Fig. 1. Comparison of scheelite and wolframite ABO_4 structures [2].

After energy scale calibration [6], the W L_3-edge X-ray absorption spectra were analysed by the EDA software package [7, 8] following standard procedure. The EXAFS part of the spectra was singled out by the Fourier filtering procedure and best-fitted within the multi-shell Gaussian/cumulant model [7, 8]. Theoretical scattering amplitudes and phase shift functions, calculated by the FEFF8 code [9] for the $SrWO_4$ structure [10], were utilised in the model. The complex Hedin-Lundqvist exchange-correlation potential [11] was used to account for the inelastic losses of photoelectron, and the cluster potential was calculated self-consistently.

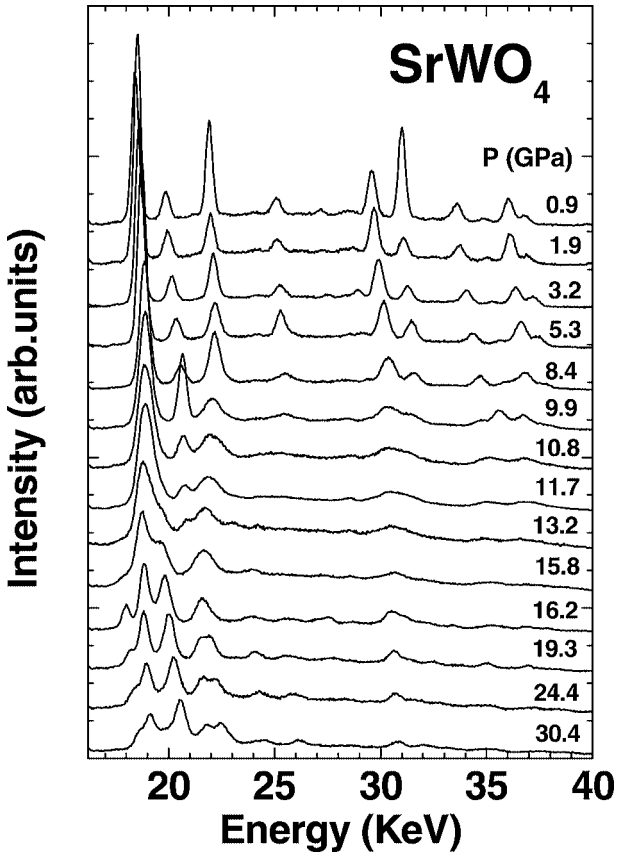

Fig. 2. Energy-dispersive X-ray powder diffraction patterns of polycrystalline $SrWO_4$. All visible peaks belongs to $SrWO_4$. Note a transition from tetragonal to monoclinic phase at about 11.7 GPa.

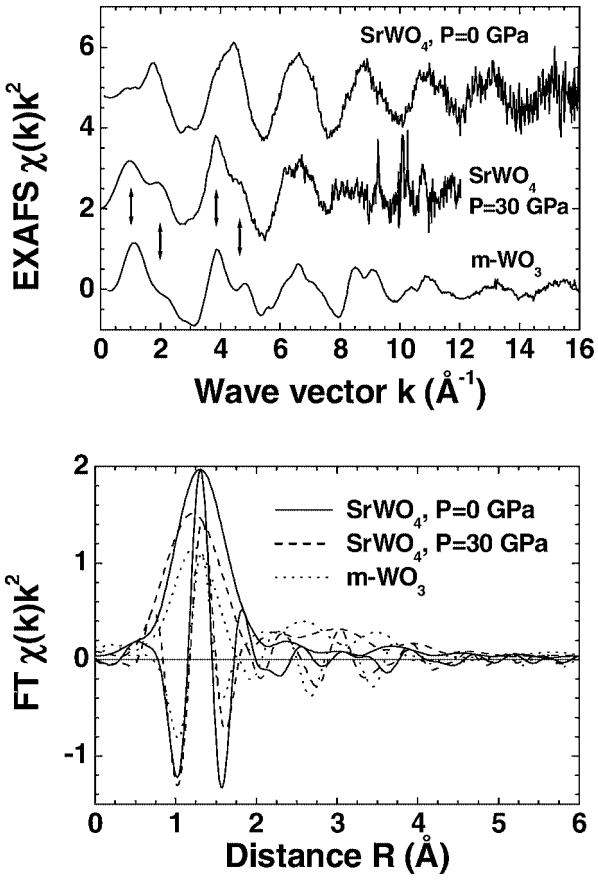

Fig. 3. The experimental W L_3-edge EXAFS $\chi(k)k^2$ signals and their FTs in $SrWO_4$ (at $P = 0$ and 30 GPa) and m-WO_3 [12]. Arrows in the upper panel indicate well visible similarities in the EXAFS signals of $SrWO_4$ at 30 GPa and m-WO_3, in which tungsten ions are six-fold coordinated. Note that the FTs are not corrected for the phase shifts.

3. Results and discussion

XRD patterns of $SrWO_4$ at different pressures are shown in Fig. 2. The transition from tetragonal scheelite phase to monoclinic wolframite phase is observed at about 11.7 GPa, when a new peak starts to grow at 20 KeV on the right side of the first strong peak. This result is in perfect agreement with Raman studies in [4, 5].

The analysis of the W L_3-edge EXAFS spectra confirm and complements the results of XRD. The W L_3-edge EXAFS spectra are strongly sensitive to the local environment around tungsten atoms. In Fig. 3 we present two EXAFS spectra and their Fourier transforms (FTs), corresponding to the extreme points at 0 and 30 GPa. Large modifications caused by the phase transition are well visible. Comparison of the spectrum at 30 GPa with the one of monoclinic WO_3, in which tungsten atoms have distorted octahedral environment, shows their similarity. The FTs are dominated by the first coordination shell peak at 1.25 Å. The group of peaks located above the first one are due to outer coordination shells and multiple-scattering effects.

The best-fit analysis of the first peak at 1.25 Å (Fig. 4) within the multi-shell Gaussian/cumulant models allowed us to determine the variation of the local environment around tungsten atoms. The fits were performed using the one-shell and two-shells and three-shells models with and without the cumulants [7, 8]. We found that at low pressure the one-shell Gaussian model is adequate to describe the experimental EXAFS signal. Thus, in scheelite phase, tungsten atoms are four-fold coordinated by oxygen atoms with the mean distance R(W-O) = 1.78 Å and the Debye-Waller (DW) factor σ^2(W-O) = 0.002 Å^2. Next nearest oxygen atoms are expected at 3.08 Å [10] and do not contribute under the first peak in FT. An increase of pressure results in the rise of the DW factor to

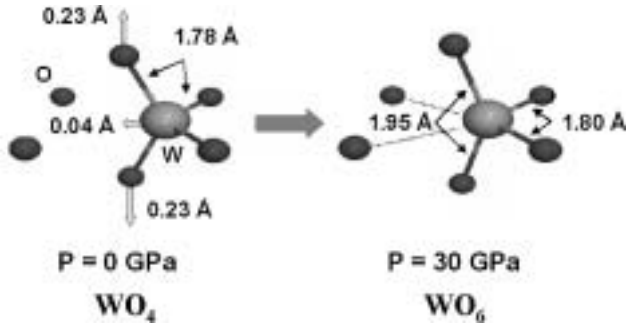

Fig. 4. Model of the local structure modification around tungsten atoms in $SrWO_4$ upon high-pressure phase transition. Large grey spheres are tungsten atoms, small black spheres are oxygen atoms. Wide arrows in the left part of the figure indicate directions of atomic displacements. The bonds of two weakly bound oxygen atoms, which complete the octahedron at high-pressure, are shown by dotted lines in the right part of the figure.

σ^2(W-O) = 0.007 Å^2, that indicates an increase of static disorder due to the beginning of tungsten atoms displacements.

Above the phase transition, the two-shells model becomes more adequate to describe the experimental EXAFS signals. The results suggest that there are two oxygen atoms at R(W-O) = 1.80 Å with σ^2(W-O) = 0.002 Å^2 and two oxygen atoms at R(W-O) = 1.95 Å with σ^2(W-O) = 0.005 Å^2 and C_3 = 0.006 Å^3.

Thus, the application of pressure forces tungsten atoms to displace by about 0.04 Å in the direction of the tetrahedron edge to reconstruct it till octahedron (Fig. 4). At the same time, two oxygen

atoms displace in opposite directions by about 0.23 Å, to allow for the tungsten to pass. As a result, the coordination of tungsten atoms at 30 GPa becomes distorted octahedral with two short (1.80 Å), two middle (1.95 Å) and two long bonds (not detectable in our experiment due to probably their large DW factors). The values of the W-O bonds in high-pressure phase are typical for octahedral coordination of tungsten atoms [13]. However, stronger bonding of tungsten atoms with four oxygen atoms show that tungstens tend to preserve tetrahedral-like environment. This conclusion is supported by recent high-pressure Raman studies [5]. It was found [5] that the frequency of the stretching $A_g(\nu_1)$ mode of the WO_4 tetrahedra changes smoothly across the phase transition pressure, suggesting sufficient stability of tetrahedral units.

4. Conclusions

The pressure-induced scheelite-to-wolframite structural transition in $SrWO_4$ was studied for the first time by in situ XAS and XRD techniques. We confirmed the occurrence of the phase transition at about 11.7 GPa. The analysis of the W L_3-edge EXAFS spectra allowed us to follow in details a transformation of tungsten coordination polyhedron from regular tetrahedron in scheelite phase to distorted octahedron in wolframite phase.

Abstract

Lithium intercalation and deintercalation in amorphous MoO_3-electrodes was investigated *in situ* using grazing incidence reflection mode X-ray absorption spectroscopy. Small changes observed in the near edge X-ray absorption spectra indicated that the Mo^{6+} ions are reduced by the electrochemical lithiation, leading to a formal Mo^{5+} oxidation state. Angle dependent experiments reveal that the intercalation is not complete for the applied conditions, i.e. the Li-ions are not homogeneously distributed in the entire volume of the amorphous working electrode. In addition, a certain amount of Li remains in the Mo-oxide electrode after a complete intercalation/deintercalation cycle. The results suggest that Li ions are accumulated at the electrode/electrolyte interface during both intercalation and deintercalation.

1. Introduction

Lithium ion intercalation in metal oxides is one of the main objectives of recent battery research (see, e.g. [1–3]). Rechargeable lithium ion batteries are attractive for their use as lightweight, compact energy storage devices in applications ranging from portable electronics to vehicles. Up to now, the published work mainly dealt with Li intercalation in crystalline oxide materials. The intercalation processes are in many cases limited by the diffusion of the Li ions into the electrode material, and thus amorphous electrodes should have principal advantages: Due to their more open structures, the diffusion of the inserted Li ions into the electrode should be significantly facilitated. Up to now, however, only few publications dealing with Li intercalation in amorphous electrode materials have appeared in the literature [4, 5]. These studies are based on electrochemical techniques and thus no information about the structural changes occurring during the intercalation could be derived so far. In this context, grazing incidence X-ray absorption spectroscopy is a well suited technique to obtain structural and electronic information about the electrode surfaces during the intercalation and de-intercalation *in situ*. We have studied Li-intercalation in different transition metal oxides such as Ta_2O_5, Nb_2O_5, MoO_3 and WO_3 [6]. In the present paper, we will focus on grazing incidence X-ray absorption near edge structure investigations of the lithiation of amorphous MoO_3-thin films.

2. Experimental

The X-ray absorption experiments presented here were performed at the bending magnet station RÖMO II [7] at the DORIS III storage ring at HASYLAB (Hamburg, Germany). A double-crystal monochromator with two flat Si(311) crystals was used. Reflectivity EXAFS data were collected at room temperature in the vicinity of the Mo K-edge (20000 eV). The incident, monochromatic X-ray beam was collimated to a size of about 240 µm (vert.) and 10 mm (horiz.). Incident and reflected intensities were measured by argon and argon/krypton filled ionization chambers. A second slit system in front of the second ionization chamber suppresses the intensity of non specularly reflected X-rays and shields this detector from the direct beam. All components of the reflectometer, i.e. the sample position, the angle of the detector arm and the slit system can be adjusted by stepper motors. Simultaneously with each EXAFS scan, a Mo metal foil was measured in transmission between the second and a third ionization chamber in order to calibrate the energy scale of the monochromator. Reference spectra were obtained in transmission from a Mo metal foil and polycrystalline MoO_2 and MoO_3 powders.

Thin film working electrodes (thickness ≈60 nm, length 10 mm, width ≈35 mm) were prepared by reactive magnetron sputtering from a Mo-metal target in an O_2-containing atmosphere. Smooth float glass covered with a thin electrical gold contact of about 10–20 nm thickness was used as substrate. The electrode was glued into the PTFE body of the electrochemical cell, which was sealed by two thin Kapton foils which served as X-ray windows. High purity Cu-wires were used as reference and counter electrodes and all the electrochemical preparations were performed in an electrolyte containing 1 M $LiClO_4$ in propylene carbonate (PC). The whole assembly was mounted in a metal vessel which was continuously flooded with He-gas in order to maintain an inert atmosphere for the experiments. The metal vessel has two X-ray windows for the impinging and the reflected beam and a third window in the top flange to visualize the surface of the electrode with a small video camera even during the X-ray experiments. More details about the cell will be given elsewhere [8].

3. Results and Discussion

In Figure 1, a near edge reflection mode XANES spectrum of the untreated Mo-oxide working electrode measured *in situ* under open circuit conditions is presented for a glancing angle $\Theta = 0.07°$. The edge position at about 20015 eV as well as the intense pre-edge feature at 20005 eV which are typical for MoO_3 [9] are clearly resolved. For the further data processing, a linear pre-edge background $R_0(E)$ was fitted to the experimental data as shown in Fig. 1 (a) and extrapolated to the post edge region. The normalized difference $R_0(E) - R(E)$ was calculated subsequently in order to obtain a measure of the absorption. In Fig. 1(b), these data are compared to the absorption of polycrystalline MoO_3 measured in transmission. Obviously, both spectra are very similar with respect to the edge position, the pre-edge peak and its intensity.

It is well known that electronic excitations can be observed in near edge X-ray absorption spectra depending on the

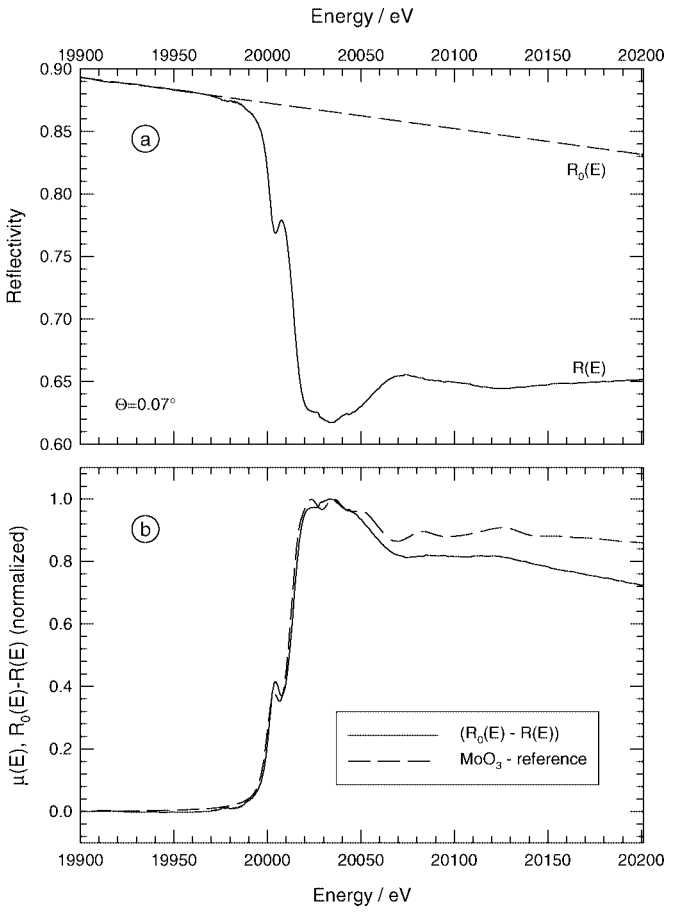

Fig. 1. (a) *In situ* reflection mode XANES spectrum of an amorphous MoO_3 working electrode ($\Theta = 0.07°$) in 1M $LiClO_4$ + propylene carbonate at the Mo K-edge. The pre-edge background $R_0(E)$ was subtracted from the spectrum in order to give approximate values for the absorption, which is compared to the normalized absorption of polycrystalline MoO_3 in (b).

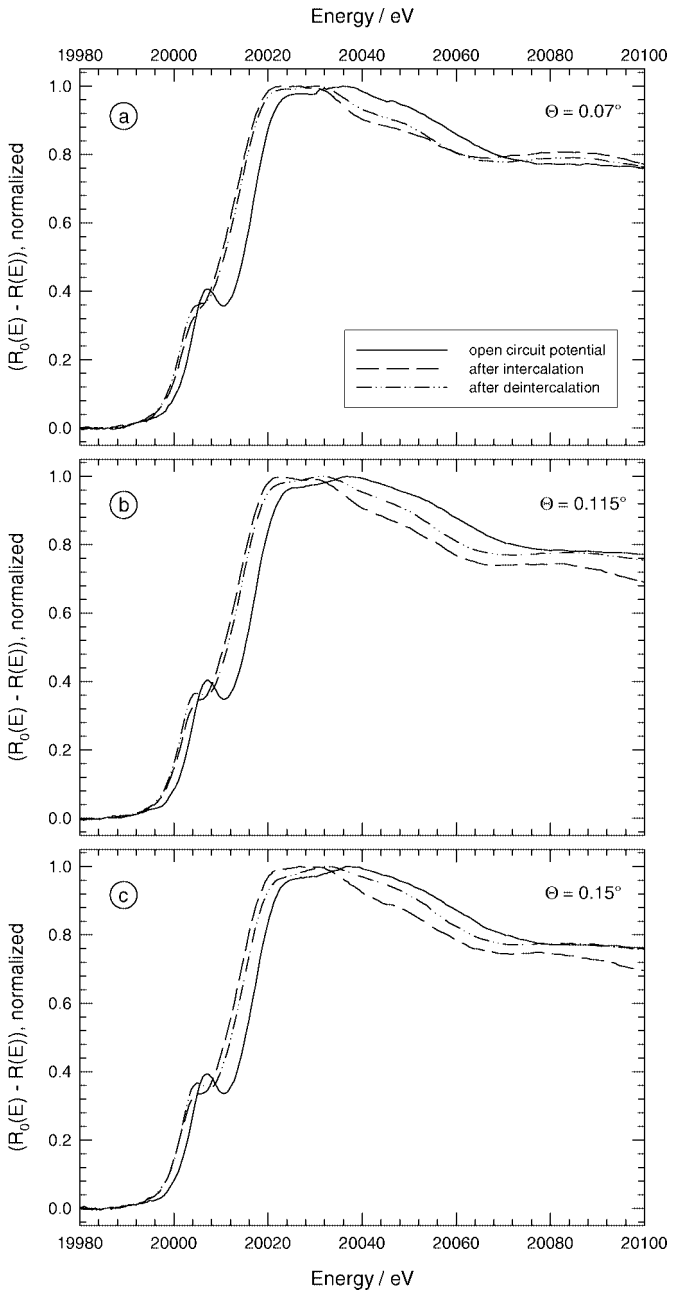

Fig. 2. Normalized difference spectra ($R_0(E) - R(E)$) obtained *in situ* from an amorphous MoO_3 electrode in 1 M $LiClO_4$ + propylene carbonate for different conditions and glancing angles.

local geometry [9, 10]. A pseudo-atomic model leads to the conclusion that the observed pre-edge structures may be due to $1s \rightarrow 4d$, $1s \rightarrow 5s$ and $1s \rightarrow 5p$ transitions [11]. The first of these transitions is partially allowed in a tetrahedral oxygen surrounding, but it is strictly forbidden in an octahedral oxygen geometry [11]. In crystalline MoO_3, the first Mo-O coordination consists of a complex structure with four short Mo-O distances between 1.67 and 1.94 Å with a structure close to a tetrahedron, and two additional long Mo-O distances of 2.25 and 2.33 Å which complete a deformed octahedral coordination [12]. This is the reason why a prepeak is observed for MoO_3, but not for MoO_2, which crystallizes in the rutile structure in which Mo is surrounded by 6 oxygen in a distorted Mo-O octahedra [9, 11, 12]. For an ideal tetrahedral Mo-O coordination, the intensity of the prepeak is even much more enhanced and a shift toward higher binding energy is observed, i.e. the position and the intensity of the prepeak are a sensitive tool for detailed studies of the Mo-O coordination [10, 13]. Thus, it can be concluded that the first coordination in the amorphous films does not consist of ideal tetrahedral structures but is more similar to that of polycrystalline MoO_3. Furthermore, also post edge features at about 20022–20050 eV are located at similar energies for both samples, whereas their intensity differs significantly. These differences may be related to the influence of the rather simple treatment of the reflectivity data and the influence of the anomalous dispersion – it has to be kept in mind that both the imaginary and the real part of the refractive index $n(E) = 1 - \delta(E) - \mathrm{i} * \beta(E)$ contribute to the reflectivity [14].

In Fig. 2, normalized difference spectra $R_0(E) - R(E)$ are shown for several grazing angles and different experimental conditions. Spectra of the sample at open circuit conditions prior to any electrochemical treatment are compared to those after the Li-intercalation at −1.54 V (vs. Cu) for 2 h and to spectra measured after the deintercalation at +0.9 V (vs. Cu) for 2 h. The most obvious change after the intercalation is the shift of the Mo K-edge position towards smaller values, i.e. the Mo^{6+} states of the amorphous MoO_3-electrode are electrochemically reduced. Furthermore, the position of the prepeak is also shifted to smaller energies and its intensity is reduced. After the electrochemical deintercalation, a slight shift of the edge towards higher energies is observed. However, the edge position of the untreated MoO_3 electrode is not reproduced, suggesting that a certain amount of Li remains within the Mo-oxide sample.

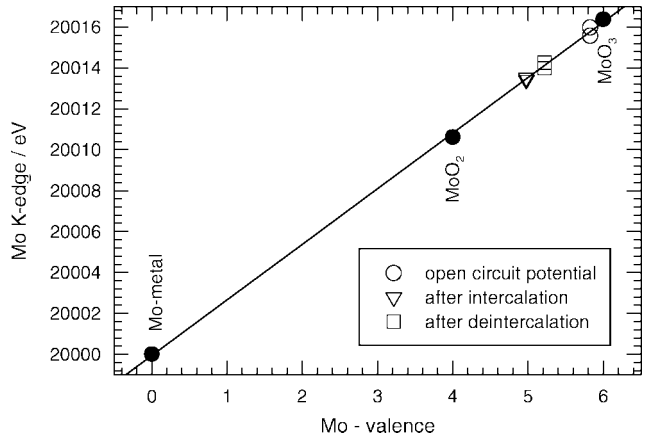

Fig. 3. Mo K-edge positions and chemical valences of polycrystalline Mo-reference compounds (Mo-metal, MoO_2, MoO_3). Indicated are the edge positions and the determined valences calculated from *in situ* measured grazing incidence Mo K-edge spectra prior to the lithiation (open circuit potential), after intercalation at -1.54 V and deintercalation at $+0.9$ V.

A closer inspection of the graphs also shows that the observed features change as a function of the grazing angle. For example, the shift between the XANES spectrum of the intercalated sample and that of the deintercalated sample is larger for a grazing angle $\Theta = 0.15^\circ$ compared to $\Theta = 0.07^\circ$ and $\Theta = 0.115^\circ$. This observation can easily be understood if a layered structure consisting of a thin Li_xMoO_3 layer on top of the bare MoO_3-oxide is assumed as follows. The penetration depth for the X-rays is about 3–4 nm for $\Theta = 0.07^\circ$, ca. 40 nm for 0.115° and ca. 300 nm for 0.15°. For the intercalated sample, the measured spectra at 0.07° and 0.115° are very similar, while small changes are observed for the spectrum at 0.15°. Therefore it can be assumed that the intercalated layer has a thickness of about 40–50 nm, and that the inner region of the MoO_3 layer towards the gold contact is not affected by the intercalation. Furthermore, after deintercalation, changes are visible between the spectrum recorded at 0.07° and 0.115°, thus the Mo-oxide electrode is not deintercalated completely. Still, Li ions are accumulated in a thin surface layer of about 10–20 nm thickness.

The edge positions and the chemical valences derived from the reflection mode near edge spectra measured at 0.07° are compared to those of Mo-oxide reference compounds in Fig. 3. First of all, the edge position of the electrode under open circuit conditions is almost identical to that of polycrystalline MoO_3 as already deduced from Fig. 1. Assuming a linear relation between the Mo K-edge position and the valence, we determined a value of about +5 for the Mo valence after the intercalation at -1.54 V for 2 h, and a slightly increased value of about +5.2 after the deintercalation at +0.9 V. Since the penetration depth is only some few nm for these experiments, the similarity of the derived edge positions clearly indicate that Li ions are accumulated at the electrode/electrolyte interface during the both the intercalation and the deintercalation. This agrees quantitatively with the edge positions determined for higher grazing angles, for which the edge positions are shifted to higher energies as can be seen in Fig. 2(b) and (c). This data interpretation is also consistent with results of extended X-ray absorption spectroscopy investigations [6, 8]. In the future, further time dependent grazing incidence XAFS experiments are very desirable in order to obtain a comprehensive picture of the structural changes of the amorphous Mo-oxide electrodes during the intercalation and deintercalation at different potentials. This also comprises a detailed analysis of EXAFS data.

Abstract

The local structures of semi-metal Sb have been studied by *in-situ* XAFS in the temperature range of 298 and 913 K. The radial structural functions of Sb atoms reveal that the local structure of the pre-molten Sb (893 K) is similar to that of crystalline Sb (298 K), except the increase of thermal disorder degree. With the temperature increasing up to 913 K, the position of the first peak located at 2.63 Å in the liquid Sb is kept the same as that in the pre-molten Sb, while the intensity of the first peak is strongly reduced by about 30% during the solid-liquid transition. This feature indicates that the melting results in a large increase of disorder degree of the liquid Sb, and that there exists covalent bonded clusters $(Sb)_n$ in the liquid Sb (913 K).

1. Introduction

It is well known that there are larger difficulties in performing a reliable structural study on the molten matters from the viewpoint of theory and experiment [1]. Up to date, no clear structural information in the liquid area has been shown for most of phase diagrams of metals, alloys and compounds [2]. However, it is essential to understand the structures and properties of the molten matter, since these high quality materials such as semiconductors, metals and alloys, are generally coming from their molten states. In the last two decades, Möller *et al*. [3] Bellissent -Funel *et al*. [4] Zhang *et al*. [5] and Mizuki *et al*. [6] have studied the structures of liquid metallic Sb, Ga, GaAs and GaSb with X-ray diffraction (XRD) and neutron diffraction (ND). More recently, because of the applications of the high brilliance synchrotron radiation light source, a high ratio of signal to noise could be obtained for the data of the liquid matters by X-ray absorption fine structure (XAFS). Filipponi *et al*. [7] and Wang *et al* [8] have investigated the local structures of liquid Rh, Pd and GaSb (or InSb) with *in situ* XAFS.

Sb is a unique element, which is a semi-metal at ambient condition with the density of 6.684 g/cm^3 and conductance of 1.11×10^3 $(\Omega{\cdot}\mathrm{cm})^{-1}$, and that is a liquid metal at above melting point (903 K) with the density of 6.53 g/cm^3 and conductance of 5.45×10^3 $(\Omega{\cdot}\mathrm{cm})^{-1}$ [9]. In early stage, Lamparter *et al*. [10] have studied the structure of the liquid Sb with neutron diffraction (ND) technique, and reported that the coordination number N of the first shell of liquid Sb is about 4.6. Whereas, Waseda *et al*. [11] have showed that the N of the first shell of liquid Sb is about 8.7 from their ND results. They have given a contradictory interpretation on the structure of the molten Sb. In order to understand the structure and property of the liquid Sb, it is necessary to make a reliable study for the structure of the liquid Sb.

In the present paper, *in situ* XAFS has been used to measure the local structures of the pre-molten and liquid element Sb.

2. Experimental

The fine powders of Sb (about 10 μm size), which were prepared from single crystals by grinding and sieving, were sufficiently mixed with LiF powder made from a single crystal. The mixed powder was pressed into tablets of diameter 10 mm and thickness 1 mm. The ratio of Sb to LiF powder was optimized as the X-ray absorption jump $\Delta\mu \approx 1$ at the Sb K-edge. The tablet was sealed in a vacuum quartz tube and sintered at 880 K for about 4 h, and then put into a quartz sample holder with two thin windows (of thickness 200 μm) sealed in the vacuum.

The measurements of Sb K-edge XAFS spectra were performed at the BL01B1 of SPring-8 of Japan Synchrotron Radiation Research Institute. The electron energy was about 8 GeV with a maximum current of 100 mA. The Si(311) double crystal was used as monochromator. For the higher harmonics rejection an Rh-coted quartz mirror was used. Data were collected in transmission mode using ion chambers filled with the mixed gas of Kr/Ar at the temperatures of 298, 893 and 913 K, respectively. XAFS data of Sb samples were analyzed by USTCXAFS3.0 [12] and UWXAFS3.0 codes [13].

3. Results and discussions

The Sb K-edge XAFS spectra for the antimony at the temperatures of 298, 893 and 913 K are shown in Fig. 1 (the melting point of crystalline Sb is 903 K). It can be observed clearly that the shape of the XAFS spectrum for the pre-molten Sb (893 K) is similar to that of crystalline Sb (298 K). In the energy range from 50 to 400 eV above the K-edge for crystalline Sb (298 K), there are six XAFS oscillation peaks located at 30550, 30586, 30635,

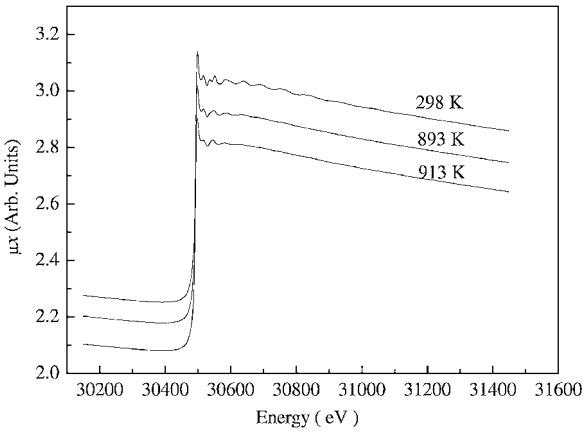

Fig. 1. The Sb K-edge XAFS spectra for the Sb at the temperatures of 298, 893 and 913 K.

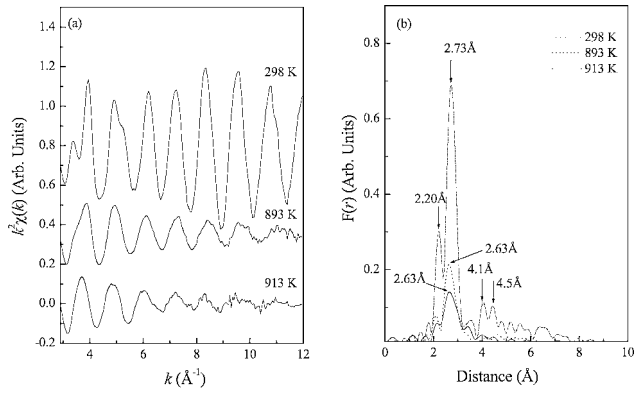

Fig. 2. (a) The Sb K-edge XAFS functions $k^2\chi(k)$, (b) the radial structural functions for the Sb at the temperatures of 298, 893 and 913 K.

30688, 30759 and 30835 eV, respectively. As the temperature increases to 893 K, the oscillation amplitudes of the pre-molten Sb (893 K) drop markedly for these peaks from the fourth to the sixth. This feature shows that the local structure of the pre-molten Sb (893 K) is mostly identical with that of Sb (298 K), except a large increase in the disorder degree. When the temperature rises to 913 K, only three peaks located at 30546, 30581 and 30625 eV can be observed evidently in the XAFS spectrum of the liquid Sb (913 K) in the energy range from 50 eV to 400 eV above the K-edge. The positions of these oscillation peaks shift to the lower energy side by about $4 \sim 10$ eV and the amplitudes drop obviously as compared with those of Sb (298 K). This result indicates that the coordination environment and the disorder degree around Sb atoms in the liquid Sb (913 K) change largely in the process of solid-liquid transition.

Fig. 2 (a) and (b) demonstrates the Sb K-edge XAFS functions $k^2\chi(k)$ and the radial structural functions (RSF) for the Sb samples at the temperatures of 298, 893 and 913 K. Seen from Fig. 2 (a), the magnitude of the oscillations of the liquid Sb (913 K) strongly decreases in the high k range, compared with that of the pre-molten Sb (893 K). It means that the melting can increase the disorder degree around Sb atoms greatly. Furthermore, Fig. 2 (b) shows that there are three peaks located at 2.73, 4.1 and 4.5 Å in the RSF curve for the Sb (298 K). The main peak at 2.73 Å (un-calibrated) is corresponding to the first coordination shell of Sb in which the bond length R_1 and coordination number N_1 of the first sub-shell are 2.90 Å and 3, and that the R_2 and N_2 of the second sub-shell are 3.36 Å and 3. The shoulder peak at 2.20 Å originates from the non-linearity of the phase shift function of back-scattering atom Sb. The two peaks located at 4.1 and 4.5 Å are contributed to the XAFS signals of the Sb-Sb second shell and the Sb-Sb-Sb multiple scattering paths. Compared with the RSF of the Sb (298 K), the intensity of main peak for the pre-molten Sb (893 K) drops abruptly by about 70%, and its position moves by about 0.1 Å toward low-R direction. Moreover, the peaks at 4.1 and 4.5 Å corresponding to the high coordination shells almost disappear for the pre-molten Sb (893 K). With the temperature further increasing to 913 K (exceeding the melting point of Sb), the position of the main peak of the liquid Sb corresponding to the first coordination shell is kept the same as that of the pre-molten Sb (893 K), while its intensity decreases by about 30% of that of the pre-molten Sb (893 K).

In the previous studies of liquid matters [14], Stern *et al.* [15], Wei *et al.* [16] as well as Di Cicco *et al.* [17] have investigated the local structures of Pb and Ga with XAFS. They have found that the positions of the first RSF peak for both Pb and Ga atoms move by about $0.1 \sim 0.2$ Å toward the low-R direction during the process of solid-liquid transition. Hoshino *et al.* [18] have reported the local structures of As_2Se_3 covalent compound in the solid and liquid states. Their XAFS results have shown that the positions of the first RSF peak of both As and Se atoms always remain at about 2.5 Å in the liquid or solid state of As_2Se_3. Tamure *et al.* [19] have studied the local structures of solid and liquid Te with XAFS. Their results indicate that the position of the first peak of the solid Te shifts by about 0.1 Å toward the low-R direction when the temperature increases from 298 to 573 K, but the melting does not change the RSF peak position of Te. Summarizing above results, one can find that in temperature range of the solid state, the change of RSF curves of the Sb with temperature is similar to those of metallic elements (i.e., Pb, Ga and Te), but is different from those of As and Se in the A_2Se_3 covalent compound. However, in the process of solid-liquid transition, the change of RSF curves of the Sb is similar to those of element Te and covalent compound As_2Se_3. In addition, Menelle *et al.* [20] and Yamagcuchi *et al.* [21] have investigated the structure of the liquid Te using the neutron diffraction technique. Their results imply that there are fragmented-chains $(Te)_n$ connected by the covalent bonds in the liquid Te. Hence, the local structural change of Sb with the temperatures is in good agreement with that of Te in the solid and liquid state. Similarly, we consider that there may exist $(Sb)_n$ clusters combined by the covalent bonds in the liquid Sb (913 K). The quantitative structural studies of the pre-molten and liquid Sb by the reverse Monte Carlo calculation will be published elsewhere.

Acknowledgments

We would like to thank SPring-8 for giving us the beam time for XAFS measurement. This work was supported by the Chinese National Science Foundation Committee (Grant No.10174068) and the development of high-level university of University of Science and Technology of China.

Abstract

The nature of passive film grown on the bulk surface of Fe-20Cr alloy in a pH 8.4 boric-borate buffer was investigated with *in situ* synchrotron X-ray absorption spectroscopy. The main electrochemical test method was potentiostatic polarization and various potentials were applied from −1.0 V to 0.6 V vs. saturated calomel electrode (SCE). X-ray absorption data from the passive film formed in the boric-borate buffer were collected from an *in situ* reflection X-ray absorption spectroscopic experiment in a grazing-incident geometry that is suitable for investigating the nanometer-thick passive film. It was observed in the Fe K-edge XANES (X-ray absorption near-edge structure) region that the Fe absorption edge moved from the absorption edge of metal Fe to that of Fe oxide as the applied potential increased. It was observed from an analysis of the Radial Distribution Function (RDF) from Fe K-edge EXAFS (Extended X-ray Absorption Fine Structure) data that the Fe-Fe bond intensity of the first shell decreased and Fe-O bond intensity increased as the applied potential increased. The RDF of the Fe oxide is consistent with γ-Fe_2O_3.

1. Introduction

Despite many investigations, the nature and stability of the passive film on Fe alloy in borate buffer solution is still poorly understood. Much of the research performed has been on the iron/borate buffer system. The system was chosen due to the high efficiency of film formation and the thin, protective passive film that is formed. But, one of the major problems in investigating the passive film is that the separation of the behavior of passive film from that of the underlying metal or alloy is not a straightforward task. In order to obtain information purely on the passive film, studies on model systems such as synthetic bulk or thin film oxides are necessary. Sugimoto *et al.* studied the chemical stability of synthetic (Fe, Ni, Cr)-oxide films prepared by metal-organic chemical vapor deposition in a strong HCl solution and showed that the corrosion rate is mainly determined by the chromium content of the mixed oxides [1]. However, the reaction mechanism of oxide in a certain solution can be explained with using synthetic oxide but the experiment using synthetic oxide cannot give an account of the oxide structure formed on the bulk metal surface. Another problem is that the passive film formed in an aqueous solution could be analyzed in an *in-vacuo* condition by XPS and AES so far. The passive film formed on the surface of metal in a solution is likely to vary its physical and chemical property with time out of the solution. Thus, we have not been able to define the nature of passive film in a solution exactly. Bardwell *et al.* found that Cr(IV) ion in passive film on Fe-26Cr was completely absent several hours after air exposure [2]. Recently, in order to overcome the problem, an attempt on *in-situ* passive film in solution were made with synchrotron radiation [3–7].

In situ XANES studies by Nagayama and Cohen provided considerable insight into the nature of the passive film on iron [8]. They suggested that the passive film is a multi-layer structure, consisting of an inner layer of Fe_3O_4 and an outer layer of γ-Fe_2O_3, which is cation deficient at the surface. Davenport *et al.* reported that the passive film on iron at 0.4 V mercurous sulfate electrode (MSE) in a pH 8.4 borate buffer resembled a ferric oxide such as γ-Fe_2O_3 [3]. A recent *in situ* X-ray diffraction measurement of the passive film on iron in a borate buffer confirms the spinnel structure although the oxide differs from the standard bulk γ-Fe_2O_3 and Fe_3O_4 [9]. But most *in situ* corrosion studies have been performed with a sputtered thin film metal or oxide, so the properties of passive films on these samples may be different from the passive film formed on the bulk metal surface. The main purpose of this study is to investigate the passive film grown on the bulk metal surface by *in situ* synchrotron X-ray absorption spectroscopy. In this study, XANES and EXAFS data are collected from passive film on Fe-Cr alloy at a specific potential in the pH 8.4 boric-borate buffer solution.

2. Experimental Procedure

Synchrotron X-ray absorption data were collected at 8C1 XRD/XAS beamline at the Pohang Light Source (PLS). For the analysis of thin passive film on the alloy surface, the reflection XAS method in grazing-incident geometry was used. In reflection XAS (X-ray Absorption Spectroscopy) measurements, the angle of incident X-ray beam was adjusted to be lower than the critical angle of the alloy for inducing a total reflection of X-rays, and a Si(Li) scintillation detector counted the reflected X-rays. Before the *in situ* XAS experiment, the critical angle for the total reflection was determined to be 0.375° from X-ray reflectivity measurement of the alloy. The incident angle of X-ray beam was fixed at 0.3° during the *in situ* XAS measurement. The focused size of X-ray beam used for the XAS experiment was 3 mm(H) 0.5 mm(V).

The specimen having a dimension of 1.8 mm(w) × 10 mm(l) × 4 mm(t) was prepared from Fe-20Cr alloy. The bulk specimen sat at the center of a chemical cell for the *in situ* XAS experiment, held by an epoxy regin that also provided an electrical connection (Figure 1). Ports in the cell allowed insertion of a platinum wire counter electrode and saturated calomel electrode (SCE) reference. A polymide film was used as an X-ray window. The test solution was a pH 8.4 boric-borate buffer solution. The passive film was grown artificially by applying potentials of 0.0, 0.2, 0.4, 0.6 V for a passivation time of 120 min. The EXAFS data were collected after the passivation time. In order to minimize X-ray absorption through the test solution, the specimen width was reduced to 1.8 mm and the real path length of X-rays in the cell was 2.0 mm.

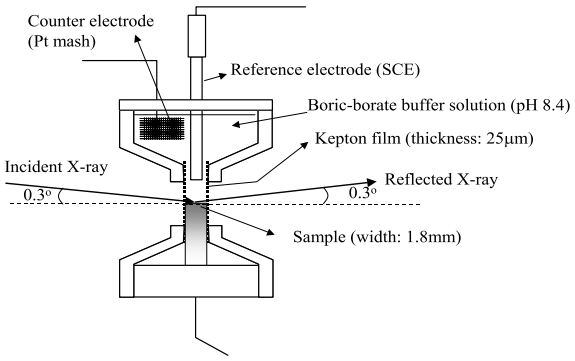

Fig. 1. Schematic diagram of *in situ* electro-chemical cell.

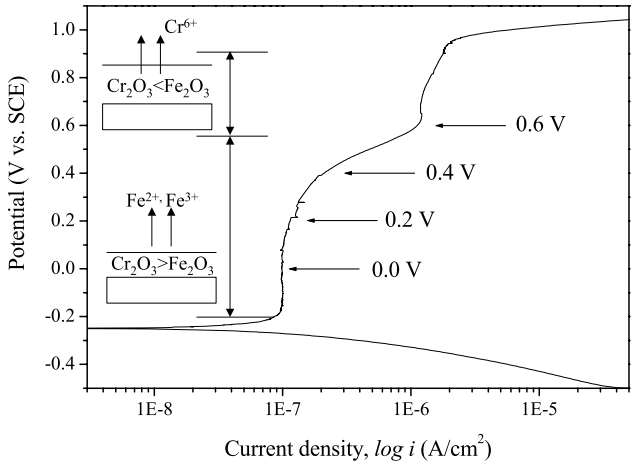

Fig. 2. Potentiodynamic curve of Fe-20Cr in pH 8.4 boric-borate buffer solution.

3. Results and Discussion

For the determination of applied potential, a potentiodynamic test was performed. Figure 2 shows a potentiodynamic curve of Fe-20Cr alloy in pH 8.4 borate buffer solution at room temperature. There are several reports explaining the passive film structures in the distinct potential regions [10, 11]. For low passive potentials below 0.6 V, the film consists of a mixture of Fe_2O_3 and Cr_2O_3 but in this potential range Cr_2O_3 is predominantly formed on the steel surface. Above a potential of 0.6 V, Cr_2O_3 is dissolved out in solution as Cr(VI) ion and Fe_2O_3 is the dominant element of the passive film.

Figure 3 shows the variation of normalized Fe K-edge XANES and EXAFS spectra as a function of applied potential. The XANES curves below the potential of 0.6 V are nearly similar to the pure Fe, but a shift of absorption edge is clearly observed at the potential of 0.6 V. Generally, the edge energy of Fe is shifted to higher values as the average valence of iron increases, thus, the edge position is a clear indication of the valence number. So, the edge shift observed from Figure 3 indicates that Fe is correlated with the metal elements in passive film below the potential of 0.6 V. In this region, although the surface of an alloy can be covered with a Fe-Cr complex oxide, Cr oxide may be more stable than Fe oxide because Fe oxide can be dissolved out as Fe^{2+} and Fe^{3+}. In this case, Fe oxide can not be observed dominantly in the XAFS measurement. However, Cr oxide can be dissolved out as Cr^{6+} above the potential of 0.6 V and the ratio of Fe oxide to Cr oxide increases with the passivation time [12]. From this time, Fe oxide can be measured in XAFS.

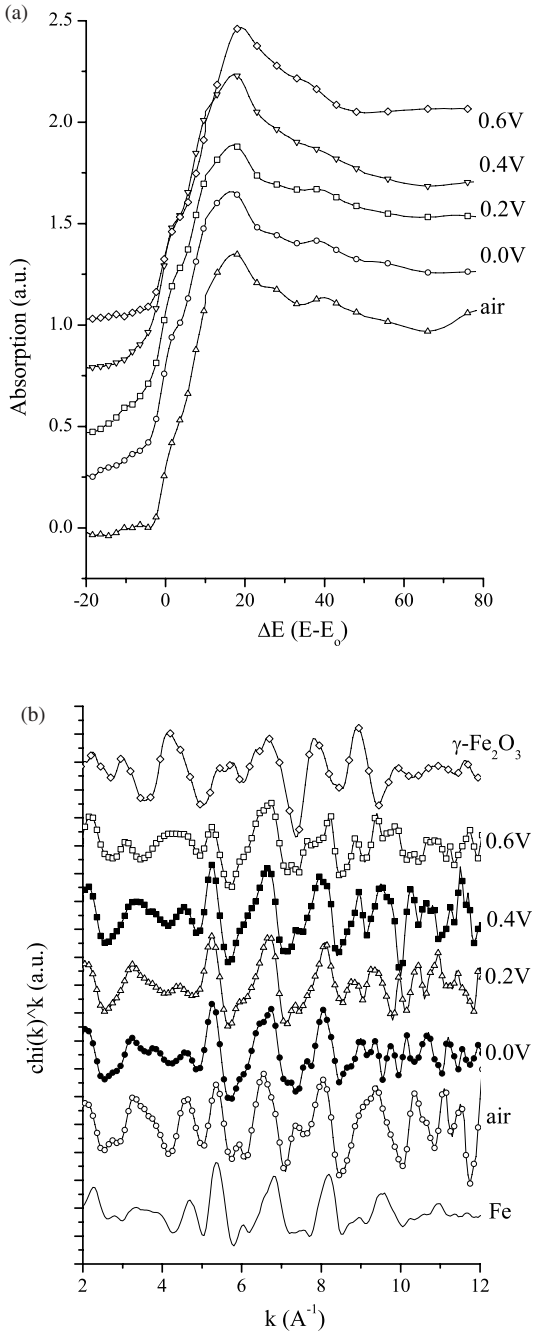

Fig. 3. XANES and EXAFS spectrum from Fe-20Cr alloy measured at Fe K-edge of 7112 eV as a function of applied potential in pH 8.4 buffer solution. (a) XANES spectra, (b) EXAFS spectra.

Figure 4 (a) shows the magnitude of Fourier transformations of the XAFS data at potentials of 0.2 V and 0.6 V, and those of pure Fe and various oxides. The RDF was calculated from the measured XAFS data by using UWXAFS program. The XAFS data was not good enough to obtain chemical information of Fe atom with simulation. So the nature of passive film was identified in comparison with Radial Distribution Functions (RDF) of pure Fe and various Fe oxides. The first shell of pure Fe and γ-Fe_2O_3 was calculated from data measured from reference sample as shown in Figure 4 (b). At an applied potential of 0.2 V, the RDF of the first shell is analogous to that of pure Fe. At this potential, Cr oxide may be more stable than Fe oxide. The penetration depth of X-rays in the passive layer at the incident angle of 0.3° was calculated to be $\sim$ 40 Å [13]. Generally, the thickness of the passive film formed on stainless steel has a range from 10 to 40 Å. In addition, the

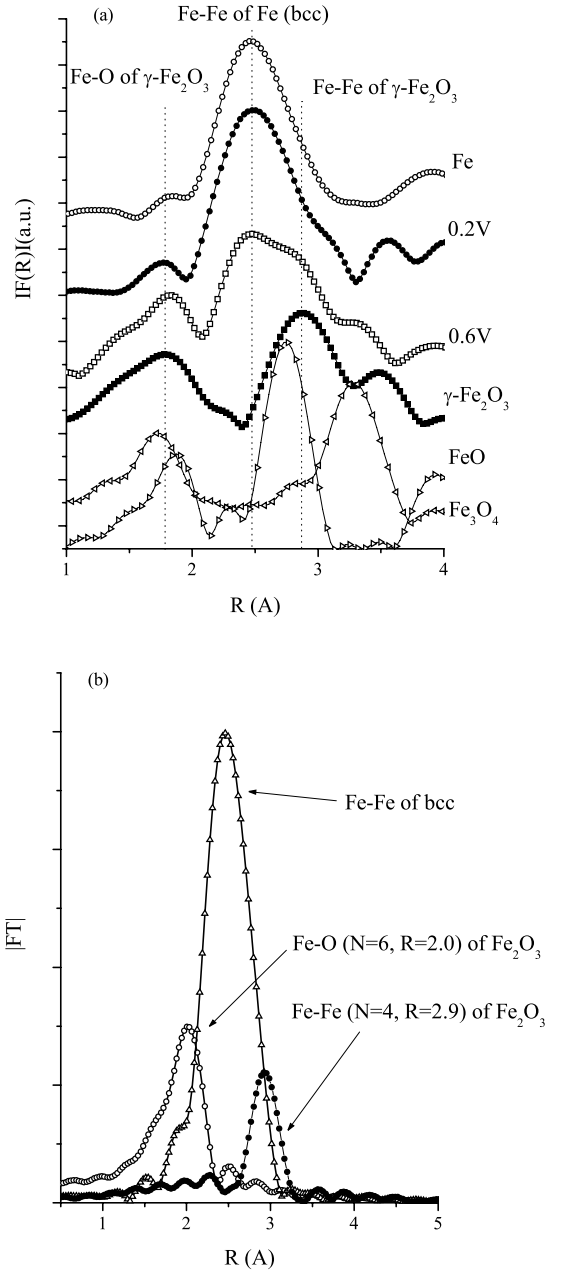

Fig. 4. (a) Magnitude of Fourier transformation of EXAFS data from applied potential of 0.2 V and 0.6 V, and those of pure Fe and other Fe-oxide sample. All spectra have been transformed over $k = 3.0\,\text{Å}^{-1}$ to $k = 11\,\text{Å}^{-1}$ using a hannig window function times k. (b) First shell of Fe and γ-Fe_2O_3 calculated from theoretical data.

thickness of passive film composed of Cr oxide has a range from 5 to 30 Å. Thus, in this potential range, the substrate effect cannot be completely ruled out even with the grazing-incident reflection method. However, as the potential increases, the intensity of Fe-Fe bond decreases and the Fe-O and Fe-Fe single scattering bond of γ-Fe_2O_3 appear clearly at a potential of 0.6 V. The thickness of Cr oxide in passive film may have a limitation by dissolution of Cr oxide in the high potential range. The potentiodynamic curve also shows an increase of current density from 0.6 V, presumably due to the dissolution of Cr oxide as CrO_4^{2-}. Due to the dissolution of Cr_2O_3 by oxidation, the passive film becomes porous and the ratio of Fe oxide to Cr oxide may increase. From the RDF analysis, the valid Fe oxide seems to be γ-Fe_2O_3.

4. Conclusion

We have studied the passive film grown on bulk metal surface as a function of applied potential by *in situ* reflection XAS method for Fe K-edge. In boric-borate buffer solution, Fe oxide in passive film seems to be unstable at potentials below 0.6 V. The RDF analysis indicates that Fe appears to be correlated with metallic element in this region. However, at a potential of 0.6 V, it was observed that the absorption edge of Fe moved from metal Fe absorption edge to Fe oxide absorption edge. It seems that the Fe oxide formed on Fe-20Cr alloy at the potential 0.6 V is γ-Fe_2O_3.

Abstract

X-ray absorption fine structure measurements at zinc K-edge in the corrosion product of super plastic processed zinc doped magnesium alloy has been performed to clarify the corrosion mechanism. The XANES spectra and the radial distribution functions obtained from Fourier transformed EXAFS oscillations of the corrosion product of zinc doped magnesium alloy and reference compounds of ZnO, zinc carbonate ($2ZnCO_3{\cdot}Zn(OH)_2{\cdot}H_2O$), $ZnCl_2$ and zinc foil suggest that the local structure of Zn compound in corrosion product is close to that of zinc carbonate.

1. Introduction

Magnesium (Mg) alloy is an advanced material for applications of light weight metal. Recently, it is adopted in electric appliances, such as TV case and Compact Disks, and applications of railway vehicles and automobile are future demands [1]. It is difficult to process parts using Mg alloy under cold working, because these alloy systems with a hexagonal close-packed structure hardly slip. So new process method is important for Mg alloy application.

One recent advantage of processing of Mg alloy, super plastic behavior which shows high ductility, more than 300%, has been applied to light weight metal such as aluminum and titanium alloy. The super plastic behavior has also occurred in high strength zinc (Zn) doped Mg alloy (ZK) for structure material, and middle strength aluminum (Al) doped Mg alloy (AZ) for electric appliances. Super plastic processed Mg alloy is given attention due to its toughness and lightness. Zn doped Mg alloy is studied as a good candidate of super plastic processed Mg alloy. Super plasticity is one of the metallurgical reactions such as creep. It can be possible to elongate so long under specific temperature, elongated velocity [2]. In order to apply the super plastic property in metallic materials processing, microstructural treatment such as the control of the grain size is important. The super plastic behavior in Mg alloy would be applied for the processing of the parts [3–5].

Mg alloy is very sensitive to corrosion, because Mg has the property of the lowest galvanic voltage in metallic material and a sensitive surface [6]. Therefore, the corrosion mechanism has been investigated and factor analysis for the corrosion has been done. It has been reported that [7] the effect of precipitation on the grain, ratio of Fe/Mn contents, surface active layer after processing is large. With these reports, Zn shows advantages for corrosion in Mg alloy.

Among other alloying elements in Mg alloy, Zn is generally believed not to have a significant effect on the corrosion behavior of Mg alloys [8]. However, the super plastic processed ZK alloy has one severe problem corroded more easily than conventional processed alloy. ZK alloy is a good candidate for the high strength one. Clarifying the corrosion mechanism is an urgent subject because the corrosion causes trouble to put super plastic processed ZK alloy to practical use.

We have done corrosion tests in water of super plastic processed AZ and ZK alloys. We observed the conditions of corrosion by Scanning Electron Microscopy (SEM). In Zn doped Mg alloy, it was found that corrosion pits occurred and corroded easily by the corrosion test. On the other hand, as for Al doped Mg alloy that Zn is very poor, it is confirmed that no corrosion pits occurred though the material is corroded. The existence of Zn compound contained in the corrosion product is confirmed by Energy Dispersion Spectrum analysis (EDS) measurement.

It is very important in the realization of super plastic processed Mg alloy to clear the corrosion mechanism investigating the influence which a small amount of element contained in Mg alloy exerts on the corrosion. The main ingredient of the corrosion product in the Mg and Mg-Al alloy is MgO which shows amorphous structure [9]. The corrosion product of ZK alloy also show amorphous like structure obtained by X-ray diffraction. In order to clarify the corrosion process of super plastic processed Zn doped Mg alloy, we have investigated the local structure of Zn compound in the corrosion product using X-ray absorption measurements, paying attention to Zn which exists in the alloy in a small quantity.

2. Experimental

2.1. *Specimen*

Two types of Mg alloys, super plastic processed Al doped Mg alloy (AZ) and Zn doped one (ZK), were prepared in corrosion test. The specimens are screw shaped and were processed by rolling with super plastic works. The chemical compositions of specimens are listed in Table I. On processing screw, solid solution treatments were done in 573 K for 10 hours to solve the precipitation into grains for Mg alloy matrix. After that, screw processing was performed by a rolling machine under 646 K that is the condition of super plastic behavior. The grain size is larger than 10 μm before the rolling process, while it becomes less than 1 μm after the process; the numbers were obtained by optical microscope observation.

*e-mail: honma@spring8.or.jp

Table I. *Chemical compositions of used specimens (unit : Mass%).*

	Al	Zn	Zr	Mn	Fe	Si	Cu	Ni	Ca	Mg
AZ31	3.5	0.2	—	0.2	0.003	0.08	0.02	0.003	0.025	Bal.
ZK61	—	4.8	0.45	—	—	—	0.02	0.003	—	Bal.

2.2. *Corrosion tests*

The specimens were put into water and corrosion was accelerated during 5 months with constant temperature of 298 K and constant humidity of 60%.

2.3. *Evaluation of corrosion*

Scanning Electron Microscope (SEM) was performed to investigate the surface microstructure of specimens after the corrosion test and Energy Dispersion Spectrum analysis (EDS) was done to analyze the chemical composition of the corrosion product. Accelerated voltages in SEM observation were 15 kV. The point focus analyses for corrosion products by EDS were estimated.

X-ray absorption fine structure (XAFS) experiments of the corrosion product were carried out on the beam lines BL38B1 and BL19B2 at SPring-8 to investigate the local structure of Zn compound. A Pt mirror was inserted to eliminate the harmonics. Zn K-edge XAFS were measured in the transmission mode at room temperature with a Si(111) monochromator. As reference samples, ZnO, $ZnCl_2$, Zinc carbonate ($2ZnCO_3{\cdot}3Zn(OH)_2{\cdot}H_2O$) were also measured because it could be considered that Zn compound in the corrosion product is oxide, chloride and/or carbonate.

3. Results and discussion

Figure 1 shows SEM micrographs of the cross section view of screws (sample AZ and ZK) which are made of AZ and ZK alloys with super plastic works. The corrosion was shown in both samples, and then the corrosion damage in ZK sample was more serious than that of AZ in this corrosion test. It was found that the charge up image in SEM photographs in the surface of AZ sample and the corrosion area of ZK. In general, it has not observed the charge up image in SEM for electrical conducted samples. Following these results, the corrosion products were aggregated in the area of the charge up image of AZ and ZK samples. From EDS spectra of AZ and ZK samples, Mg, Al, Cu and Si was found in the corrosion product of AZ sample and Mg, Zn and Si in that of ZK. It was reported that Zn hardly contributes to corrosion mechanism in Mg alloy by protection of anode reaction in galvanic corrosion [7].

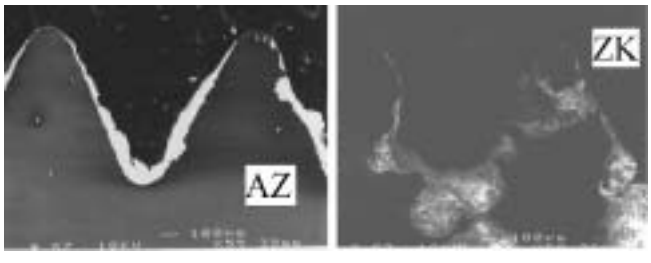

Fig. 1. SEM micrographs show surface of specimens of AZ and ZK alloys (cross section view).

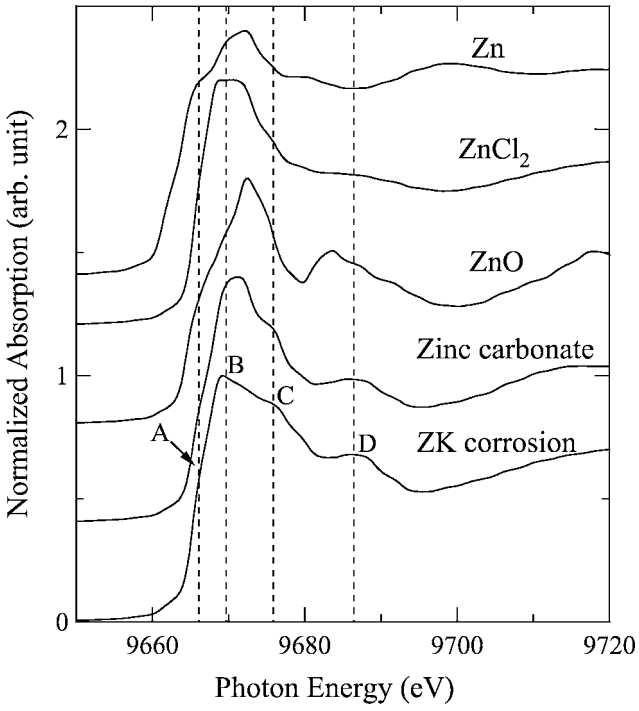

Fig. 2. Zn K-edge XANES spectra of the corrosion product of ZK sample and references.

However, the component of Zn in the corrosion product of super plastic processed ZK sample was found in this case. Therefore, we have focused on Zn compound contained in the corrosion product of ZK sample and performed XAFS analyses that is useful for investigating the amorphous materials as this corrosion product.

Figure 2 shows Zn K-edge XANES spectra of the corrosion product of ZK alloy and reference compounds of ZnO, $ZnCl_2$, Zinc carbonate and Zn foil. The Zn K absorption edge energy E_0 of these samples, except for Zn foil, is about 9665 eV. This indicates that the valences of those samples are almost +2. The spectrum of the corrosion product shows a slight shoulder A around 9666 eV, a peak B (white line) around 9670 eV, a shoulder C around 9676 eV and a small peak D around 9687 eV. In ZnO, a sharp peak (white line) is shown in the position higher than 3 eV from the peak B of the corrosion product and a small peak lower than 3 eV from peak D. The spectrum of $ZnCl_2$ shows a plateau (white line) around peak B and a broad peak around peak D. The spectrum of Zinc carbonate is similar to that of the corrosion product, except for the structure of the white line.

Figure 3 shows the Fourier transforms (radial structure function (RSF)) without corrections for errors in the phase shift of k^3-weighted Zn K-edge EXAFS of the corrosion product of ZK sample and reference compounds of ZnO, $ZnCl_2$ and Zinc carbonate. The profile of the corrosion product of ZK alloy shows a peak at ~0.15 nm, which is due to Zn-O bond. The distance of the Zn-O bond in ZnO is a little longer than that in the corrosion product and a clear peak structure shows around 0.3 nm of the Zn-Zn bond. In $ZnCl_2$, there is only a peak around 0.18 nm, which is due to Zn-Cl bond. The profile of FT in zinc carbonate has a peak around 0.15 nm and a small peak around 0.28 nm. The profile of the corrosion product is very similar to that of zinc carbonate.

The profiles of XANES and FT of the corrosion product of ZK sample and references indicate that the local structure of Zn in the corrosion product of ZK alloy is very similar to that of

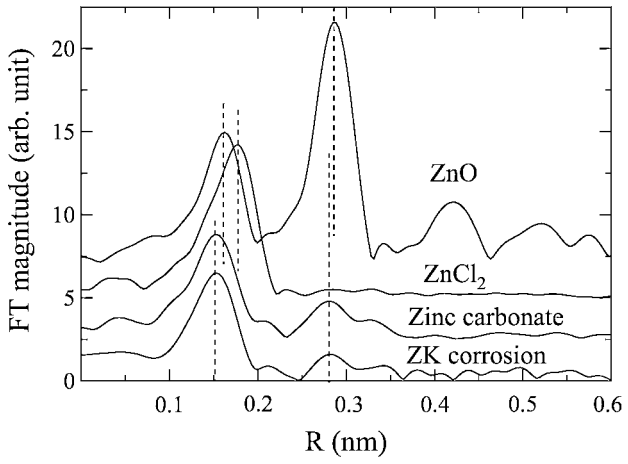

Fig. 3. Fourier transformed $k^3\chi$(K) at Zn K-edge of the corrosion product of ZK sample and references.

zinc carbonate. These results obtained by XAFS measurements suggest that Zn in the super plastic processed ZK alloy is corroded by carbonic acid in the water.

4. Conclusions

Corrosion tests have been done in super plastic processed Al doped and Zn doped Mg alloys (AZ and ZK). The corrosion damage in ZK sample was more serious than that of AZ. The point focus analysis by EDS for corrosion products of ZK alloy indicates that Zn is contained in the corrosion product. These results suggest that Zn in the super plastic processed ZK alloy influences the corrosion.

In order to clarify the corrosion process of super plastic processed Zn doped Mg alloy, we have investigated the local structure of Zn compound in the corrosion product using XAFS measurements, paying attention to Zn which exists in the alloy in a small quantity. The XANES spectra and RSF obtained from Fourier transformed EXAFS oscillations of the corrosion product of ZK sample and reference compounds of ZnO, zinc carbonate ($2ZnCO_3{\cdot}3Zn(OH)_2{\cdot}H_2O$), $ZnCl_2$ and Zn foil suggest that the local structure of Zn compound in corrosion product of super plastic processed ZK alloy is close to that of zinc carbonate.

From the above results, it is important to consider the role of Zn in corrosion mechanism on super plastic processed Zn doped Mg alloy. The XAFS analyses will provide the important information to investigate the corrosion products in microscopic terms.

Acknowledgments

The XAFS experiments were performed at SPring-8 with the approval of Japan Synchrotron Radiation Research Institute (JASRI) (Proposal No. 2002B0614-NI-np, 2002A0409-NX-np). We would like to thank the JASRI beamline staff Dr. Tanida for support and help.

Abstract

X-ray K-absorption studies have been carried out on Al-Mn system comprising $Al_{90}Mn_{10}$, $Al_{88}Mn_{12}$, $Al_{86}Mn_{14}$, $Al_{84}Mn_{16}$, $Al_{82}Mn_{18}$ and $Al_{81}Mn_{19}$ samples. These samples have been characterized by X-ray diffraction (XRD) studies which support the formation of icosahedral phase. The X-ray K-absorption discontinuities in case of the Al-Mn system have been found to be shifted towards the high energy side with respect to the K-absorption edge of pure metal Mn, which indicates the behaviour of manganese atom as the cation. The X-ray absorption chemical shifts suggest a covalent bonding. The studies also indicate that with the increase in Mn concentration chemical shifts also increase.

We have attempted to correlate the values of the electron to atom ratio (e/a) with the chemical shifts (ΔE). The nature of relationship between e/a and ΔE is quite similar to that between ΔE and Mn concentration. Further, we have estimated the density of states at the Fermi level $D(E_F)$ for these samples and plotted them against chemical shift values. Extrapolation from this graph between $D(E_F)$ and ΔE indicates a $D(E_F)$ value for Al metal which is quite near to the actual value for Al metal. These studies establish the existence of a pseudo gap in the case of presently investigated Al-Mn samples. The present studies also support our assumption of assigning the chemical shift values to the Fermi level in the case of Al-Mn system under present investigation.

1. Introduction

Various aspects of the Al-Mn system have been studied by many workers [1–8], even then the Al-Mn system still remains of interest in the scientific community. In the present paper, we have reported the X-ray spectroscopic studies on Al-Mn system. The data on the chemical shifts (ΔE) of the Al-Mn quasicrystalline system have been reported in order to know the nature of bonding in such materials. The samples studied are:

(*i*) $Al_{90}Mn_{10}$, (*ii*) $Al_{88}Mn_{12}$, (*iii*) $Al_{86}Mn_{14}$,
(*iv*) $Al_{84}Mn_{16}$, (*v*) $Al_{82}Mn_{18}$ and (*vi*) $Al_{81}Mn_{19}$.

2. Experimental

The Al-Mn samples have been prepared by standard method. XRD results support the formation of icosahedral phase [9–11].

X-ray absorption spectra (K-absorption discontinuity of Mn) have been recorded using a Cauchois type bent crystal spectrograph of 0.4 m diameter. The analyzing crystal used in the present work was mica with (100) reflecting plane. The detailed experimental procedure for the X-ray spectroscopic investigations has been described in an earlier publication [12].

3. Results and discussion

The X-ray diffraction (XRD) studies carried out in the present investigations reveal that there is a mixing of fcc Al, and icosahedral phases. The XRD results are in conformity with those of others [13–16]. The grain size of the samples was found to be of the order of 90 to 400 Å.

Table I. *Data for X-ray K-absorption spectra of Mn in Al-Mn system.*

Sample	E_K (eV)	Chemical Shift (ΔE_K) (eV)	Edge-width ($E_A - E_K$) (eV)	e/a	$D(E_F)$
$Al_{90}Mn_{10}$	6546.5	9.9	6.9	2.2	3.10×10^{45}
$Al_{88}Mn_{12}$	6546.8	10.2	9.7	2.4	3.58×10^{45}
$Al_{86}Mn_{14}$	6547.1	10.5	12.4	2.5	3.83×10^{45}
$Al_{84}Mn_{16}$	6547.6	11.0	13.0	2.6	3.98×10^{45}
$Al_{82}Mn_{18}$	6547.9	11.3	14.1	2.7	4.27×10^{45}
$Al_{81}Mn_{19}$	6548.3	11.7	15.5	2.8	4.35×10^{45}
Mn Metal	6536.6	—	—	—	—

The values of energy of K-absorption discontinuities of manganese in Al-Mn system have been reported in Table I. The values of the edge-widths are also included in the same table.

From Table I, it can be seen that the K-absorption discontinuities in case of the Al-Mn system have been found to be shifted towards the high energy side with respect to that of pure Mn metal. This shift of the absorption discontinuities is referred to as the chemical shift which indicates the behaviour of manganese atom as the cation. It is well known that the chemical shifts of the X-ray absorption discontinuity in compounds are governed by the nature of chemical bonding [17–18]. The general observation regarding the chemical shifts is that whenever the absorbing atom is a cation, X-ray absorption discontinuity shifts towards the high energy side and whenever the absorbing atom is an anion it shifts towards the low energy side with respect to that of pure metal. In a binary compound the more electronegative atom should behave as an anion while the less electronegative atom behaves as a cation. In the case of Al-Mn system, the electronegativity difference between Al and Mn is zero as per the Pauling electronegativity scale [19]. On the basis of other electronegativity scales, for Al (1.61) and Mn (1.55) the electronegativity difference is too small in order to be used to conclude upon the cationic or anionic behaviour of Mn in Al-Mn system. The Al-Mn system in the present case shows the quasicrystalline nature having the icosahedral structure as proposed by XRD studies of these samples. Keeping into consideration the quasicrystalline nature of these samples, such a magnitude of chemical shifts of the quasicrystalline materials can be interpreted as due to iono-covalent bonding. It is important to note that the Al-Mn system although appearing to be an alloy of Al and Mn, shows insulating behaviour instead of metallic one [20–21]. A strong covalent bond may be responsible for such a behaviour. The magnitude of chemical shifts observed by us in the case of Al-Mn system

*e-mail: skjoshi_rlm@sancharnet.in

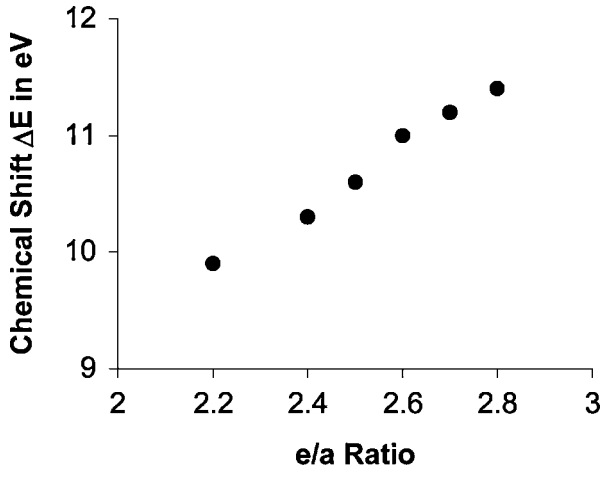

Fig. 1. Variation of Chemical Shift ΔE with electron to atom ratio (e/a).

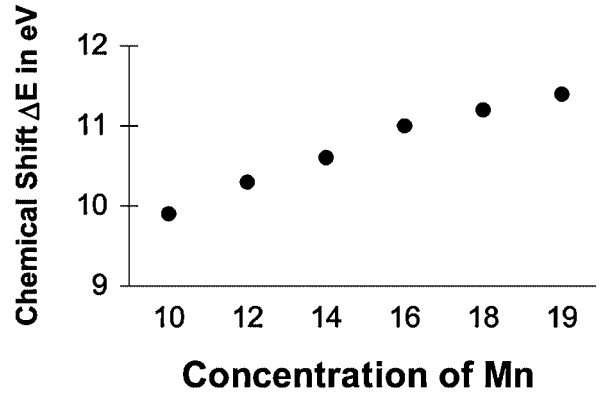

Fig. 2. Variation of Chemical Shift ΔE with concentration of Mn.

are indicative of their strong covalent bonding character. The Al-Mn in quasicrystalline form has the icosahedral decagonal phase. A change in concentration of Mn distorts the decagonal phase which in consequence is responsible for change in ionicity. The X-ray diffraction analysis of the present samples gives evidence for distortion in the icosahedral decagonal phase.

The electron to atom ratio plays a very important role in bonding. The values (e/a) for the presently studied system have been estimated following a procedure described elsewhere [22]. We have plotted in Fig. 1 the values of the electron to atom ratio (e/a) against the chemical shift (ΔE) in the case of the Al-Mn system. In Fig. 2 we have also plotted chemical shift vs. Mn concentration. Roughly an exponential relationship between e/a and ΔE is observed. The nature of this relationship is quite similar to that obtained between ΔE and Mn concentration in the Al-Mn system studied in the present investigations. The effect of the ionicity and in turn the e/a ratio on the chemical bonding as reflected in the chemical shift can be obviously seen from the above relationship.

As per the tight binding approximation, in many cases, the density of states is determined mainly by the actual potential of the atom and its nearest neighbours. The valence band and conduction band then tell whether or not they overlap with each other. When they overlap, the density shows a minimum which is called a pseudo gap. Such a pseudo gap was shown by Weaire [23] and Heine [24] for amorphous covalent materials such as Si.

It has been shown by several workers [25–27], that the inflection point on the K-absorption discontinuity in the case of pure metals corresponds to the Fermi energy. The Fermi level shifts in the case of different alloys have been studied by a number of workers [28–29]. In the case of compounds, however, the Fermi energy being uncertain, the inflection point on the absorption discontinuities can not be attributed to the Fermi level. The transition in such cases takes place from the inner level to the first available unoccupied states in the conduction band. It has been further shown [25–27], that there are a sizable number of holes on the top of the valence band where there is a reasonable transition probability. In the case of the present Al-Mn system, the conduction band is composed of manganese 3d and aluminium p-orbitals and higher orbitals of manganese. The band picture for the system is that of the valence band and the conduction band separated by a wide energy gap with the Fermi level lying in a pseudo gap. The inflection point of K-absorption discontinuity of the Al-Mn system can be attributed to the half filled Fermi level. Since there is an appreciable number of holes on the top of the valence band, the absorption discontinuity can extend from the top of the valence band to the first available state in the conduction band, which we may assume to be the bottom of the conduction band. Thus the edge width of K-absorption discontinuities of manganese in Al-Mn system can be regarded as the band gap.

Following Kimura and Takeuchi [30], we have obtained the density of states at the Fermi energy $D(E_F)$ given by:

$$D(E_F) = m/\hbar^2(M/d)^{3/2}\{3(e/a)N_A/4\}^{1/3}. \quad (1)$$

Here, $D(E_F)$ = density of states at Fermi level; M = effective atomic number; d = density of atoms; e/a = electron/ atoms; N_A = Avogadro's number; and $\hbar = h/2\pi$, where h is Planck's constant.

The density of states at the Fermi level $D(E_F)$ drops drastically when the electron density approaches 2.1 in units of (e/a) showing thereby the existence of a pseudo gap at the Fermi level [31]. In Table I, we have reported the e/a values and $D(E_F)$ for the Al-Mn samples.

We have plotted in Fig. 3 $D(E_F)$ vs. chemical shift ΔE. $D(E_F)$ varies linearly with the chemical shifts. If we extrapolate this curve to the lower energy side, we reach the $D(E_F)$ value for Aluminium metal which is equal to 2.05×10^{45} from the graph. The actual value of $D(E_F)$ for pure Aluminium is 2.17×10^{45}. The agreement between the two values establishes our assumption of assigning the chemical shifts to the Fermi level in case of Al-Mn system. The $D(E_F)$ value for pure manganese is 2.17×10^{45}. This means that if we want to extrapolate the same curve on the other side towards pure manganese, the curve should show a maximum somewhere midway and then show a decreasing trend until it reaches $D(E_F)$ for pure manganese. The dependence of electronic

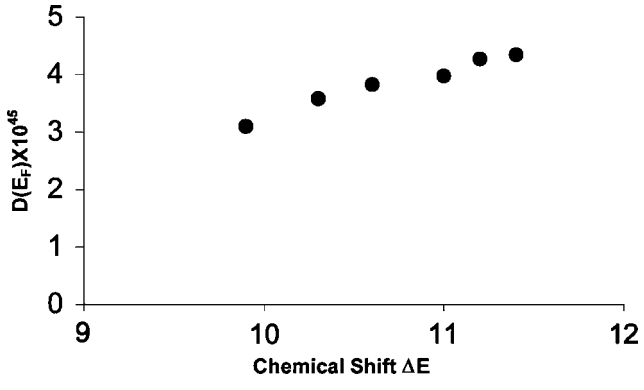

Fig. 3. Chemical Shift ΔE versus density of states at the Fermi level $D(E_F)$.

specific heat coefficient on Mn concentration of Al-Mn system shows a broad bump and a rapid increase at lower concentration while a rapid decrease at the higher concentration of Mn. This means the existence of a pseudo gap at E_F [32]. Also soft X-ray emission spectra have shown a decrease in the partial density of states of s and d electrons at E_F for Al-Mn icosahedral phase [33, 34].

Abstract

X-ray K-absorption edges along with their extended X-ray absorption fine structure (EXAFS) have been recorded using a laboratory XAFS spectrometer for the Co(II) imidazoles viz., $Co(etImz)_2Cl_2$, $Co(iprImz)_2Cl_2$, $Co(tvImz)_2Cl_2$, $Co(vImz)_4Cl_2$, $Co(vImz)_4(SCN)_2$, $Co(tvImz)_4Cl_2$, and $Co(tvImz)_4(SCN)_2$. The chemical shifts for these samples have been reported and the present studies reveal that the anions in $Co(ligand)_4Cl_2/(SCN)_2$ do not interact strongly with the metal ion. The studies further show that the complexes have tetrahedral structure in which anions $Cl_2/(SCN)_2$ remain outside the first coordination shell in $Co(ligand)_4Cl_2/(SCN)_2$ type complexes. The total phase shifts δ_1 and phase parameters β_1 for these samples have been estimated using the modified graphical method for the determination of bond distances. The values for phase parameter β_1 explain the dominance of backscattering in the various complexes studied.

1. Introduction

Imidazole is a molecule of biological importance. It is contained in the structure of several biomolecules like amino acids and peptides and serves as ligand to the metal ions in a variety of metalloenzymes. Metal complexes of imidazole and substituted imidazole are therefore important biological entities. The substituted imidazoles included in the present studies are: $Co(etImz)_2Cl_2$, $Co(iprImz)_2Cl_2$, $Co(tvImz)_2Cl_2$, $Co(vImz)_4Cl_2$, $Co(vImz)_4(SCN)_2$, $Co(tvImz)_{4D}\ Cl_2$, $Co(tvImz)_4(SCN)_2$ where etImz = ethyl imidazole; iprImz = isopropyl imidazole; vImz = vinyl imidazole and tvImz = thiovinyl imidazole.

1.1. *Structure*

Imidazoles normally form tetrahedral complexes with most of the transition metal ions. The complexes included in the present investigations may be grouped into two classes:

$Co(ligand)_2Cl_2$ and $Co(ligand)_4Cl_2/(SCN)_2$. Further it is obvious that all the ligands have only one nitrogen group available for coordination so that they will behave as a monodentate nitrogen donor ligands. All the $Co(ligand)_2Cl_2$ type complexes may therefore be given a tentative structure, as proposed and represented in [Fig. 1(a)]. $Co(ligand)_4Cl_2/(SCN)_2$ complexes may also be assigned the tetrahedral structure if only four substituted imidazole molecules are included in the coordination sphere and the interactions from the anions (Cl or SCN) are negligible [Fig. 1(b)]. Alternatively, if the anions interact significantly with the metal they are also included in the coordination sphere and a distorted octahedral structure may result [Fig. 1(c)]. The motivation behind the present work is to find whether the anions Cl and SCN are included in the first coordination shell and contribute to the X-ray absorption chemical shifts on the central metal ion cobalt. However, the results of the present studies reveal that the anions in $Co(ligand)_4\ Cl_2/(SCN)_2$ do not interact strongly with the metal ion and hence they are outside the first coordination shell. So structure as proposed in Fig. 1(b) is confirmed by X-ray absorption studies.

2. Experimental

The X-ray absorption spectra for the above samples including the fine structure up to nearly 280 eV have been recorded using a 40 cm curved crystal spectrograph of Cauchois type. Tungsten ($_{74}$W) L-emission line or Ni Kα_1 line has been used as a reference line; the other reference line being the Kα_1 emission line of copper. The remaining experimental details have been in general similar to those described earlier [1, 2]. The K-edge positions have been estimated using the derivative spectra.

3. Results and Discussion

Figure 2 shows the cobalt K-absorption edge along with the EXAFS features of the Co (II) imidazoles. In Table I, the values of the energies of the K-absorption edges of the samples, chemical shift values and phase parameter β_1 for these complexes have been included. In Table II, we have included the energy values of the EXAFS features, k in (Å^{-1}) and total phase parameter δ_1 in rad.

3.1. *Chemical shift*

Earlier also X-ray chemical shifts [3–7] and XAS studies [8, 9] have been utilised to obtain important chemical information regarding the coordination in the complexes belonging to transition metals.

The edge shift ΔE (known as chemical shift) is defined as follows $\Delta E = E_{K(Compound)} - E_{K(Metal)}$. The position of the X-ray K-absorption edge depends on the valence of the absorbing ion [10]. But valence state is not the only factor that governs the magnitude of the chemical shift. At least three factors that must be considered to explain the chemical shift values in metal complexes are valence state, the effective charge on the central metal ion [11, 12], stereochemistry and covalent bonding. Here we have observed that the chemical shifts are positive and lie in the range 6.6 to 8.9 eV. On the basis of previous reports [13–15] for cobalt (II) complexes, and our chemical shift values, we infer that all the presently studied cobalt imidazole samples possess oxidation state +2. A perusal of the values of the chemical shift in Table I indicates that among $Co(ligand)_2Cl_2$ type complexes, Co $(etImz)_2Cl_2$, (7.1 eV) and $Co(iprImz)_2Cl_2$, (7.3 eV) show nearly the same values of chemical shifts. This indicates that merely a change in the chain length of R has little effect on the chemical shift value. The chemical shift value of $Co(tvImz)_2Cl_2$ (6.8 eV) is definitely lower than those of $Co(etImz)_2Cl_2$ (7.1 eV)

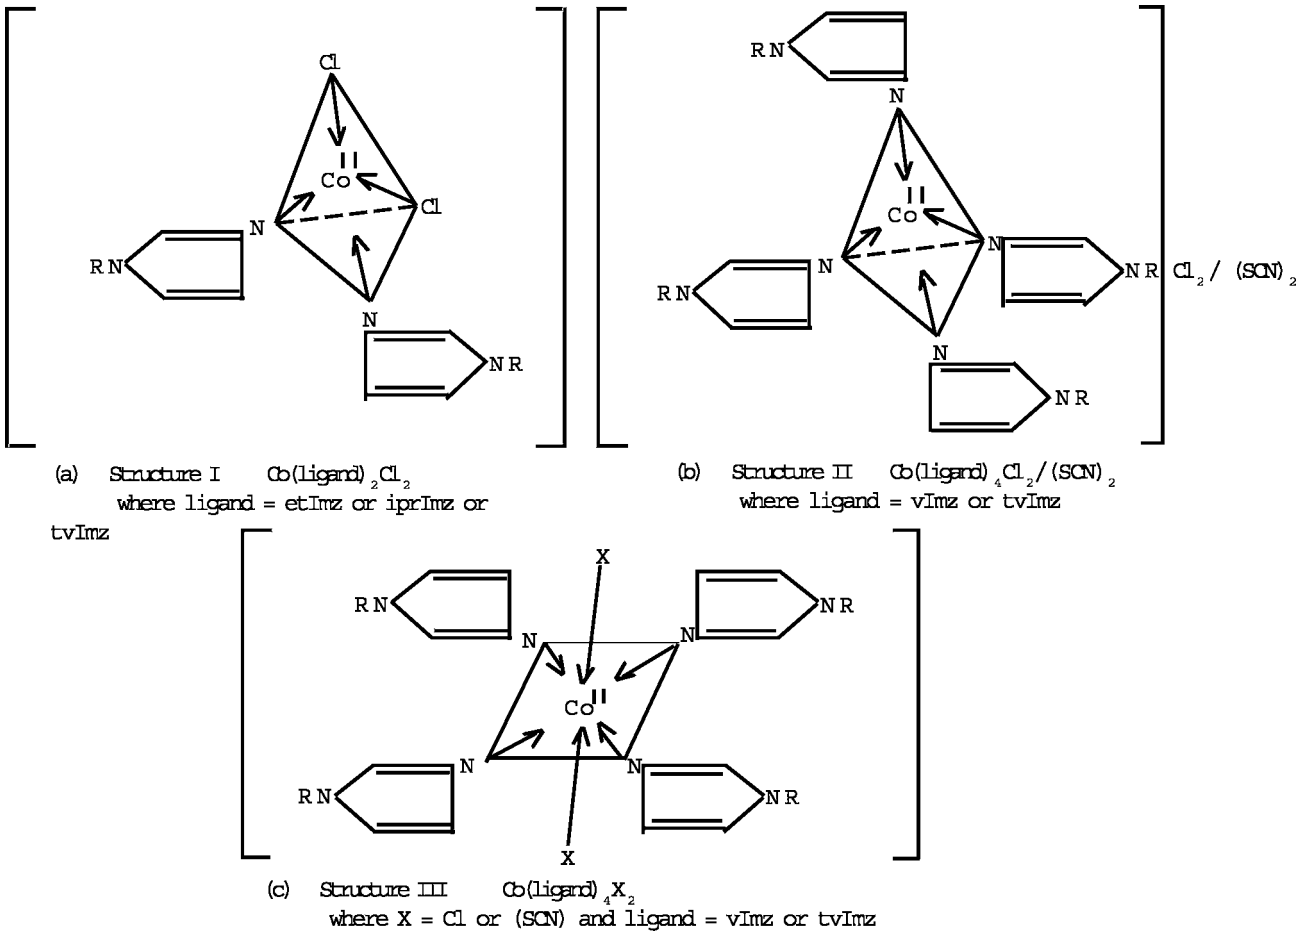

Fig. 1. Structures of Co(II) Imidazole complexes.

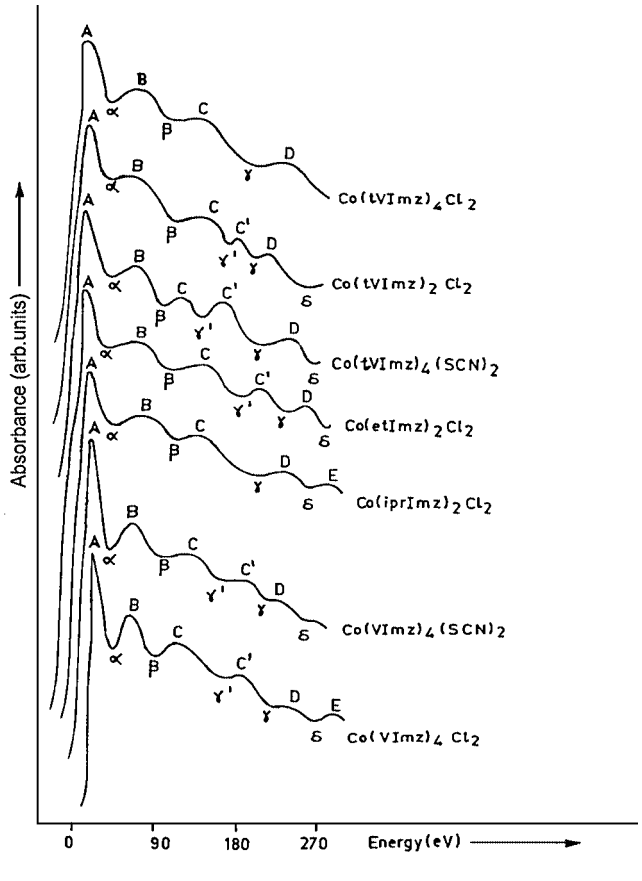

Fig. 2. EXAFS at the K-absorption edge of Cobalt in its Imidazoles.

Table I. *Chemical shift of K-absorption edge of Cobalt in Co(II) imidazole and phase parameter* β_1.

S. No.		E_K (eV)	Chemical shift ΔE_K (eV)	Phase Parameter β_1 (Rad.)
	Cobalt Metal	7709.7	—	—
I.	Co $(etImz)_2Cl_2$	7716.8	7.1	−1.88
II.	Co $(iprImz)_2Cl_2$	7717.0	7.3	−3.53
III.	Co $(tvImz)_2Cl_2$	7716.5	6.8	−1.88
IV.	Co $(vImz)_4Cl_2$	7718.6	8.9	−0.47
V.	Co $(vImz)_4(SCN)_2$	7718.5	8.8	−0.78
VI.	Co $(tvImz)_4Cl_2$	7716.3	6.6	−1.72
VII.	Co $(tvImz)_4(SCN)_2$	7716.7	7.0	−2.67

and $Co(iprImz)_2Cl_2$ (7.3 eV). Thus a major change in the nature of *R* can certainly influence the donor properties of the coordinated nitrogen atom and hence the effective charge of the metal ion.

Compounds $Co(vImz)_4Cl_2$ and $Co(vImz)_4(SCN)_2$ show nearly the same values of chemical shift; similarly compounds $Co(tvImz)_4Cl_2$ and $Co(tvImz)_4(SCN)_2$ also show nearly the same values of chemical shift indicating that there is no change in the value of chemical shift when Cl_2 is replaced by $(SCN)_2$. Therefore Cl_2 and $(SCN)_2$ are outside the coordination sphere.

A perusal of Table I also reveals that the value of chemical shift for $Co(vImz)_4Cl_2$; (8.9 eV) is greater than the value of chemical shift for $Co(tvImz)_4Cl_2$; (6.6 eV). Similarly the shift

for Co(tvImz)$_4$(SCN)$_2$; (8.8 eV) is greater than the value of shift for Co(tvImz)$_4$(SCN)$_2$; (7.0 eV). Thus when imidazole is replaced by thioimidazole the other factors remaining the same there is a decrease in the chemical shift indicating more covalent nature of thiovinyl-imidazoles.

3.2. *Data generation*

The values of the wave vector k (Å^{-1}) have been obtained using the expression

$$k = (0.263E)^{1/2}, \tag{1}$$

where E is the energy (in eV) of the peaks in the EXAFS measured from the inflection point on the component K of the absorption curves. The phase parameter β_1 and the average metal – ligand bond length R_1 have been estimated [16] with expression (2) where R_1 (in Å) is the radius of the first coordination sphere and n is the order of the position of EXAFS maxima and minima,

$$(\tfrac{1}{2} + n) = 2k(R_1 - \alpha_1) + 2\beta_1 - \pi. \tag{2}$$

Finally the total phase shifts δ_1 have been calculated [17] from the expression

$$\delta_1 = -\alpha_1 k + \beta_1 - \tfrac{1}{2}\pi. \tag{3}$$

It is well known that the sine term in the EXAFS equation determines periodicity. The determination of phase shifts is very important for this purpose. Several attempts [16–18] have been made to determine phase shifts theoretically. The total phase shift given by Equation (3) may be compared with the theoretical phase shift given by Teo and coworkers [16–18].

$$Q_{ab} = Q_a(k) + Q_b(k) - \pi. \tag{4}$$

This indicates that the phase parameter $2k\alpha_1$ resembles Q_a, the phase shift due to the central atom, while the phase parameter $2\beta_1$ resembles Q_b, the back scattering phase shift.

The values of δ_1 when plotted against the wave vector k (Fig. 3) give a curve similar in character to the theoretical curves obtained by Mckale *et al.* [19]. It has usually been assumed that the total phase shift for compounds belonging to a given system should be the same. However, in the present case we found that δ_1 vs. k curves (Fig. 3) are different for the Co(II)) imidazole complexes. The δ_1 vs. k plots are straight lines and are nearly parallel to each other. Hence, we can conclude that there is a linear variation between the total phase shift δ_1 and k. Earlier workers have applied the modified SLS (Stern, Lytle and Sayer's) method for the determination of the total shift (δ_1) in the case of ternary compounds [20], cobalt (III) complexes of ethylene diamine [21] etc. We have attempted to estimate the total phase shift (δ_1) and phase parameter (β_1) for the seven Co (II) imidazole complexes for the first time.

Phase shift determinations have been carried out by several workers in various systems [22–28]. Stearns and Stearns [22], using the Fourier transformation method, have observed that the parameter α_1 (b in their case) can be interpreted as corresponding to the scattering size of the atoms, whereas the parameter β_1 (a in their case) is associated with the depth of the potential well in which the absorbing atom is placed. They have further shown that an atom pair in any condensed material has a unique linear phase function in the operating k range.

A close perusal of Table II shows that the phase parameter β_1 for samples Co(etImz)$_2$Cl$_2$ i.e., sample (I) and Co(iprImz)$_2$Cl$_2$ i.e. sample (II) are respectively -1.88 and -3.53. This clearly indicates that as the chain length increases from ethyl to isopropyl, the back scattering phenomenon in the first coordination shell dominates and this is reflected in the larger value of phase parameter β_1 for sample (II). The phase parameter β_1 for sample (IV) i.e., Co(vImz)$_4$Cl$_2$ and sample (VI) i.e., Co(tvImz)$_4$Cl$_2$ are respectively -0.47 and -1.72. Similarly for Co(vImz)$_4$(SCN)$_2$ [sample (V)] and Co(tvImz)$_4$(SCN)$_2$ [sample(VII)] the phase

parameter values are -0.78 and -2.67 respectively. Hence, the conclusion may easily be drawn that in going from (vImz) to (tvImz) in both the pairs the contribution of backscattering from sulphur present in the thiovinyl imidazole is perceptible to be dominating the back scattering process. As discussed above on the basis of chemical shift values it has been proposed that $Cl_2/(SCN)_2$ are outside the first coordination shell in complexes of the type $Co(ligand)_4Cl_2/(SCN)_2$. The $Cl_2/(SCN)_2$ groups are in the second coordination shell and their contribution to the phase parameter β_1 is visible as seen obviously from different values of β_1 for the four complexes of $Co(ligand)_4Cl_2/(SCN)_2$ type. Further, β_1 values indicate strong backscattering from $(SCN)_2$ group as compared to Cl_2 group on the basis of slightly higher values i.e., $Co(vImz)_4(SCN)_2$ $(-0.78) > Co(vImz)_4Cl_2$ (-0.47) and also $Co(tvImz)_4(SCN)_2$ $(-2.67) > Co(tvImz)_4Cl_2$ (-1.72). The present method of phase shift determination using the modified graphical technique is simple and comparable to the above theoretical methods [22–28]. The above analysis provides a physical picture of the X-ray absorption process. This method may be used for studying systems such as amorphous materials, metallic glasses and bio molecules in which knowledge of the environment of atoms is desired.

Abstract

The structural change and charging process for $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ were determined by X-ray diffraction and XAFS measurement. XAFS has been employed to investigate the change in electronic structure of cathode material. As the cell charged, the Ni K-edge XANES spectra showed chemical shift towards higher energy, while Mn K-edge showed no significant shift. Divalent nickel metal is oxidized to trivalent with Li-deintercalation, in association with the phase transition from hexagonal (*R3m*) to monoclinic (*C2/m*).

1. Introduction

In the field of Li-ion batteries, new cathode materials with high theoretical energy density and good cycleability alternatives to $LiCoO_2$ have been extensively pursued such as $LiNiO_2$ or $LiMn_2O_4$. Several problems, including thermal stability and capacity fading at elevated temperatures, limit practical utilization, and few materials satisfy all properties that support high performance. $LiNi_{0.5}Mn_{0.5}O_2$ is one of the promising cathode materials of lithium secondary battery. It adopts a hexagonal unit cell like a layered $LiCoO_2$ or $LiNiO_2$, and the cell performance using Li exhibits a specific capacity of 150 mAh/g in the voltage range of 2.5 to 4.3 V which corresponds to one-half of the theoretical capacity (280 mAh/g) [1]. In addition, this material shows the superior characteristics of a larger capacity than $LiMn_2O_4$ and better thermal stability than $LiNiO_2$. Dahn *et al.* reported that Ni^{2+} and Mn^{4+} coexist in the layered materials [2]. When the cell is charged, Ni^{2+} is oxidized to Ni^{4+}, while Mn^{4+} retains its oxidation state. The charging process corresponds to the electrochemical Li extraction from the layered structure of $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$. However, the details of the crystal structure of charged $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ and the charging process are still ambiguous. In a previous study, we determined the crystal structure of this material by neutron powder diffraction. It was found that $LiNi_{0.5}Mn_{0.5}O_2$ has a hexagonal lattice, and the parameters are $a = b = 2.89109$ Å, $c = 14.297$ Å and the ion distribution can be expressed as $[Li_{0.91}Ni_{0.09}]_{3b}[Li_{0.09}Mn_{0.5}Ni_{0.41}]_{3a}O_2$ [3, 4]. In this study, the structure of charged $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ ($x = 0.5$), which corresponds to the composition for showing rechargeable capacity, was determined and XAFS of Ni, Mn and O K-edges were used to investigate the charging process and the electronic structure changes during Li-deintercalation.

2. Experimental

Samples were prepared from $LiOH{\cdot}H_2O$ and dry precipitates of $Ni(OH)_2$ and $Mn(OH)_2$ which were kindly supplied by TOSOH Company. They were mixed and then calcinated at 873 K for 12 h. The obtained powders were pressed into a disk under a pressure of 5 t/cm^2, and sintered at 1273 K for 12 h. Lithium was electrochemically deintercalated at a rate of 170 μA/cm^2, by use of a coin-type cell. The cathode material was composed of the following materials; sample : acetylene black : poly vinylidene fluoride (PVDF) = 86 : 4 : 10 in wt%, and 1 M $LiClO_4$ in propylene carbonate (PC) : 1,2-dimethoxycarbonate (DMC) = 1 : 1 by volume was used as the electrolyte. X-ray diffraction measurement was performed by use of synchrotron radiation, at a wavelength of $\lambda = 0.500$ Å on BL02B2 at SPring-8. Rietveld crystal structural refinement was carried out by use of the program RIETAN-2000 [5]. X-ray absorption measurements at the Mn- and Ni-K edges by transmission mode were performed on BL01B1 at SPring-8. The software programs WinXAS2.1 [6] and FEFF8.10 [7] were used for XAFS analysis. Oxygen K-edge XANES was measured on BL8B1 at UVSOR (Okazaki, Japan) in total electron yield and fluorescence yield mode.

3. Results and discussion

3.1. *X-ray diffraction*

Figure 1 shows X-ray diffraction patterns for electrochemically lithium-deintercalated samples, using synchrotron radiation source. Each sample corresponds to the composition in the charge curve. Rietveld analysis showed that a structural change occurred with the phase transition from hexagonal (*R3m*) to monoclinic (*C2/m*) resulting from the ordering of cations in the layered structure. Electron diffraction patterns by HR-TEM support these results. The change of lattice parameter during the charging process is summarized as follows: *a* and *b* in the plane of the structure decrease linearly, and *c* of the vertical axis increases. The charging process proceeds with the electrochemical Li extraction from the layered structure of $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$, associated with the oxidation reaction of transition metals (Ni or Mn). The change in lattice parameters can be explained by decreased ionic radius of oxidized transition metals and electrostatic repulsive force between oxygen ions, after lithium is extracted.

3.2. *XAFS*

Figure 2 shows Ni and Mn K-edge XANES spectra for $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ together with spectra of NiO, $LiNiO_2$ and Li_2MnO_3 as reference compounds for Ni^{2+}, Ni^{3+} and Mn^{4+}.

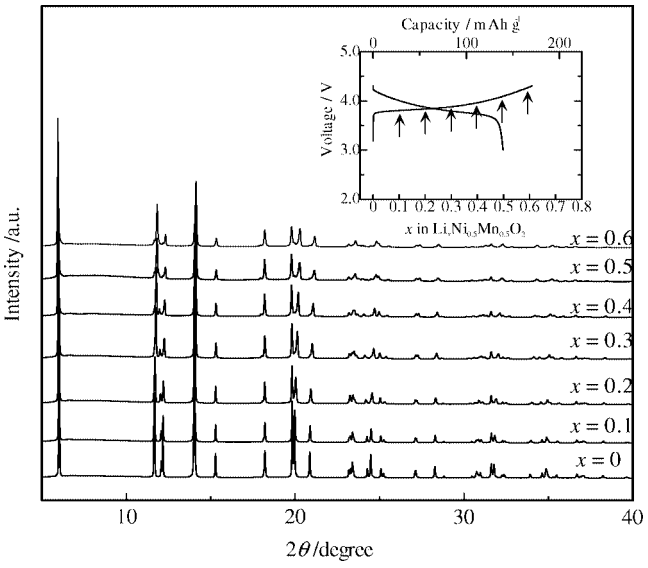

Fig. 1. X-ray diffraction patterns for $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$. The insert shows Charge and Discharge curves of the $Li/Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ measured with a current density of 0.1 mA/cm^2 and cut-off voltages of 3.0 and 4.3 V.

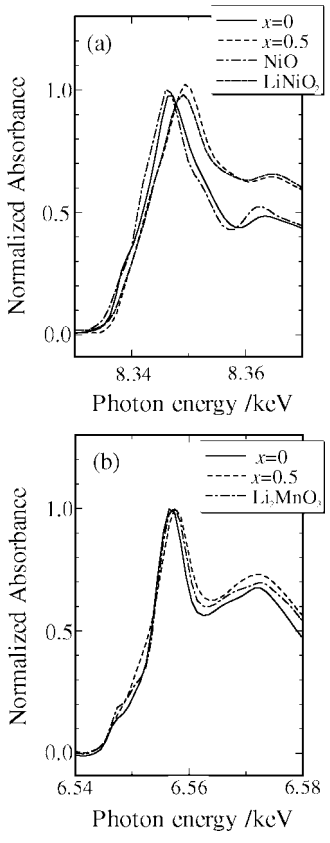

Fig. 2. XANES spectra of (a) Ni and (b) Mn K-edge for $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ and reference compounds.

As the cell charged, XANES spectra of Ni K-edge showed a chemical shift towards higher energy in the voltage range of 2.5–4.1 V and no remarkable shift was observed up to 4.5 V. On the other hand, in the Mn K-edge no chemical shift was observed. The Ni K-edge XANES spectra correspond to a valence state of Ni^{2+} for the $x = 0$ sample and show a change in the valence state to Ni^{3+} for the $x = 0.5$ sample, while the Mn K-edge XANES spectra almost correspond to a valence state of Mn^{4+} for the $x = 0$ sample and show essentially small deviation from the valence state of Mn^{4+} for the $x = 0.5$ sample. These results demonstrate

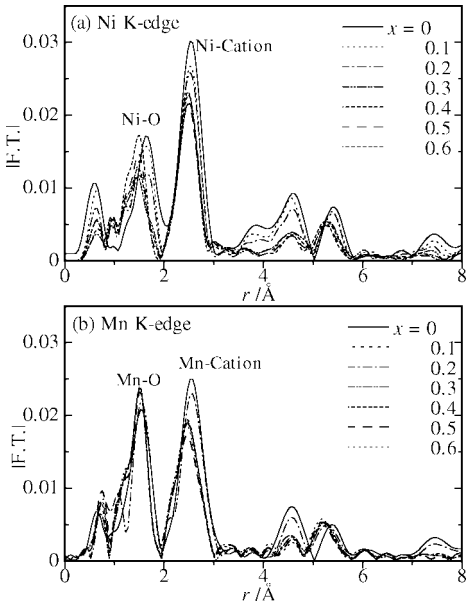

Fig. 3. Fourier transforms of (a) Ni and (b) Mn K-edge EXAFS for $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$.

that $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ ($x = 0$ and 0.5) can be represented as $Li(Ni^{2+}{}_{0.5}Mn^{4+}{}_{0.5})O_2$ and $Li_{0.5}(Ni^{3+}{}_{0.5}Mn^{4+}{}_{0.5})O_2$ respectively. Thus, the charging process of this material up to $x = 0.5$ is proceeded by continuous oxidation of Ni, not oxidation of Mn. Figure 3 shows XANES spectra of O K-edge obtained by fluorescence yield (F.Y.) for charged $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$. The sample of $x = 0.7$ was prepared at different electrochemical conditions from that of Fig. 1. The sampling depth in F.Y. mode is much deeper than that in the electron yield. These spectra reflect on the internal chemical state of the sample. The broad peak at about 547–552 eV may correspond to the transition to the band composed of transition metal (Ni,Mn) 3d and O2p. The slight peak shift towards lower energy implies that oxygen participates in the oxidation of the material. Explanation of O K-edge spectra in details using first principle calculation are under progress. Figure 4 shows Fourier transforms of (a) Ni and (b) Mn K-edge for $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ after the charging process. The spectra show similar features in relation to the radial distribution, in reflection of

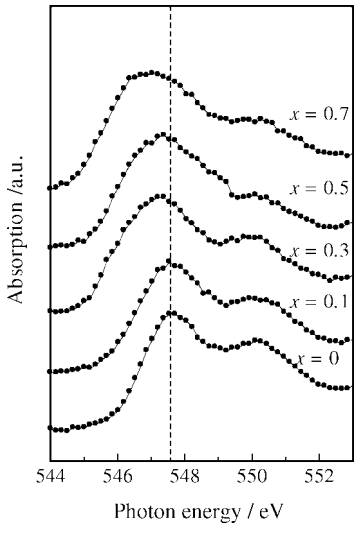

Fig. 4. O K-edge XANES spectra of $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$.

the two metals being placed in similar environment. In Figure 4(a), the first peak in the FT corresponds to the first neighbor of Ni; i.e., a Ni-O shell in the structure. The second peak in the FT corresponds to the second neighbor of Ni; i.e., a Ni-Cation shell where the cation can be either Ni or Mn. The first peak shifted to shorter distance after charging, since the oxidation of Ni^{2+} to Ni^{3+} shortens the bonding length of Ni-O. On the other hand, no shift is observed in the Mn K-edge. By use of the structural model obtained by X-ray diffraction analysis, backscattering amplitude and phase parameter were calculated by FEFF and fitting was carried out. The results show that as the cell charged, the distance of the first neighbor, Ni-O, decreased as a result of reduction in the ionic radius of nickel. A structure model using two shells yielded good fitting for the composition of $x = 0.5$ ($R = 2.49\%$), because Ni and O in monoclinic phase show two different bonding distances (2.053 Å for $x = 0$, 1.915 Å (C.N. = 4.0) and 2.043 Å (C.N. = 2.0) for $x = 0.5$).

In summary, the structural change and charging process for $Li_{1-x}Ni_{0.5}Mn_{0.5}O_2$ were determined by X-ray diffraction and XAFS measurement. The $x = 0$ sample has a hexagonal lattice in which a small part of Ni occupies the Li(3b) site, and as the cell charged the monoclinic phase appeared from the composition of $x = 0.3$. Lithium was mainly removed by the oxidation of Ni, resulting in the ordering of cations in the layer; that is, appearance of the monoclinic phase. However, it is likely that oxygen participates in the charging process. It was found that nickel was divalent and manganese tetravalent at the octahedral site respectively. The results of EXAFS analysis showed that as the cell charged, the distance of the first neighbor Ni-O decreased. It results from the decrease of the ionic radius for nickel by oxidation. Therefore, it can be concluded that the main role of charging reaction in the cell is the oxidation of nickel, Ni^{2+} to Ni^{3+}.

Acknowledgement

The synchrotron radiation experiments were performed at SPring-8 with the approval of the Japan Synchrotron Radiation Research Institute (JASRI) (Proposal 2001B0484-NX-np, 2002A0370-ND1-np). Oxygen K-edge XANES was performed on BL8B1 at UVSOR (Okazaki, Japan).

Abstract

The magnetic properties of a few atomic Pt layers on a 15 nm thick Co film were studied by X-ray magnetic circular dichroism spectroscopy at the Pt $L_{2,3}$ edges. The spin and orbital magnetic moments of the Pt 5d electrons were separated using the magneto-optical sum rules. The Pt magnetization profile as a function of distance from the Co-Pt interface was determined using data from a series of films with various Pt thicknesses. This magnetization profile was approximated by an exponential function with a decay length of 0.41 nm, which characterizes the effective range of the magnetic coupling between Co and Pt. The total magnetic moment of a Pt atom at the interface was 0.7 μ_B/atom including a 13% orbital moment. This is discussed in the context of the thermal stability of magnetic recording media capped with a thin layer of Pt.

A high recording density of 100 Gbits/in^2 was recently developed in magnetic recording media, and now researchers aim to achieve even higher recording densities in the range of 1 Tbits/in^2. An alternative to present longitudinal recording for storing data is perpendicular recording. Perpendicular recording can reduce the area needed for unit data bit storage on a medium and consequently, will significantly increase the recording density. The target size of a single recording bit is $10 \times 45 \times 20\,\text{nm}^3$ for some perpendicular media being developed. This small size requires reducing the magnetic grain size to the nanometer scale for reliable reading/writing operations with a good signal-to-noise ratio. However, even in perpendicular recording, thermal decay may limit further reductions in the grain size because the magnetic grain thermal stability depends on the anisotropy constant K_u and the volume V using the relationship $K_u V/k_B T$, where k_B is the Boltzmann constant and T is temperature. Thus, higher magnetic anisotropy is required to maintain thermal stability of the material used in high density perpendicular media with a smaller grain volume. Sonobe *et al.* reported that capping with a 1 nm thick Pt layer improved the thermal stability of granular $CoCr_{18}Pt_{12}$ perpendicular media [1]. They pointed out that the Pt cap layer possibly has induced ferromagnetism, which gives rise to the large perpendicular anisotropy and increases the in-plane exchange coupling. As reported in Co/Pt multilayer systems [2] and Co-Pt alloys [3–5], Pt atoms that are paramagnetic in the bulk are significantly polarized in the vicinity of the ferromagnetic atoms such as Co due to their large Stoner factor, and have crucial effects for magnetism of the system.

This paper reports the magnetic properties of single Pt layers less than 2 nm thick located on a Co film, studied using X-ray magnetic circular dichroism (XMCD) spectroscopy at the Pt $L_{2,3}$ edges. The aim of this study is to determine the role of the surface Pt layer of the CoCrPt perpendicular media in improving the thermal stability. Several Co/Pt bilayer films were investigated as models for real perpendicular media that contains Pt in the host granular layer. We use the element specificity of the XMCD technique to probe the magnetization of only the Pt, which was a few atomic layers, with high sensitivity. The spin and orbital moment of the Pt 5d electrons were separated using the sum rules [6]. The distributions of the both moments as a function of the distance from the Co-Pt interface were determined from a series of XMCD data taken with samples of varying Pt layer thickness.

Table I. *Characteristics of Co/Pt bilayer films. The $\Delta\theta_{50}$ denotes the angular dispersion of the c-axis, which is determined by the full width at the half maxima of the X-ray rocking curve profile.*

Pt thickness (nm)	Co thickness (nm)	$\Delta\theta_{50}$ of Co (°)
0.15	14.3	13.4
0.5	15.1	9.5
1.0	15.0	10.8
2.0	14.6	9.04

Co/Pt bilayer films of four different Pt thicknesses were prepared by dc magnetron sputtering. A magnetic Co layer, approximately 15 nm thick, was deposited onto a glass substrate following a 10 nm thick Ti seed layer, and a Pt layer was deposited on the top. The samples were grown at room temperature to minimize the interface diffusion. Table I summarizes the characteristics of these samples. The thickness of the Pt layer was estimated from the amount of sputter growth time after a carefully calibrating the Pt deposition rate. The Pt thickness was measured by the XAS edge jump at the Pt $L_{2,3}$ edges and is consistent with the designed value. In the present study, Co was chosen as the magnetic layer instead of granular CoCrPt used in real perpendicular recording media, so that the magnetic properties of the top Pt layer could be studied using element specificity of XMCD technique. Consequently, the present Co/Pt bilayers did not show perpendicular magnetic anisotropy.

XMCD experiments at the Pt $L_{2,3}$ edges were conducted in the fluorescence mode at BL39XU of SPring-8 [7]. Monochromatic X-rays were incident on a Co/Pt sample perpendicularly to the film plane. A magnetic field of 20 kOe was applied perpendicular to the film plane to attain saturation magnetization. Intensities of fluorescent X-rays were detected using a silicon drift detector. The detector allowed total count rates as high as 10^5 counts/s and efficient separation of the Pt Lα (L_3 excitation) and the Lβ (L_2 excitation) lines from the elastic scattering, which mainly

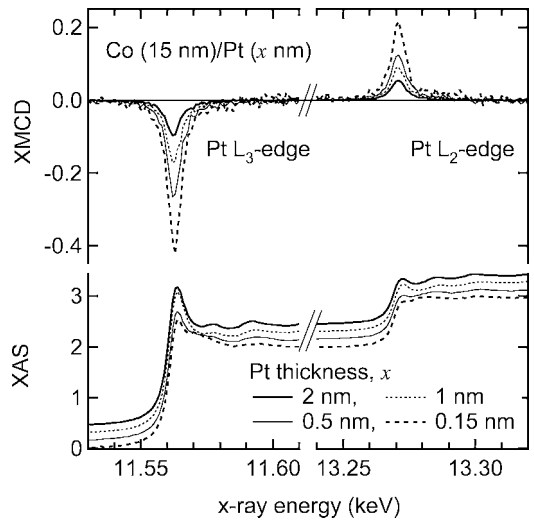

Fig. 1. X-ray magnetic circular dichroism spectra (top) at the Pt $L_{2,3}$ edges in Co/Pt bilayer films of different Pt thickness x, compared with spin-averaged XAS spectra (bottom). The XAS spectra are shown with vertical shifts for better display.

originates from the substrate. A 2.7 mm thick diamond crystal was used as an X-ray phase retarder to generate circular polarization incident on the sample and to switch the photon helicities every two seconds. The degree of circular polarization was higher than 90%. The difference in sample fluorescence yields for right- and left-circular polarizations was recorded as a function of the X-ray energy, while the direction of the applied magnetic field was fixed. This setup allowed the XMCD spectra in a few atomic Pt layer on Co film to be successfully obtained with a high signal-to-noise ratio.

Figure 1 shows the observed XMCD spectra in Co/Pt films with various Pt thicknesses, and at the bottom spin-averaged XAS spectra are compared. The XMCD and XAS amplitude include the same scale factor so that the XAS step height at the L_3 and L_2 edges is 2.07 and 1.00, respectively. This branching ratio was experimentally determined from XAS measurement for the present samples. The sign of the XMCD spectra was negative at the L_3 edge and positive at the L_2 edge, which indicates that the Pt magnetization is parallel to the external field and to the magnetization of Co. At both the L_3 and L_2 edges, the XMCD amplitude decreased as the Pt thickness increased, indicating that the Pt magnetization decreases as the distance from the interface with Co increased. The shape of the XMCD spectrum was independent of the Pt thickness. The 0.15 nm Pt thick sample showed the largest XMCD amplitude, 22% with respect to the XAS edge jump. To the best of our knowledge, this XMCD value is larger than any XMCD data of Pt in Pt-transition metal alloys [3–5], Pt/Co [2] or Pt/Ni [8] multilayers reported to date. The Pt atoms located very close to the Co-Pt interface may have a considerable magnetic moment.

The spin and orbital magnetic moments of the Pt layer was determined by applying the sum rules [6]. We have used a Lorenz function to fit the XMCD and XAS components arising from the dipole transition to the 5d band. The continuum background in the XAS spectrum was subtracted using an arctangent curve. When applying the spin sum rule, the magnetic dipole term was neglected. It is noteworthy that results of the spin sum rule for XMCD data taken with in-plane magnetization [9] differ from the present one by less than 15% even for the 0.15 nm thick Pt. We consider that this anisotropy is due to either the real anisotropy in the spin moment or the magnetic dipole term, or both. Therefore, the spin moment presented below may include up to a 15% contribution from the magnetic dipole term.

Table II. *The magnetic moments per 5d hole in the top Pt layer of Co/Pt bilayers of different Pt thickness x.*

x (nm)	m_{spin} (μ_B/hole)	m_{orb} (μ_B/hole)	m_{total} (μ_B/hole)
0.15	0.36	0.053	0.41
0.5	0.21	0.036	0.25
1.0	0.14	0.021	0.16
2.0	0.079	0.011	0.09

Table II shows the observed 5d magnetic moments in the Pt layer. A larger magnetic moment was observed for the sample with a thinner Pt layer. For the 0.15 nm thick Pt layer the total moment was 0.41 μ_B/hole. This value gives 0.7 μ_B/atom when using the Pt 5d hole number 1.7, which was reported in a theoretical calculation for a similar system [10]. This value is two and three times larger than the Pt moments reported in $Co_{50}Pt_{50}$ alloy thin films [5] and Ni/Pt multilayers [8], respectively. The orbital moment was 0.053 μ_B/hole (0.09 μ_B/atom), which is a 13% contribution to the total magnetization.

The results shown in Table II give the average moment per Pt atom over the entire layer. From these, the distribution of the Pt magnetization as a function of the distance from the Co-Pt interface can be obtained [11]. For this analysis, we made products of the average moment listed in Table II and the corresponding Pt thickness, then took the difference one from the other.

Figure 2 plots the result of the analysis. The total moment of the Pt 5d electrons was determined to be $m_{spin} + m_{orb} = 0.41\ \mu_B$/hole (0.7 μ_B/atom) for a Pt atom that is in contact with Co atoms at the interface. An exponential function, $m(d) = m_0 \exp(-d/\delta)$, well reproduces the variation in the the total moment $m(d)$, where d is the distance from the interface, and m_0 and the decay distance,

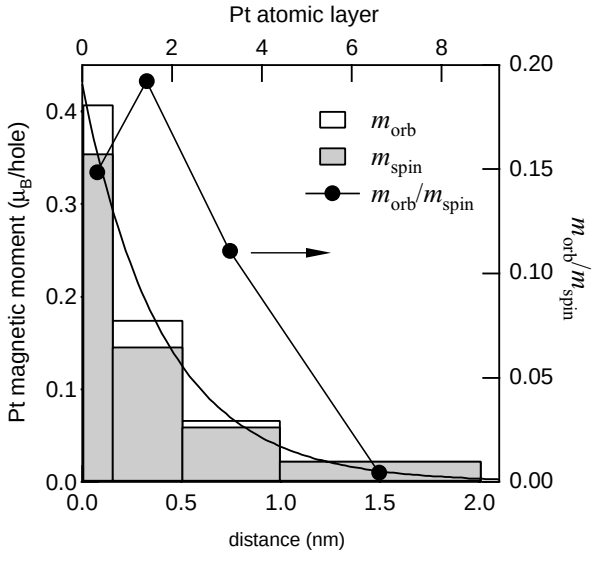

Fig. 2. Distribution of the Pt magnetic moment as a function of the distance from the Co-Pt interface. The top axis shows the corresponding Pt atomic layer number. The m_{orb} and m_{spin} denote the orbital and the spin moments, respectively. The solid curve shows an exponential function fitted to the total magnetic moment $m_{spin} + m_{orb}$. Solid circles, referred to the right axis, show the ratio of m_{orb} to m_{spin}.

δ are the fit parameters. The decay distance $\delta = 0.41$ nm gives the best fit. This value corresponds to two atomic layers of Pt and characterizes the effective range of magnetic coupling between Co and Pt. The fit curve is shown by the solid line in Fig. 2.

From these results, we can conclude that only four or less atomic Pt layers have a substantial amount of induced magnetic moments and contribute to the thermal stability of magnetic films. Regarding the orbital moment, it decreases more rapidly than the spin moment, and almost vanishes at 1.5 nm away from the interface. The magnetic anisotropy in a Co magnetic film may be enhanced by two or three atomic Pt layers, which show considerable amount of the orbital moment, near the Co-Pt interface.

The present result is consistent with the reported magnetization profile determined by resonant X-ray magnetic reflectometry in another Co/Pt bilayer [12], except the regime within 0.3 nm from the Co-Pt interface, where our results show larger magnetization values. In addition to the total magnetization profile, which can be obtained by the magnetic reflectometry, we have separately determined the distribution of the spin and orbital magnetization. Moreover, the magnetization in single atomic layer of Pt located very close to the interface has been observed.

In this study, the distribution of Pt magnetization induced by the Co underlayer was quantitatively determined and effective range of magnetic coupling was estimated in the vicinity of the Co-Pt interface. In future studies, the magnetic anisotropy of the Pt layer, which may be crucial for the thermal stability of the perpendicular media. needs to be investigated. Angular dependent XMCD experiments [9, 13] would provide useful information related to the magnetic anisotropy.

Abstract

The effect of CO adsorption on the magnetic easy axis of Co/Pd(111) magnetic thin films has been studied by C 1s X-ray photoelectron spectroscopy (XPS) and Co L-edge X-ray magnetic circular dichroism (XMCD) in absorption spectroscopy. We found by the XMCD measurements that the CO adsorption at 200 K induces the spin reorientation transition of a 4–6 monolayer (ML) Co thin film, but it does not cause spin reorientation at 300 K. Simultaneous XPS measurement showed that the C 1s spectrum has a single peak at 285.8 eV at 300 K, while it has an additional shoulder at 285.3 eV at 200 K. The main peak is associated with the CO atop adsorption, and the shoulder might be ascribed either to bridge or hollow site adsorption. Temperature and CO coverage dependences of XMCD and C 1s XPS spectra reveal that the bridge or hollow site CO adsorption is responsible for the spin reorientation of the Co thin film. This is the first direct observation to correlate the magnetic anisotropy of a magnetic thin film with the molecular adsorption site.

Co thin films on Au, Pt, and Pd(111) surfaces exhibit a strong perpendicular magnetic anisotropy (PMA) [1, 2, 3, 4] and have widely been studied. In particular, multilayer systems have attracted much attention, because they have a wider range of perpendicular magnetic easy axis than single layer systems. XMCD studies reveal that the perpendicular orbital magnetic moment is enhanced at the interface of these systems [4–6]. We can also expect a large anisotropy of the orbital magnetic moment at the surface of the magnetic thin films because there is no atom above the surface. However, it has not widely been examined due to difficulty of preparing a clean surface.

Recently, it has been revealed that the magnetic anisotropy and the magnetic easy axis of thin films are influenced by gaseous adsorption on the surfaces [7, 8, 9, 10, 11]. This is phenomenologically explained by the reason that atomic or molecular adsorption reduces the absolute value of the surface magnetic anisotropy constant which favors parallel magnetization, and as a result, perpendicular magnetization becomes energetically stable [10, 11]. In addition, induced magnetization of the adsorbates has also been studied [12]. The sign of the magnetic coupling between adsorbates and thin films was found to be related to the magnetic easy axis of the films. These facts suggest that the magnetic anisotropy of thin films is affected by the adsorption of gaseous molecules.

In the present work, we have observed the spin reorientation transition of Co/Pd(111) induced by CO chemisorption by means of XMCD and XPS measurements. XMCD provides information on the magnetization of the Co thin film. We found that quenching of the surface parallel magnetic orbital moment by CO adsorption is a key of PMA stabilization [13, 14]. On the other hand, XPS is a powerful surface analytical method, which is sensitive to the chemical environment. Especially for CO adsorption systems, their adsorption sites can be discriminated by the XPS cheical shift and high resolution. Thus, we have examined the correlation between the CO surface adsorption fashion and the spin reorientation transition of Co thin film induced by stepwise CO adsorption and desorption. It is a new approach to observe magnetism of a thin film from the view of surface chemistry.

All the experiments have been performed at the soft X-ray bending magnet station, BL-7A, which is equipped with a varied-line-spacing plane grating monochromator, in the Photon Factory of the Institute of Materials Structure Science, High Energy Accelerator Research Organization (KEK-PF) [15].

Co thin films were prepared on a Pd(111) single crystal by the following procedure. The Pd(111) substrate was cleaned by repeated cycles of Ar sputtering (2 keV) and annealing at 1000 K in an ultrahigh vacuum chamber. The cleanliness and order of the surface were confirmed by NEXAFS (near-edge X-ray absorption fine structure), LEED (low-energy electron diffraction) and XPS. Co thin films were deposited on Pd(111) at room temperature with the electron-beam evaporation method. As RHEED (reflection high-energy electron diffraction) oscillation has not been observed in the present system, we estimated the thickness of each film by the edge jump of NEXAFS and the Auger intensity ratio between Co and Pd.

The C 1s X-ray photoelectron spectra were taken with a hemispherical electrostatic analyzer (GAMMADATA-SCIENTA, SES-2002) with an incident X-ray energy of 430 eV. The X-ray incident angle was fixed at $\theta = 30^\circ$ from the surface and normally emitted photoelectrons were detected. For Co L-edge XMCD measurements, we used elliptically polarized X-rays emitting downwards from the electron orbital plane by -0.4 ± 0.1 mrad. The circularly polarization factor was estimated to be 0.85. The absorption spectra were recorded with the partial-electron-yield mode with a retarding voltage of 500 V using a microchannel plate (MCP), which was placed below the sample. The XMCD spectra were obtained by reversing the magnetization of the films. Each sample was mounted in a Helmholtz coil and was magnetized by a current pulse (0.1 T) along the incident X-rays and the remnant magnetization was examined. We could measure XPS and XMCD in absorption spectroscopy under the same conditions without changing the sample and/or detector position.

Figures 1 and 2 show the perpendicular and parallel effective spin magnetic moments of Co/Pd(111) magnetic thin films with various thicknesses, which were obtained by the observation of Co L-edge XMCD and the application of the magnetic sum rule analysis. In order to check the magnetic easy axis of each thin film, XMCD measurements were performed at normal incidence ($\theta = 90^\circ$) for the detection of perpendicular magnetization, and at

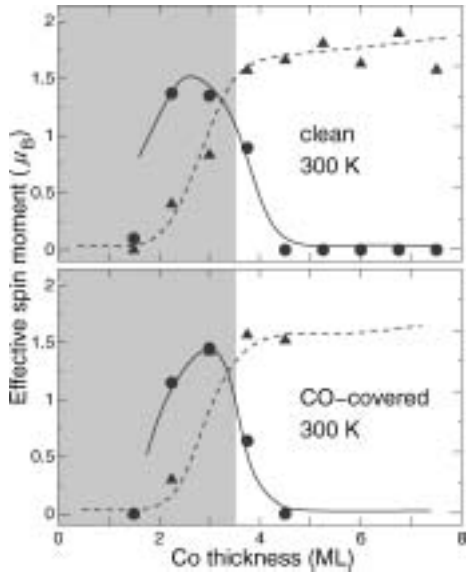

Fig. 1. Effective spin magnetic moments of clean (up) and CO-covered (down) Co thin films on Pd(111) at 300 K as a function of Co thickness. Circles and solid lines correspond to the surface normal direction, while triangles and dashed lines correspond to the surface parallel one. Hatched areas indicate the PMA regions.

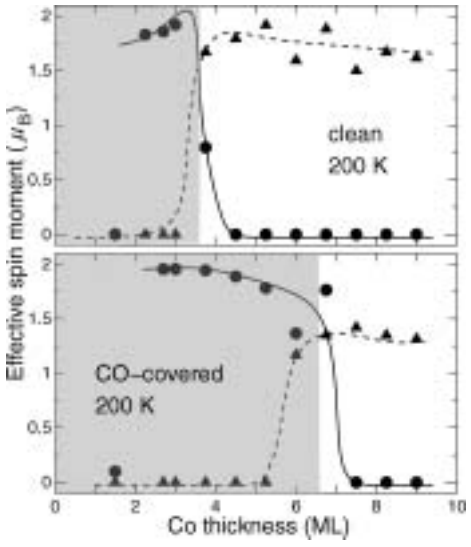

Fig. 2. Effective spin magnetic moments of clean (up) and CO-covered (down) Co thin films on Pd(111) at 200 K as a function of Co thickness. Circles and solid lines correspond to the surface normal direction, while triangles and dashed lines correspond to the surface parallel one. Hatched areas indicate the PMA regions.

grazing incidence ($\theta = 30^\circ$) for the detection of surface parallel magnetization. For the clean Co/Pd(111) system, the region of the perpendicular magnetic easy axis is below 3.5 ML at both 300 K and 200 K. CO adsorption at 300 K does not shift the critical thickness of the Co/Pd(111) at all. On the other hand, in the case of 200 K, CO-covered films show a wider region of perpendicular magnetic easy axis than the clean one by about 3 ML. Co films with thickness of 4–6 ML inherently show a parallel magnetic easy axis and undergo a spin reorientation transition from surface parallel to perpendicular direction upon CO adsorption at 200 K. These results indicate that PMA is stabilized by CO adsorption at 200 K and not affected by that at 300 K.

Figure 3 shows C 1s photoelectron spectra of CO adsorbed on Co/Pd(111) taken at 300 K and 200 K. The C 1s spectrum at 300 K consists of a single peak at 285.8 eV, while that at 200 K has an additional shoulder at 285.3 eV, suggesting two

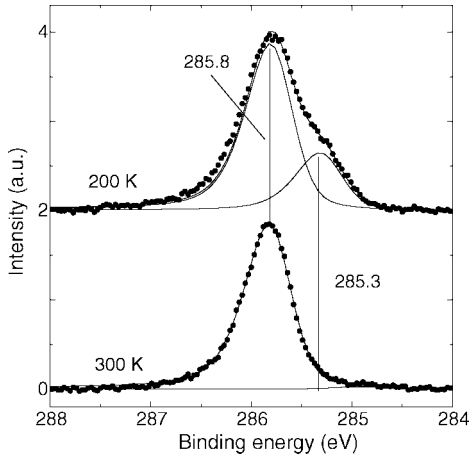

Fig. 3. C 1s X-ray photoelectron spectra from CO adsorbed on 4.5 ML Co film on Pd(111), taken at temperatures of 300 K and 200 K. The vertical lines indicate the positions of peaks assigned to atop (285.8 eV) and bridge or hollow (285.3 eV) adsorptions sites (see text).

kinds of adsorption sites at 200 K. Previous XPS experiments for CO adsorbed on *hcp* Co(0001) single crystal suggest that CO molecule occupies atop sites at 300 K and bridge or hollow sites as well as atop sites at 200 K [16]. Photoelectron diffraction study indicated that epitaxially grown Co films have a *fcc* structure up to 20 ML [17], which is different from the *hcp* structure in the bulk. Although it is not certain that the CO adsorption behavior on the Co film is the same as that on *hcp* Co (0001), the C 1s peak of bridge and hollow sites generally appears at the lower energy position than that of atop sites by 0.5–1.0 eV on several metal surfaces. Thus, we can deduce that CO molecules are adsorbed exclusively on atop site of Co/Pd(111) at 300 K and both on atop and bridge (or hollow) sites at 200 K.

In order to examine both the surface adsorption behavior of CO molecule and the change in magnetism of the Co thin film, C 1s XPS and Co L-edge XMCD spectra were measured at stepwise CO adsorption. Figure 4 shows the relationship between C 1s and

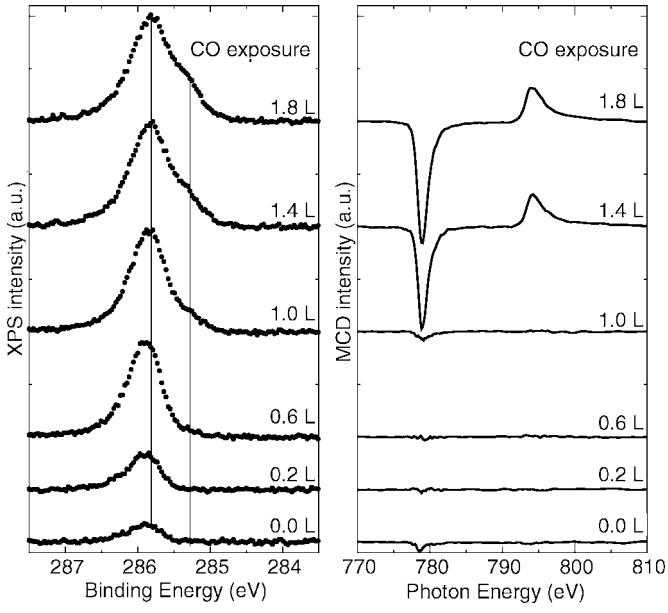

Fig. 4. C 1s X-ray photoelectron spectra (left) and normal incident Co L-edge XMCD spectra (right) from 4.5 ML Co thin film on Pd(111) during step by step CO adsorption at 200 K.

Co XMCD spectra for a 4.5 ML Co film during CO dosage at a temperature of 200 K. The Co film undergoes spin reorientation transition from surface parallel (before CO adsorption) to perpendicular magnetization (after being completely covered with CO). Note that the X-ray incident angle was normal so as to detect only perpendicular magnetization for the XMCD measurements. Nearly zero XMCD signal during the low CO coverage does not indicate that the Co thin film is not magnetized, but is fully magnetized in parallel direction before CO dosage, as confirmed by the XMCD observation at grazing incidence (not shown). The growth manner of the main XPS peak at 285.8 eV suggests that the atop sites are occupied at the low coverage. At around 1.0 L (1 L = 10^{-6} Torr · s; 1 Torr = 133 Pa) CO dosage, the main peak became saturated and the shoulder at 285.3 eV gradually grew up. At the same time, Co XMCD gradually appeared, which means that the easy axis of Co had just begun to rotate the orientation of spin from surface parallel to perpendicular direction. At around 1.8 L CO exposure, both C 1s and XMCD peak intensities were saturated, which means that CO adsorption was completed and Co was fully magnetized perpendicularly. We observed the same correlation between CO occupation of bridge or hollow sites and the perpendicular magnetization of Co thin film in thermal heated desorption process. We found that the spin reorientation transition in Co/Pd(111) is induced as a consequence of CO adsorption on bridge or hollow site and not induced by CO adsorption on atop site which is the most energetically favored adsorption position. We have repeated these adsorption and desorption experiments for several films which consist of 4–6 ML Co films on Pd(111) and observed similar behavior.

As for the behavior of the spin reorientation transition induced by surface adsorption, we compare CO on Co/Pd(111) with H or CO on Ni/Cu(001). A linear shift of the critical thickness accompanied with the coverage of H or CO on Ni/Cu (001) was pointed out by using magneto-optical Kerr effect (MOKE) [10, 11]. It was concluded that H or CO adsorption reduces the absolute value of the surface magnetic anisotropy constant with the adsorption coverage. On Ni/Cu(001), CO resides at atop sites at 300 K and H resides at fourfold hollow sites at 200 K. For both cases the site occupation is unique. Our result shows that the chemisorption-driven spin reorientation transition of Co/Pd(111) is induced only when CO is adsorbed on bridge or hollow sites, while it is not induced when CO occupies the atop site which is the most favorable adsorption site. This suggests that the change of the surface magnetic anisotropy is expressed not only by the coverage, but also by the adsorption structure of the surface.

Surface and interface magnetic anisotropies of the thin films originate in structural and electronic effects. Some studies point out that the in-plane interatomic distance of a few ML Co film on Pd(111) seems to be the same as that of Pd due to the epitaxial growth [17]. From the view of the structural effect, such an elongated interatomic distance at the interface creates an interface magnetic anisotropy. CO adsorption on the atop site does not affect the Co-Co interatomic distance much, while CO atoms adsorbed on bridge or hollow sites might push in the Co substrate and elongate the Co interatomic distance. This could be the reason why CO adsorbed on atop sites does not change the surface magnetic anisotropy while occupation of bridge or hollow sites creates the PMA.

We have reported the chemisorption-driven spin reorientation transition of the Co/Pd(111) magnetic thin film by simultaneous measurements of XPS and XMCD on the same system in order to solve the correlation between the surface adsorption structure and the magnetic anisotropy of the thin film. We found that the spin reorientation transition of Co/Pd(111) induced by CO chemisorption is exclusively accomplished by CO adsorbed on bridge or hollow sites and occupation of atop sites has no effect on the spin reorientation transition. We would like to emphasize that if one considers surface magnetic anisotropy of a thin film, it is important to know the surface structure of adsorbates. Because surface adsorption shows various structures under certain conditions, these results allow us to have a new research field between surface chemistry and magnetic thin films.

Abstract

We report on XMCD measurements at the $L_{2,3}$ edges of the early 3d transition metals, Ti, V and Cr, polarized by Fe. In contrast to the classical ferromagnets Fe, Co and Ni, the XMCD spectra reveal a complex and detailed fine structure. We analyze the experimental data with the help of full-relativistic *ab initio* calculations of the X-ray absorption cross section $\mu(E)$ that provide the energy-dependent XMCD spectrum and the correlated magnetic moments μ_s and μ_l. We demonstrate that the use of the so-called integral sum-rules, which interrelate certain areas of the XMCD spectra to μ_s and μ_l, yield erroneous results for the early 3d elements due to 2p–3d core hole correlations in $L_{2,3}$ absorption spectra.

To study the magnetic properties of thin films and magnetic nanostructures the determination of element-specific magnetic moments and the separation into their spin and orbital components (μ_s and μ_l) is one of the striking applications of the X-ray magnetic circular dichroism (XMCD). Concerning the spin and orbital magnetic moments of 3d transition metals (TM's) the magneto-optical sum-rules [1] interrelate certain areas of the $L_{2,3}$ absorption spectra to the magnetic ground state of the d valence shell. Even though certain approximations might limit the validity of the sum-rules [2], it has been demonstrated that they can successfully be applied to the late 3d transition metals (TM's), i.e. Fe and Co bulk metals [3]. In this way orbital and spin magnetism of thin films, multilayers, clusters and one-dimensional chains have been explored by means of XMCD, since most of the magnetic nanostructures are composed of the 3d ferromagnets Fe, Co, and Ni. On the other hand investigations of the induced magnetic moments in the non-ferromagnetic constituent of magnetic multilayers, e.g. Fe/TM with TM = V, and Cr [4, 5], have also attracted considerable interest. The observation of circular dichroism at the L edges of the early 3d TM's can evidence the existence of a net magnetic moment. However, the application of the sum-rules to the early 3d TM's in order to determine quantitatively the spin and orbital moments has several drawbacks: (*i*) The $L_{2,3}$ edges partially overlap which makes a deconvolution of the individual contributions of the L_3 and L_2 edge difficult. (*ii*) The branching ratio, i.e. the fraction of the $2p_{3/2}$ transition channel, strongly deviates from the statistical 2 : 1 due to the 2p–3d core-hole interaction [6]. (*iii*) According to (*i*) and (*ii*) the core hole interaction may become competitive to the small spin-orbit coupling in the core shell (few eV) resulting in apparent spin moments derived by the spin sum-rule. This has been demostrated for Mn, Fe, Co and Ni ions on the basis of atomic calculations [7] where deviations between 30% and 8% were found for Mn and Ni, respectively. (*iv*) Early 3d TM's are either non-magnetic (Ti, V) or antiferromagnetic (Cr) in their bulk configurations and it makes an independent validation of the sum-rule results difficult.

In this work, we extend the discussion of the sum-rule limitations to the early 3d TM's Cr, V and Ti. The question is how information contained in the XMCD spectra can safely be transferred to spin and orbital moments. Contrary to the idea of integral sum-rules, it has been proposed to analyze the spectral line shape of the circular dichroism in more detail [8, 9]. This approach deals with deriving magnetic moments from the absorption fine structure of the circular dichroism which depends on the magnetic ground state properties of the 3d band. For this purpose we compare the experimental absorption spectra to *ab initio* calculations based on a full-relativistic spin-polarized Korringa-Kohn-Rostoker (SPR-KKR) Greens-function method, for details see Ref. [2]. The theory provides both the energy-dependence of the $L_{2,3}$ absorption coefficient $\mu^+(E)$, $\mu^-(E)$ for left- and right-circularly polarized light, respectively, and the corresponding spin and orbital magnetic moments. Recently, we have demonstrated that the application of the spin sum-rule to V-XMCD spectra of a $Fe_{0.90}V_{0.10}$ standard sample yields erroneous moments that are 5 times smaller [10]. Hereby, systematic errors introduced exclusively by the commonly used procedure do not account for the strong deviation. Here, we assign this concept to Ti and Cr in order to provide trends across the 3d series in view of 2p–3d core-hole interaction.

All the samples were prepared *in situ* under ultrahigh vacuum conditions ($\sim 2 \times 10^{-10}$ mbar) by evaporation from high-purity rods on an annealed Fe(110) buffer layer (10 nm) on a Cu(100) single crystal. The Fe/Ti/Fe(110) and Fe/Cr/Fe(110) trilayers were deposited successively at 300 K similar to the prototype Fe/V/Fe(110) trilayers in Ref. [11]. The Fe/V alloy has been prepared by co-evaporation from a triple-e-beam evaporator that allows for individual control of the deposition rates, for details see Ref. [10]. Interestingly, for the Fe/Ti trilayers we observed that the Ti-XMCD signal is independent of the deposited Ti-thickness (<1.5 nm). This suggests that in average all Ti-atoms became equally polarized through Fe. This result can be understood from considering the formation of a $TiFe_2$ structure in our trilayers as it was recently reported for Fe/Ti multilayers in Ref. [12]. The XMCD measurements were carried out at the third generation synchrotron radiation facility of Berlin (BESSY II). At the insertion device beamline UE56/1-PGM the so-called 'gap-scan' technique, driving both the undulator and the monochromator simultaneously, allows for absorption measurements with a constant high degree of circularly polarized light (90%) and high photon-flux in the required energy-range (Ti-Cr: 420–640 eV). The XMCD spectra at the $L_{2,3}$ edges were obtained by reversing the sample magnetization with an electric pulse-driven coil and alternatively, by inverting the helicity of the X-rays. The samples

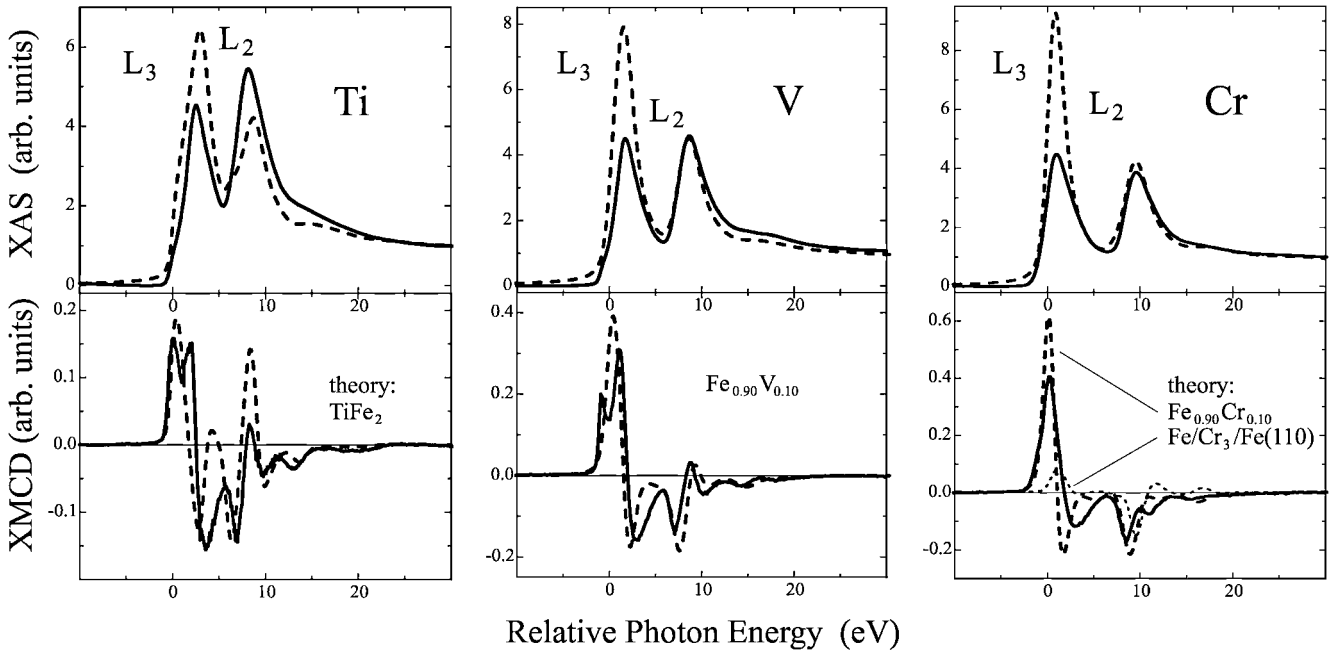

Fig. 1. Normalized (above) XAS and (below) XMCD spectra for the early 3d TM's Ti, V, and Cr at the $L_{2,3}$ edges: (solid lines) experimental data versus (dashed lines) *ab initio* calculations. The experimental data have been corrected corresponding to measurements with 100% circularly polarized light with the *k* vector parallel to the magnetization. Note that scaling factors between theory and experiment as well as between the XAS and XMCD intensities do not exist.

were probed in magnetic remanence using the total electron yield detection mode. The easy-axis of magnetization for all the present samples is in-plane along the [001] Cu direction. Therefore, the absorption measurement were performed under 20° grazing incidence of the X-rays and consequently, all spectra have been corrected for saturation effects. To ensure that the XMCD spectra can be safely transferred to magnetic moments the Fe-XMCD signals have been cross-checked with the one of bulk Fe/Cu(001).

In Figure 1 the experimental XAS and XMCD spectra (solid lines) are presented for Ti, V and Cr at the $L_{2,3}$ edges together with the *ab initio* calculations (dashed lines). The positive onset of the dichroism at the L_3 edge reveals antiparallel orientations of the net magnetization of Ti, V, and Cr with respect to Fe in agreement with theory. Because core-hole correlation effects [6] were not taken into account in the calculations, the branchings ratios in the XAS spectra for the experiment and theory are different. Those effects result in a transfer of spectral weight in favor of the L_2 edge and govern the XAS spectra of 3d TM's towards lower d-counts as it can be clearly observed in Figure 1. The overlap of the $L_{2,3}$ edges hinders to distinct band-structure related features in vicinity to both edges. However, there are broad satellites slightly above the L_2 edge that stem from van Hove singularities in the bcc-Brillouin zone identified by the theory.

The XMCD spectra (average of 4 couples) are almost free of noise bringing the detailed absorption fine structure to light. For the investigated samples, the XMCD to XAS peak height ratio at the L_3 edge is ∼3%, ∼7%, and ∼9% for Ti, V, and Cr, respectively. In contrast to the ferromagnets Fe, Co and Ni the XMCD spectra of early 3d TM's show dispersive line shapes at the $L_{2,3}$ edges. The lower the filling of the d-valence band the more the peaks become asymmetric. In case of Ti we can demonstrate that the XMCD signal even turns completely asymmetric. This tendency across the 3d series has been modeled in terms of multipole moments of the ground state [8]. A better description of the energy-dependent XMCD spectrum can be obtained including band-dispersion [9, 10] as it is shown in Figure 1. Interestingly, calculations of the XMCD spectrum assuming perfect interfaces for the $Fe/Cr_3/Fe$ sample reveal a different XMCD spectrum. However, the agreement with the experiment improves considering partly interdiffused interfaces which in turn demonstrates the sensitivity of the XMCD signal to the electronic band-structure. Hence, we included the theoretical spectra for a $Fe_{0.90}Cr_{0.10}$ alloy serving as a reference in Figure 1. Furthermore, the theory can separately evaluate contributions of the L_3 and L_2 edge. This allows for a rough deconvolution of the edges in experimental spectra and give an estimate for systematic errors of the spin sum-rule. In correspondence to the XAS spectrum the circular dichroism for Ti, V, and Cr reveals an oscillatory fine structure above the L_2 edge that originates from the spin-dependent band structure and is perfectly reproduced by the calculations. On the other hand, the splitting of the L_3 peak in the experimental XMCD spectrum for Ti and V can be attributed to multiplets. The atomic-like features indicate that the 3d electrons remain partly correlated in early 3d TM's which might be supported by the fact that the features are missed by the SPR-KKR calculations.

The theory provides both the XMCD to XAS peak ratios and the corresponding spin and orbital magnetic moments which are listed in Table I. In order to test the validity of the integral sum-rules we compared those values with the one derived from the application of the commonly used procedure, for details see e.g. Ref. [3, 10]. The number of d-holes was taken from theory being 7.36, 6.44, and 5.45 per atom for Ti, V, and Cr, respectively. Instead of separating the $L_{2,3}$ contributions we used a simple energy cut-off determined by the local minimum between the edges. In case of V we recently reported the breakdown of the spin sum-rule since the apparent spin moments deviate by a factor 5 with respect to theory [10] and polarized neutron studies [13]. The V orbital moment shows reasonable agreement with theory, even the antiparallel alignment of the spin and orbital moments can be correctly deduced. Note that the orbital sum-rule can be applied

Table I. *The apparent magnetic moments derived by application of the sum-rules to the experimental data and the spin and orbital magnetic moments as calculated by ab initio theory corresponding to the theoretical XAS and XMCD spectra in Fig. 1. The spin moment ratio R reveals a considerable underestimation of the 'real' values by the sum-rule analysis, see text.*

	theory		sum-rules		
	μ_s (μ_B)	μ_l (μ_B)	μ_s (μ_B)	μ_l (μ_B)	R
Ti	−0.70	0.014	−0.17	0.069	0.24(10)
V	−1.01	0.020	−0.20	0.016	0.20(3)
Cr	−0.95	0.014	−0.28	0.011	0.47(15)

without deconvoluting the $L_{2,3}$ edges. Ti acquires an induced spin moment of $-0.7\,\mu_B$ predicted by theory for the Fe_2Ti structure. Even though the XMCD to XAS peak ratios are in reasonable agreement between experiment and theory the spin sum-rule fails similar to V. The experimental Cr data indicate a magnetic moment of about $-0.6\,\mu_B$ in comparison with the $Fe_{0.90}Cr_{0.10}$ reference and with XMCD measurements on Fe/Cr trilayers reported by Idzerda *et al.* [5], while the application of the spin sum-rule yields $-0.28\,\mu_B$. Finally, the apparent spin moment (sum-rule) to expected spin moment ratio R is given in Table I. It appears that going towards the late 3d elements the deviation of the spin sum-rule reduces systematically from 80% (Ti) to 50% (Cr) while it varies for the late 3d ions between 30% (Mn) to 8% (Ni) in atomic calculations [7]. The deviation of the spin sum-rule is related to the remixing of the 2p transitions channels and elucidates why the sum-rule holds for Fe and Co [3]. In case of the early 3d TM's the influence of the core hole is much stronger, because the core hole interaction increases with the vacancy of the d-band while the spin-orbit coupling in the core shell decreases. It is valuable to note that the orbital sum-rule provides the correct sign. This means accordingly that the spin and orbital moments are antiparallel aligned for Ti, V and Cr and aligned in parallel for Fe and Co in agreement with the theoretical expectations.

In summary we have compared state-of-the-art experimental XMCD measurements with *ab initio* theory. This allows a detailed analysis of the fine structure in the $L_{2,3}$ absorption spectra and moreover, provides the XMCD-related spin and orbital magnetic moments. The absorption fine structure of early 3d TM's reveal band-structure-related features as well as multiplet structures. We have extended the discussion of the validity of the spin sum-rule to the early 3d TM's which suffer from 2p–3d core hole correlations in $L_{2,3}$ absorption measurements. We give quantitative deviations of the sum-rules that allows to estimate realistic magnetic moments from XMCD spectra.

Abstract

We report on a polarized X-ray absorption spectroscopy study, combining experimental measurements and *ab initio* calculations, of $La_{0.7}Sr_{0.3}MnO_3$ films, epitaxially grown on tensile and compressive substrates. Measurements show significant modifications in the coordination shell around manganese atoms in the film plane for both substrates. We show that biaxial strain is locally accommodated in the coordination shell, by distortion of the MnO_6 octahedron, without change in the tilt angle. The modifications of the near edge spectra were correlated to modification in the average Mn−O bond distance and distortion of the MnO_6 octahedra. This distortion tending to localize the charge carriers may account for the decrease of the Curie temperature observed in thin films with respect to bulk systems.

1. Introduction

Among the materials exhibiting the Colossal Magnetoresistance effect [1], mixed manganite films have received special attention due to their potential application for a new generation of magneto-electronic devices [2]. From a fundamental point of view they show a variety of interesting phenomena due to the interplay of several, opposite magnetic interactions highly correlated with the crystal structure and the hole doping (metal-insulator transition, charge ordering, orbital ordering, phase segregation . . .). Moreover, high quality thin films of manganites can be brown using deposition techniques similar to the ones developed for high-TC superconductors. Structural and magnetic studies of thin films on slightly mismatched substrates have showed significant sensitivity of manganite properties to the induced strain. The temperature of the ferromagnetic transition, for example, has been observed to decrease as the external strain is increased. This would open up large possibilities to the design of tunable magnetic devices, if it were possible to address the explicit connection between the cell induced strains and the local structure around the manganese atoms, the Mn−O distances (coordination length) and the Mn−O−Mn angle (octahedral tilt), key parameters for the versatility of the magnetic and transport properties. X-ray absorption spectroscopy has been already used to investigate local order around the manganese atoms in some manganites films [3, 4], but there is no consensus yet about the relative importance of these two key parameters.

We report here on a polarized X-ray absorption spectroscopy study in $La_{0.7}Sr_{0.3}MnO_3$ (LSMO) thin films epitaxially grown on tensile and compressive substrates. Experimental measurements and *ab initio* calculations were combined to elucidate the strain induced local modification around the manganese ions.

2. Experimental

LSMO thin films (pseudo-cubic perovskite structure, $a = 3.87$ Å) were epitaxially grown by pulsed laser deposition under tensile ($SrTiO_3$ (STO) [001]) and compressive ($LaAlO_3$ (LAO) [001]) substrates with cubic and pseudo-cubic structures ($a = 3.905$ Å and $a = 3.793$ Å respectively). The low lattice mismatch between LSMO, STO and LAO allows a pseudomorphic growth for film thickness below 100 nm and 50 nm respectively [5]. MgO substrate (cubic, with $a = 4.21$ Å) was used to obtain a non pseudomorphic 3d-texturized fully relaxed film. For similar thickness the strain factor ($\epsilon_{zz} - \epsilon_{xx}$, see table I) is about twice for the film grown on LAO than for the film grown on the STO substrate.

The X-ray absorption experiments at the Mn K-edge (6539 eV) were performed at the LNLS D04B-XAS beamline using a Si (111) channel-cut crystal monochromator. The incident beam was monitored by an ion chamber and the data were collected in fluorescence mode using a Ge 15-elements solid state detector. Selective information about the bonds in a plane parallel to the film surface (IP) and perpendicular to this plane (OP) of the same film are obtained by setting the angle between electric field vector of the incident photon beam and the film surface to values close to 0 and 90 degrees (10 and 75 degrees, respectively).

3. Results and Discussion

Figure 1 shows XANES spectra of the tensile (STO substrate) and compressive (LAO substrate) strained films. The energy shift at the spectra collected can be associated to local changes on average Mn−O bond distance. We should note that the shifts for the tensile and compressive films are in opposite directions. For LSMO/STO the negative energy shift (−0.4 eV) shows that the Mn−O bond length is larger in the IP plane, as compared to the OP plane. On the contrary, in the film under compressive strain, LSMO/LAO,

Table I. *Strain components ε_{xx} and ε_{zz} (defined as $\epsilon_{xx} = \epsilon_{yy} = \frac{a_{film} - a_{ref}}{a_{ref}}$ and $\epsilon_{zz} = \frac{c_{film} - c_{ref}}{c_{ref}}$) in LSMO films.*

Substrate	film thickness	$\epsilon_{xx} = \epsilon_{yy}$	ϵ_{zz}
$SrTiO_3$ (STO)	60 nm	0.9%	−0.8%
MgO (MO)	60 nm	0%	0%
$LaAlO_3$ (LAO)	45 nm	−2.0%	2.3%

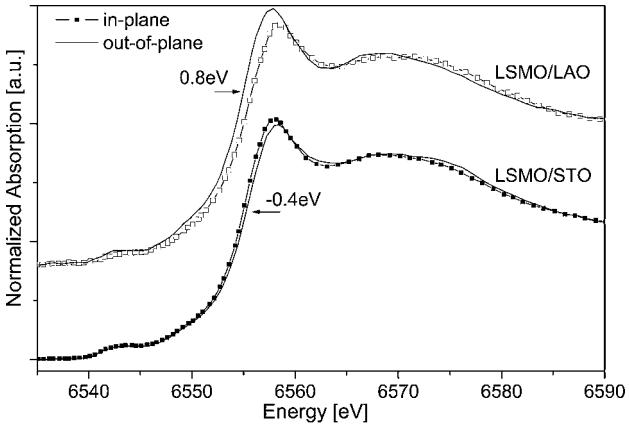

Fig. 1. Near Edge X-ray absorption spectra at the Mn K edge for the tensile ($SrTiO_3$) and compressive ($LaAlO_3$) LSMO film in plane and out of plane measurements. The energy shifts are in opposite directions and differ by a factor 2.

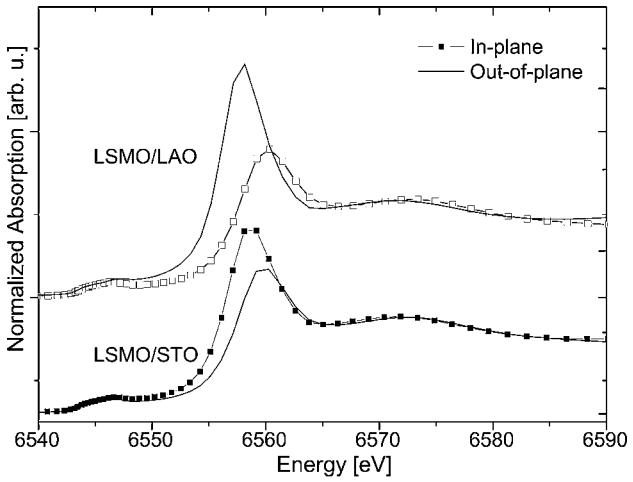

Fig. 2. XANES *ab initio* calculations of the LSMO structure in the compressive and tensile films, considering tetragonal distortion of the Mn−O octahedron. Comparison between the in plane and out of plane orientations for each film.

the positive energy shift (+0.8 eV) indicates that the Mn−O bond length is smaller in IP plane than in the OP plane of the film.

Moreover the amplitude of the shift for the LSMO/LAO film is about twice that for the LSMO/STO one and of the same order as the ratio of the long range strain factor among these films ($\epsilon_{zz} - \epsilon_{xx}$, on table I). The strain on the cell parameters is then directly related to average octahedral modifications. This indicates that the strain should be fully accommodated by changes in the coordination shell (Mn−O), without any modification of the Mn−O−Mn angle.

Slight modifications of the first line shape and intensity are observed in the XANES spectra. Such modifications already reported in the literature have been associated to distortions of the local structure.

We performed *ab initio* simulations using the full multiple scattering approach, to investigate the effect of octahedral distortion on the XANES spectra. Self-consistent calculation of the atomic potentials were performed using the Feff8.2 code [6]. The real part of the potential is modeled by an exchange-correlation Hedin-Lundqvist potential. All calculated absorption spectra were normalized by the value at 50 eV above the absorption edge allowing the *ab initio* calculations to be compared in position and intensity. Simulations were performed in a LSMO cluster considering isotropic MnO_6 and anisotropic distortions. The calculations shown in figure 2 were performed for clusters with tetragonal distortion using local order parameters scaling with the cell parameters of the films. The calculations do not take into account structural disorder or dispersion of the Mn−O length, so that for the calculated XANES spectra the differences in amplitude are higher and the rising slope steeper than in the experimental data. With this restriction, the calculated structures (figure 2) reproduce well the main differences in the features of the experimental results (figure 1) among the two orientations of the films: the energy shift amplitude and direction, and the relative reduction of the amplitude of the white line. Based on these calculations we can then certify that a model of anisotropic distortion of the MnO_6 octahedron accounts for the experimental XANES spectra.

In the LSMO system, the contribution of the spontaneous energy-lowering Jahn-Teller distortion of the $Mn^{3+}O_6$ is too small to be associated to a measurable average octahedral distortion. The substrate strain induces a larger and measurable static anisotropic distortion of the MnO_6 octahedron, with splitting of the in-plane and out-of-plane Mn−O bond lengths. This distortion leading to an increase of the splitting of the e_g levels, tends to localize the charge carriers and may account for the decrease of the Curie temperature observed in thin films with respect to bulk systems [5] .

We must point out that the XANES modifications are mainly correlated with modifications on the O−O−O angle (between the oxygens of the octahedron) by splitting of the Mn−O bond length. This splitting can appear due to different in-plane and out-of-plane bond lengths, as occurred for a tetragonal local distortion of the MnO_6 octahedron, but also in more complex distortion, as for example an orthorhombic distortion, were different Mn−O bond lengths are in the film plane. This later non-isotropic distortion in the plane may take place due to the nature of the Mn^{3+} and Mn^{4+} ions and is suggested by our EXAFS study [7]. Unfortunately, the change in the density of unoccupied states between these two situations is very small and *ab initio* calculations yield almost the same results for tetragonal and orthorhombic distortions.

4. Conclusions

In summary, we present here a combination of experimental measurements and *ab initio* calculations of polarized X-ray absorption to investigate the local scale structural distortion induced by substrate strain around manganese atoms in $La_{0.7}Sr_{0.3}MnO_3$ films. We show that biaxial strain is locally accommodated in the coordination shell, by distortion of the MnO_6 octahedron, without change in the tilt angle.

Abstract

To study pressure-induced ferromagnetic state in Mn_3GaC perovskite, we have performed X-ray absorption spectroscopy (XAS) and X-ray magnetic circular dichroism (XMCD) spectroscopy at the Ga *K*-edge under high pressure up to 29.4 GPa at room temperature. Ga *K*-edge XMCD was observed under pressure ranging from 4.5 to 29.4 GPa and results indicate that the Ga atom is magnetically polarized under high pressure. From the XMCD spectral profile, it is suggested that the pressure-induced ferromagnetic state has a canted ferromagnetic structure.

1. Introduction

The Mn_3MC (M = Al, Zn, Ga, In and Sn) system shows characteristics typical of itinerant-electron system and has received extensive interest because it exhibits a great variety of magnetic phase transitions [1]. In particular, Mn_3GaC shows a first-order phase transition at $T_t = 170$ K from a ferromagnetic (F) phase to an anti-ferromagnetic (AF) phase upon decreasing temperature [1–4], and in the AF phase metamagnetism occurs under high magnetic fields [5]. In addition, pressure-induced ferromagnetism has been reported near the Curie temperature T_C; when pressure is applied, magnetization is significantly enhanced and the T_C increases above the value of 260 K observed at ambient pressure (AP) [4]. To date, there is no evidence for the existence of magnetically polarized states.

The crystal structure of Mn_3GaC is cubic-perovskite type. Mn atoms occupy the face centers of the cubic lattice formed by Ga atoms, and C atoms are sited at the body-centered position. According to neutron diffraction experiments [3], the Mn moments are aligned along the [111] direction and coupled parallel (antiparallel) with the adjacent (111) planes in the F (AF) phase. Kaneko *et al*. [4] measured the AC susceptibility of Mn_3GaC under high pressure and found an intermediate magnetic structure between the AF and F phases. Furthermore, it was found that high pressure led to an increase in T_C and an enhancement of the F state. Kamishima *et al*. [6] recorded magnetization curves for the same substance under pulsed high magnetic field and found that pressure stabilized the F phase and enhanced the Mn moment in the F phase. They have pointed out that large spin fluctuations may play an important role in the anomalous increase of the Mn moment with pressure. However, their investigation was restricted within a relatively low-pressure region (<1 GPa) because of the difficulty in performing magnetization measurement or neutron diffraction using a high-pressure diamond-anvil-cell (DAC). Therefore, a spectroscopic method is needed to investigate the magnetic properties under high pressure using a DAC.

X-ray magnetic circular dichroism (XMCD) has attracted much interest as a tool to investigate magnetic states [7]. It is accepted that *K*-edge XMCD spectrum arises from the $4p$ orbital polarization induced by mixing with the $3d$ states of neighboring sites [8, 9]. It is possible to observe XMCD for non-magnetic constituents, because the p states of non-magnetic atoms may be polarized by the $4p$-$3d$ hybridization with neighboring magnetic atoms. Recently, Ishimatsu *et al*. established a method for measuring XMCD using a DAC [10, 11]. Then we applied this method for studying the electronic and magnetic states of Mn_3GaC under high pressure. XAS and XMCD spectra at the Ga *K*-edge were measured at room temperature (RT) up to a pressure of 29.4 GPa. In this paper, we present pressure-dependent XMCD spectrum at the Ga *K*-edge, and discuss the magnetic structure from the viewpoint of Mn electronic states.

2. Experimental

XMCD experiment were performed using the helicity-reversal method under a fixed magnetic field of 0.6 T and were carried out at the beamline 39XU of SPring-8 [12]. X-rays emitted from a linear undulator were monochromatized by Si 111 double crystals and higher harmonics rejected by a Pt coated mirror. Circularly polarized X-rays were generated using a diamond X-ray phase plate [13], 2.7 mm thick. The circularly polarized X-ray beam passed through a slit of aperture 70 × 70 μm. High pressure was applied using a DAC made of Cu-Be alloy [10]. A pair of diamond anvils, 1.0 mm thick and 0.45 mm in culet diameter, was used. Mn_3GaC powder was loaded into a hole in a SUS gasket together with several pieces of ruby and a methanol/ethanol mixture (4 : 1) as a pressure medium. The generated pressure was monitored using the ruby fluorescence method. Incident and transmitted beam intensities were monitored using an ionization chamber with flowing N_2 and Ar gases, respectively. All measurements were performed at RT.

The XMCD spectrum was recorded near the Ga *K*-edge (E_0 = 10.367 keV) at energy intervals of 0.5 eV. To obtain a thickness-independent spectrum, XAS was normalized at the higher energy region, which is the conventional method.

To determine the compressibility of Mn_3GaC at RT, X-ray diffraction (XRD) experiments under high pressure were performed at BL04B2 [14]. This beamline is dedicated to high pressure XRD experiments, and utilizes an imaging plate system for the data acquisition. Sample quality and crystallographic phase were also verified by XRD measurements.

3. Results and Discussion

Figure 1 (a) shows the pressure variation of the XAS spectrum at the Ga *K*-edge in Mn_3GaC as a function of X-ray energy.

*e-mail: naochan@spring8.or.jp

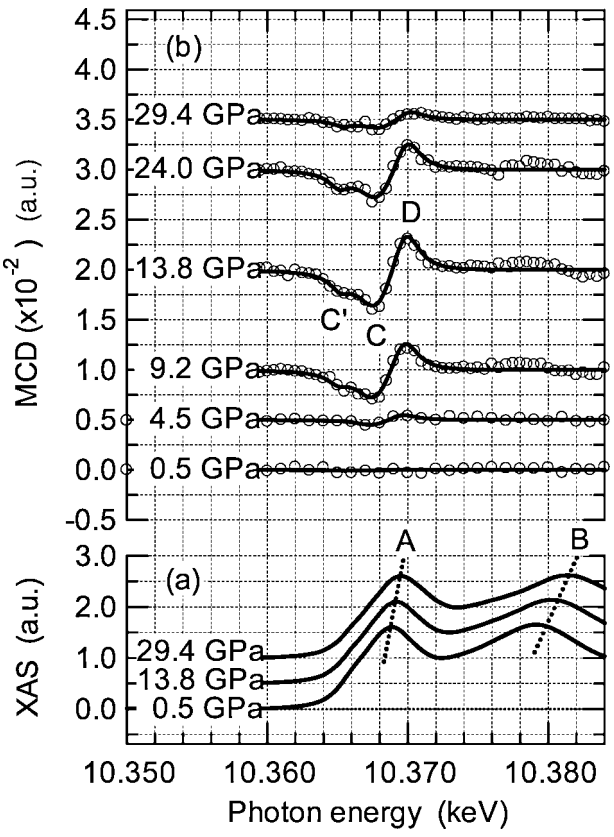

Fig. 1. Pressure variation of (a) XAS and (b) XMCD spectra at the Ga *K*-edge in Mn_3GaC.

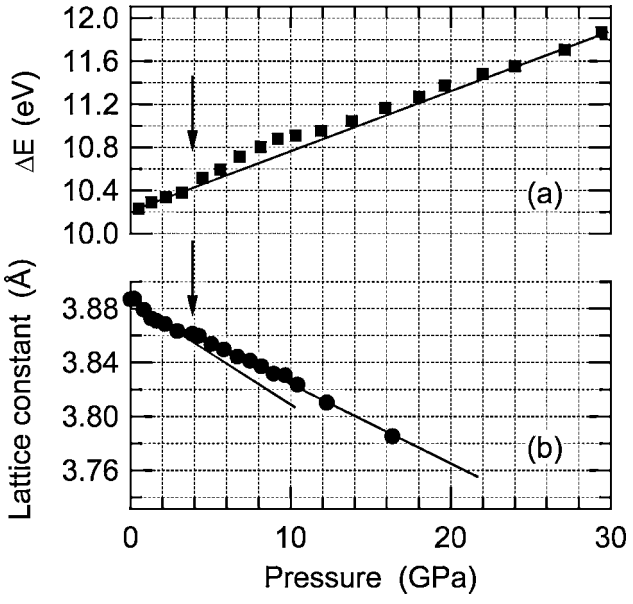

Fig. 2. (a) Energy difference ΔE between peak A and B in the XAS spectrum of Mn_3GaC (see in Fig. 1 (a)), and (b) lattice constant as a function of applied pressure. Solid lines are for an eye-guide.

The XAS spectrum consists mainly of two peaks, labeled A and B. The energy difference between the peaks (ΔE) is about 10.0 eV at 0.5 GPa. At higher pressure, the peaks A and B shift to higher energy and ΔE becomes larger. The plot of ΔE as a function of applied pressure (Fig. 2 (a)) shows that ΔE increases approximately linearly with increasing pressure. Closer inspection reveals that ΔE deviates from linearity in a convex manner above 4.5 GPa (indicated by an arrow). The lattice constant of Mn_3GaC decreases in an approximately linear manner with increasing pressure (Fig. 2(b)) but is more accurately described by two lines of distinct slope for pressures above and below 4.5 GPa. These anomalies are probably related to the ferromagnetic state resulting from the pressure applied over 4.5 GPa. For both XAS and XRD experiments, it was confirmed that the crystal structure was preserved over the pressure range.

Figure 1 (b) shows the variation with pressure of the XMCD spectrum at the Ga *K*-edge in Mn_3GaC. In the pressure range from AP to 4.5 GPa, there is no significant XMCD signal because the Mn_3GaC exists in a paramagnetic state. As more applied pressure is augmented, a dichroic spectrum appears resulting from induced polarization in the Ga $4p$ states. This XMCD profile is characterized by a dispersion-type profile changing form negative to positive sign with three peaks apparent: a negative peak (labeled C) with a smaller peak at lower energy (labeled C′) and a positive peak (labeled D). When the pressure is increased furthermore, the XMCD intensity grows until it reaches a moderate maximum at 13.8 GPa, after which it begins to gradually decrease. The dichroic signal does not disappear even at 29.4 GPa; the critical pressure to suppress the dichroic signal is estimated by extrapolation to be 32 GPa.

According to the magneto-optical sum rule for *K*-edge [8], the integrated intensity of the XMCD spectrum can be related to the expectation value of orbital angular momentum of p states. For the spectra in Fig. 1 (b), energy integration yields a negative intensity, although the value is very small. Therefore, the $4p$ moment of Ga atom is aligned parallel with the magnetic field. It is reasonable to explain Ga $4p$ polarization as being caused by $4p$–$3d$ hybridization with Mn $3d$ states at neighboring sites.

The magnetic structure under high pressure can be predicted from the spectral profile of XMCD. Experiments observing the effects of the temperature variation of the XMCD spectrum were performed at the *M K*-edge for Mn_3MC (M = Zn and Ga) under AP and results indicate that the XMCD spectral profile is closely associated with magnetic structure resulting from the magnetic states of Mn atoms [15]. This study suggests that under high pressure Mn_3GaC has a canted ferromagnetic (CF) structure because of two observations: (1) The existence of the additional peak C′ is a similar feature to the spectral profile at the Zn *K*-edge of Mn_3ZnC in a CF phase, and (2) the observed maximum XMCD intensity of 0.34% is smaller than the 0.6% intensity observed for the F phase at 200 K under AP. On the assumption that T_C linearly increases with pressure, it is predicted that an F phase has a critical pressure of 10 GPa from the results of Kaneko *et al.* [4]. However, the observed value of 4.5 GPa is much lower, so that it is suggested that a new magnetic phase exists under high pressure.

Figure 3 shows the intensity of peaks C and C′ as a function of the applied pressure. The peaks were decomposed using a multi-Lorentzian method. From this figure it is observed that peaks C and C′ exhibit the same behavior under pressure. In Mn_3ZnC, the intensity of peak C′ decreases with temperature in the CF phase, while that of peak C increases [15]. This difference may be attributed to the correlation between the magnitude of Mn magnetic moments and the canted angle of these moments in the CF phase.

According to the band calculation for Mn_3MC (M = Zn, Ga, In and Sn) by a self-consistent augmented plane wave method [16], the number of electrons in the M atom leads to a shift of the Fermi level, although the type of M atoms does not affect the overall shape of the density of states. The compression of interatomic distance when pressure is applied changes the density of states around the Fermi level. The magnitude in overlap

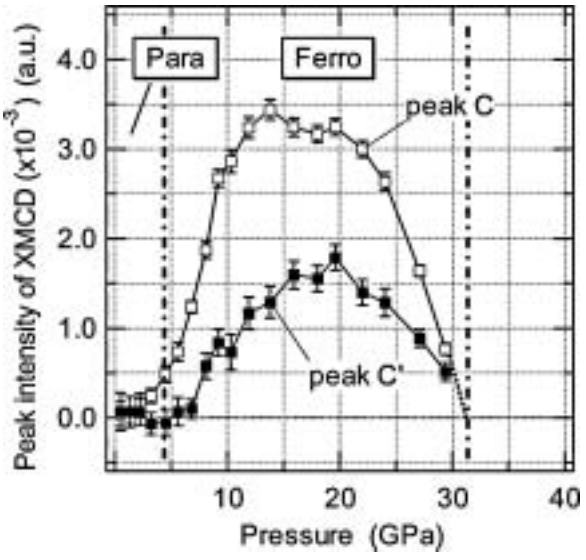

Fig. 3. The XMCD intensities of the peaks C and C′ as a function of pressure, after multi-Lorentzian curve fitting. Error bars indicate standard deviation of the fit.

between Mn 3*d* and Ga 4*p* orbitals is considered to play an important role in the underlying mechanism of the appearance of magnetism in the Mn_3MC system.

4. Conclusions

We have measured the pressure variation of XAS and XMCD spectra near the Ga *K*-edge at RT. The XMCD spectrum has been observed under pressures ranging from 4.5 to 29.4 GPa and the critical pressure that suppresses the dichroic signal is estimated to be 32 GPa. An anomaly in the result of XAS and XRD experiments has also been observed at about 4.5 GPa, and is related to the existence of a pressure-induced ferromagnetic phase. Ga 4*p* polarization is thought to originate from 3*d* polarization at neighboring Mn atoms, and for the Mn_3GaC system, calculation using the sum rule reveals the 4*p* moment is aligned parallel with the magnetic field. Consideration of the spectral profile suggests that the magnetic structure in the ferromagnetic phase is a canted ferromagnetic structure similar to that of Mn_3ZnC in low temperature phase.

Mn_3GaC exhibits interesting magnetic characteristics under high pressure near temperature T_t. Further detailed investigation, including theoretical calculation, is required to elucidate the relationship between the observed magnetism and Mn 3*d* and Ga 4*p* electronic states in different environments.

Abstract

The geometric and electronic local structure of $LaMnO_3$ across the cooperative Jahn-Teller (JT) transition at $T_{JT} = 750$ K has been studied by means of X-ray Absorption Near Edge Structure (XANES) and Extended X-ray Absorption Fine Structure (EXAFS) at the Mn K-edge. XANES spectra, as a function of temperature, do not show significant changes either in the pre-peak structures or at the absorption edge indicating similar electronic local structure for the Mn atom above and below T_{JT}. Analysis of the EXAFS spectra shows that dynamical tetragonal JT distortion of the MnO_6 octahedron is also present above T_{JT}. The structural transition is explained in terms of an orientated ordering of tetragonal distorted octahedral complexes. Above T_{JT}, the e_g electron jumps between the three degenerate vibronic states being localized and ordered below the transition.

1. Introduction

Rare-earth manganite perovskites have recently been the focus of a large number of experimental and theoretical studies [1]. This is due to the extraordinary magnetic, electronic and structural properties such as colossal magnetoresistance, different crystallographic phases (the so-called charge ordering phases) or structural changes induced by applying a magnetic field. In spite of the large number of studies performed, there is lack of a unified explanation for this large and rich phenomenology. One of the main ingredients which seems to be responsible of these properties is the existence of Mn^{3+} in octahedral coordination. This ion is unstable to the local octahedral symmetry through the Jahn-Teller effect. The distortion removes the degeneracy of the e_g orbitals in the $t_{2g}{}^3e_g{}^1$ electron configuration of the Mn^{3+} ions and stabilizes the $3d_{3z2\text{-}r2}$ orbital respect to the $3d_{x2\text{-}y2}$ one.

At ambient conditions stoichoimetric $LaMnO_3$ is a paramagnetic insulator with orthorhombic perovskite structure (space group *Pbnm* [2, 3]). The structure, can be described as formed by tetragonal distorted MnO_6 octahedron disposed in such a way that long and short Mn-O bonds alternate in the *ab* plane along the Mn-O-Mn path. In terms of the Jahn-Teller coupling, the ordering of distortions implies a spatial ordering of d-orbitals. Upon heating, $LaMnO_3$ undergoes a structural phase transition at $T_{JT} = 750$ K above which the orbital ordering disappears [3, 4]. This transition is accompanied by an abrupt change in the electrical resistivity, thermoelectric power and Weiss constant at T_{JT} [5].

Several mechanisms have been proposed to explain the orbital ordering in 3d transition metal oxides with orbital degeneracy. Some authors attribute it to the superexchange interaction between atoms in different sites [6, 7]. Other authors instead, locate its origin in cooperative Jahn-Teller effect where the lattice distortion occurs cooperatively and lifts the orbital degeneracy at the transition metal ion [8, 9]. Other mechanisms, including the combined influence of superexchange and electron-phonon interactions have also been proposed [10]. In spite of the theoretical effort to understand the orbital ordering in $LaMnO_3$ [6–10], direct experimental evidences shedding light on the mechanism responsible for the structural transition at $T_{JT} = 750$ K are not still provided. High resolution neutron diffraction experiments show that above T_{JT} the MnO_6 octahedron becomes nearly regular and the thermal parameters of the oxygen atoms are anomaly high, although there is not change of crystal symmetry [3]. The observed pseudocubic lattice would arise from the average of dynamic spatial fluctuations of the orthorhombic distortion. This result was the origin of the Zou and Goodenough [5] vibronic mechanism proposed to explain the electrical conductivity above T_{JT}.

Within this work, we study the electronic and local structure across the cooperative Jahn-Teller transition by X-ray absorption spectroscopy at the Mn K edge. We will show from the XANES and EXAFS spectra that the MnO_6 octahedra are locally distorted above T_{JT}, so the structural phase transition can reasonably be described as an ordering of local distortions that are thermally disordered above T_{JT}.

2. Experiment

The preparation and characterization of stoichiometric $LaMnO_3$ was reported elsewhere [2]. X-ray absorption experiments were performed at the ESRF's beamline BM29 (Grenoble, France). Pellets were prepared by mixing the powdered samples with boron nitride in order to optimize the thickness. A fixed-exit Si(311) double-crystal monochromator was used, the estimated energy resolution being $\Delta E/E = 7 \times 10^{-5}$. Spectra were recorded in transmission mode using ionization chambers as detectors. Another $LaMnO_3$ pellet was simultaneously measured at room temperature for energy calibration. A Displex cryostat from Oxford Instruments was used for low temperature measurements (20 K–300 K), whereas high temperature experiments were performed with a furnace.

XANES spectra were normalized to the high part of the spectrum (100 eV) after a linear background subtraction [11]. EXAFS spectra ($\chi(k)$) were obtained by removing the smooth atomic absorption coefficient (μ_0) by means of a cubic spline [14]. The spectra were analyzed using the FEFF 8.10 code that allows to correlate the Debye-Waller factor (D-W) with the interatomic distances. The structural analysis was performed in *R*-space fitting mode including multiple scattering terms up to 4 Å [12].

3. Results and Discussion

XANES spectra for several temperatures below and above T_{JT} are shown in fig. 1. The spectral shape for $LaMnO_3$ shows two

*E-mail: jgr@posta.unizar.es

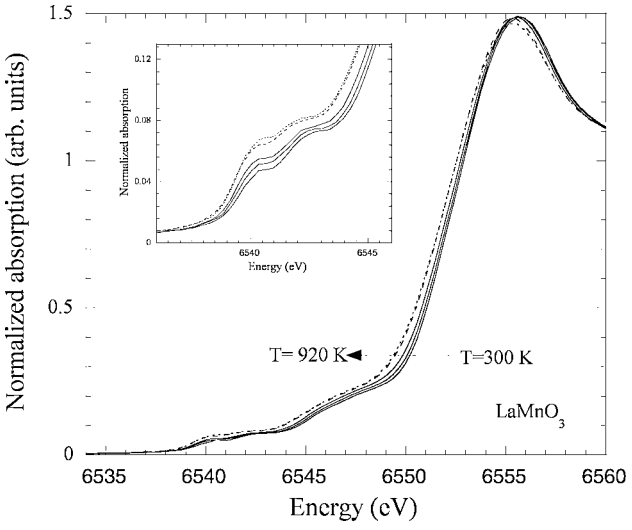

Fig. 1. Normalized XANES spectra of $LaMnO_3$ as a function of temperature. A small shift of the spectra is shown increasing temperature. Solid and dashed lines correspond to spectra taken below and above T_{JT} respectively. Inset shows a detail of the pre-peak structures.

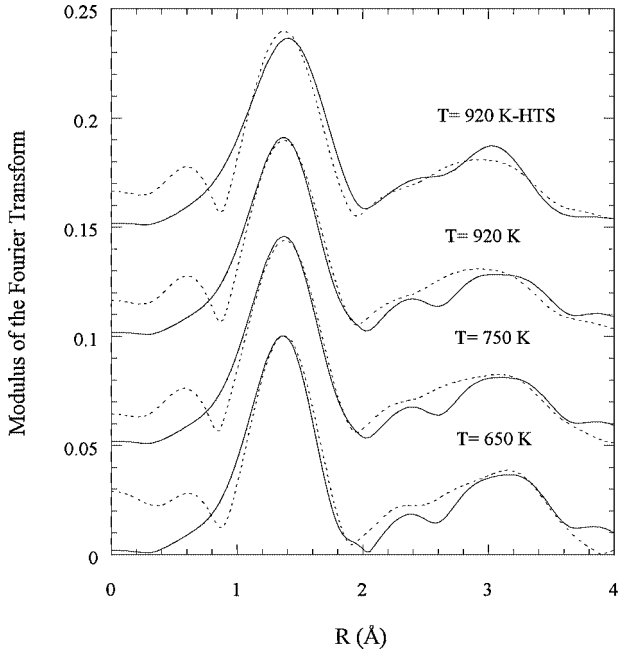

Fig. 2. Fourier Transform of the EXAFS spectra (discontinuous line) measured at temperatures closed T_{JT} and the best-fit simulation (continuous line) with the FEFF 8.10 package. Upper figure shows the best fit simulation at 920 K, above T_{JT}, using the high temperature crystallographic structure (HTS).

separate regions: The pre-edge region related with transitions to empty Mn d-states due to the covalency with the adjacent oxygen p-states and the main-edge region corresponding to dipolar transitions to the empty Mn p-band. The spectra at different temperatures are very similar to each other indicating that no large changes of the local electronic structure occur between 300 and 920 K. We note that the spectra shift to lower energies with increasing temperature, the maximum shift being of about 0.5 eV. These small differences can be ascribed to minor thermal effects: An increase of atomic vibration leads to a smoothing of the absorption features. Accordingly, an apparent shift of the absorption edge and an increase of the broadness of the main peak are observed. Moreover, as it is shown in the inset, the same pre-edge features are observed above and below the transition temperature showing that the splitting of the projected d-states occurs above T_{JT}.

EXAFS spectra of $LaMnO_3$ were recorded at fixed temperatures from 20 K up to 920 K. The spectra at low temperatures ($T < 300$ K) were measured up to $k = 12\,\text{Å}^{-1}$ in order to obtain reliable structural parameters. The Fourier Transforms of the spectra above and below T_{JT} are shown in fig. 2. We observe that the intensity of the different peaks, associated to different coordination shells, decrease with increasing temperature. This is expected for a standard evolution due to the increase of the thermal motion. It is noteworthy that no discontinuity was observed in the EXAFS spectra at T_{JT}, indicating a similar local structure for the Mn^{3+} ions above and below T_{JT}. If the tetragonal distortion disappeared at the phase transition, an increase of the intensity of the first oxygen shell peak should be expected above T_{JT}, reflecting a more symmetrical oxygen environment. In order to verify it, we have performed an accurate quantitative study. First, we have analyzed the first oxygen coordination shell by fitting the Fourier filtered first-shell contribution between 1 and 2 Å, at different temperatures. We have used the signal obtained from the room temperature EXAFS spectrum as reference. The Fourier filtered signals can be well reproduced from the room temperature spectrum by changing only the relative D-W ($\Delta\sigma^2$) factor. $\Delta\sigma^2$ increases with increasing temperature as expected for a system without changes in the local structure. In order to quantify the tetragonal distortion, we have fitted the spectra using the FEFF 8.10 code's theoretical amplitudes and phases. First and second coordination shells were included in the fitting process and multiple scattering paths were also considered. Fig. 2 shows the best-fit results for spectra in the neighborhood of T_{JT}. The obtained interatomic Mn-X (X = O, Mn, La) distances agree with the crystallographic values, except for $T > T_{JT}$. Our results show that the MnO_6 octahedron remains tetragonal distorted above T_{JT}. For instance, the interatomic distances resulting from the fit at 840 K are, $d(\text{Mn-O}_{\text{short}}) = 1.92$ Å, $d(\text{Mn-O}_{\text{long}}) = 2.13$ Å, $d(\text{Mn-Mn}_{\text{short}}) = 3.85$ Å, $\text{d(Mn-Mn}_{\text{long}}) = 4.01$ Å, similar to the values at room temperature. As comparison, we have performed the fit with the symmetric interatomic distances obtained of the crystallographic data at temperatures above T_{JT} [3]. It is observed that the fit is worse that the one using the crystallographic data at room temperature (i.e. tetragonally distorted MnO_6 octahedra). Moreover, the obtained Debye-Waller factor for this fit is anormally high, $\sigma^2 = 16 \times 10^{-3}\,\text{Å}^2$ (comparable to the tetragonal distortion). Fig. 3 shows the D-W factors of the different Mn-X contributions as a function of temperature. It is worth mentioning that long and short Mn-X bonds show close D-W factors, as expected. A small change in the $\sigma^2(T)$ evolution is observed at the phase transition for the Mn-O, Mn-La and Mn-Mn shells indicating the occurrence of the phase transition.

In conclusion, EXAFS spectra demonstrate that the MnO_6 octahedron is also tetragonal distorted at temperatures above T_{JT}. The interaction time for the photoabsorption process is lower than for the thermal motion and consequently, the local structure probed by EXAFS provide the instantaneous local structure around the absorbing atom. On the other hand, diffraction data provide the periodicity of the average structure as Rodriguez-Carvajal *et al.* [4] claim. From both experiments, we can infer that below T_{JT} the tetragonal local distortion is three-dimensional ordered giving rise to the well-known *Pbnm* structure. On the other hand, above T_{JT}, the local distortions are dynamically disordered and the average lattice is cubic.

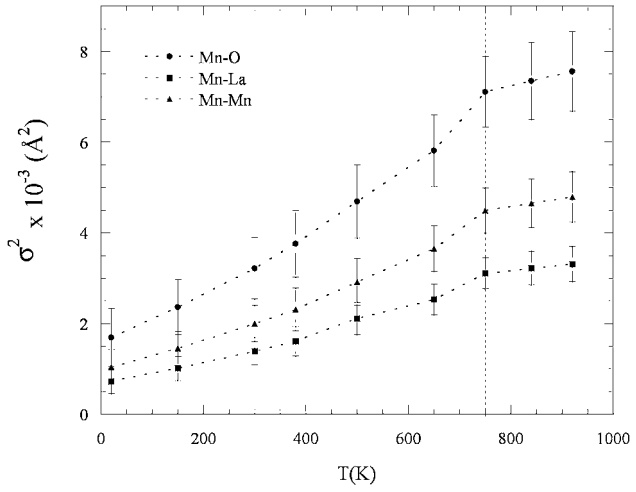

Fig. 3. Debye-Waller factor as a function of temperature for the three coordination shells. The vertical line indicates T_{JT}.

This result shows that Mn^{3+} ion displays a strong Jahn-Teller coupling giving rise to the called static JT regime [13]. Above T_{JT} each Mn octahedron is instantaneously distorted and it jumps among the three equivalent tetragonal distortions. Below T_{JT}, the tetragonal distortions are periodically ordered. From this point of view, the phase transition can be classified as an order-disorder phase transition where the statistical occupation corresponds to the three possible orientations of the tetragonal distortions on each octahedron. This also agrees with the lack of modification of the pre-peak features of the XANES spectra.

Summarizing, the following relevant results can be concluded from these experiments [14].

i) The orbital degeneracy of the Mn^{3+} ion is already lifted at temperatures above T_{JT}. XANES spectroscopy shows that the empty Mn^{3+} electronic *d*-states are unaltered crossing the JT transition whereas EXAFS spectroscopy shows that the JT tetragonal distortion remains in the pseudocubic phase above T_{JT}.

ii) The structural phase transition is then produced by the ordering of the local distortions by elastic coupling with the macroscopic strain field, giving rise to the low temperature *Pbnm* crystal symmetry.

iii) In the frame of the Jahn-Teller effect, the lowest energy for the e_g electron is coupled with the three possible distortions giving rise to three degenerate electronic states [13] $d_{x2\text{-}r2}$, $d_{y2\text{-}r2}$ and $d_{z2\text{-}r2}$ where the electron thermally jumps among them above T_{JT} and is localized and ordered below T_{JT}. In this sense the orbital ordering proposed for $LaMnO_3$ is arising from the ordering of the JT local distortions so a direct electronic origin for orbital ordering (i.e. superexchange between orbitals, or cooperative Jahn-Teller mechanisms with simultaneous lattice distortion) lifting the orbital degeneracy, should be discarded.

iv) The high temperature phase can be described as a dynamically local distorted phase with strong antiferrodistortive first neighbor coupling. Therefore, a schematic picture of the vibronic conductivity mechanism proposed by Zhou and Goodenough [5] could be the following: Above T_{JT}, the e_g electron jumps among the degenerate three orbitals on each Mn^{3+} ion. This electron can also jump to the orbital of the nearest neighbor manganese, due to the covalency with the oxygen, giving rise to a mobility of the carrier in the lattice. In the low temperature phase, the e_g electrons are ordered and localized and they cannot jump between adjacent octahedra. Although this conduction mechanism is assisted by phonons, it cannot be considered as polaronic.

Abstract

Co doped TiO_2-anatase is a promising candidate for a room-temperature ferromagnetic semiconductor. XAFS measurements have been used to investigate the local Co environment and Co valence for several Co-anatase films. The samples were grown on $LaAlO_3$ (001) by oxygen plasma assisted molecular beam epitaxy and on $SrTiO_3$ by atomic oxygen assisted MBE. Co concentrations were about 5%. The measurements were made at the PNC-CAT bending magnet and undulator beamlines at the Advanced Photon Source. For the films on $LaAlO_3$, the near edge clearly shows the presence of only Co(2+), and no evidence for metallic Co, while the films on $SrTiO_3$ showed significant metallic Co. Analysis of the extended fine structure for the $LaAlO_3$ films finds that the Co substitutes for Ti with some distortion of the lattice. Both in-plane and out-of-plane Co-O bonds are expanded from the Ti-O bonds in anatase. The in-plane bonds are expanded approximately twice as much. A deficit in the oxygen coordination number suggests a correlation of oxygen vacancies with Co sites.

1. Introduction

Spintronics devices utilize the spin of carriers, and offer the promise of new devices with enhanced functionality. Dilute magnetic semiconductors (DMS) are promising candidates for spin injectors in spintronics devices. DMS materials can have spin polarized states in their valence or conduction bands. At interfaces with nonmagnetic semiconductors they can then be used for spin polarized carrier injection, allowing for the fabrication of novel devices utilizing spin. Theory and measurements indicate that they can be much more efficient spin injectors than ferromagnetic metals.

Most traditional DMS materials require cryogenic cooling, a major disadvantage for practical devices. Therefore, extensive theoretical and experimental searches have been underway for DMS materials that exhibit ferromagnetic behavior above room temperature. To date the most robust candidate appears to be Co doped TiO_2-anatase. The ferromagnetic properties of this material were first discovered by Matsumoto *et al.* [1]. Their films were produced by pulsed laser deposition (PLD) on $LaAlO_3$ and $SrTiO_3$ substrates. The saturation moment was found to be $0.3\,\mu_B$/Co atom.

Since then films have been grown using a number of methods, and show a range of values for the saturation moments. Many of the PLD films show evidence for Co nanoparticles that could explain some of the magnetic results. Therefore, it is essential to use techniques that can distinguish the different Co oxidation states, especially techniques that average the entire film thickness. XANES provides such a tool.

In the present work, molecular beam epitaxy (MBE) techniques were used to grow the films. Either oxygen plasma or atomic oxygen was used in an attempt to prevent the production of Co nanoparticles. The oxygen plasma assisted MBE (OPAMBE) films showed a saturation moment of $1.26\,\mu_B$/Co [2]. Bulk Co has a saturation moment of $1.7\,\mu_B$/Co atom, and its formation can complicate the measurement of magnetic properties. We will demonstrate that X-ray absorption near edge measurements are a sensitive and simple probe for the formation of metallic particles. The Co is primarily in the 2+ oxidation state, although metal is detected in some of the films.

The extended fine structure (EXAFS) has been also measured to look at a number of other questions about these materials [3]. The first is the location of the Co in the anatase lattice. The Co 2+ ion is significantly larger than the Ti 4+ ion in anatase. Theory suggests that the Co may be residing in an interstitial site [4]. However, we will show that Co resides in a distorted substitutional site. There is also the question of the oxygen vacancies. For charge balance, each substitution of a Co for Ti should result in the formation of an oxygen vacancy. Additional oxygen vacancies are required to dope the films n-type. If these oxygen vacancies are associated with the Co sites they may be observable in the EXAFS coordination number. Finally, a wide range of surface morphologies have been observed in nominally identical films. Films range from atomically flat to particle laden. Scanning Auger and high resolution TEM indicates that the particles remain in the anatase structure, but have a much higher concentration of Co than the bulk film. In this paper we compare the EXAFS from films with and without these particles.

2. Samples and Measurements

Results from five samples are presented. Two of the samples were grown on $LaAlO_3$ (100) [5], and three of the samples were grown on $SrTiO_3$ on Si. The samples on $LaAlO_3$ were grown by oxygen plasma assisted MBE, and will be referred to as LAO1 and LAO2. Sample LAO1 showed no evidence for Co-rich particles, while LAO2 had about 1% of the surface area covered by Co-rich particles that seems to contain most of the Co in the film. The samples grown on $SrTiO_3$/Si were grown by MBE with atomic oxygen used in an attempt to maintain stoichiometry. These three nominally identical films will be referred to as STO1, STO2 and STO3. The films were all approximately 20 nm thick with Co concentration of about 5%.

The X-ray measurements were made at the PNC-CAT beamlines at Sector 20 at the Advanced Photon Source. Most of the measurements were made at the insertion device beamline 20-ID. Some of the LAO1 measurements were made on the bending magnet beamline 20-BM. The measurements were made at glancing angles of 1-2 deg using a focused beam of less then 10 μm in diameter (30 μm for 20-BM). The focusing mirrors also effectively rejected the beam harmonics. The fluorescence was detected using a 13-element Ge detector. 50–100 μm of Al was

Sample	*N*	*R* (Å)	σ^2 (Å^2)
$CoTiO_3$	3	2.054	0.0056 (0.0005)
	3	2.172	0.0082 (0.0007)
CoO	6	2.133	0.0069 (0.0005)
Anatase-c	2	1.966	–
Anatase-ab	4	1.937	–
CoLAO1-c	1.8 (0.2)	2.01 (0.01)	0.010 (0.001)
CoLAO1-ab	3.6 (0.3)	2.04 (0.01)	0.0095 (0.001)
CoLAO2-c	1.4 (0.3)	2.03 (0.02)	0.0079 (0.0015)
CoLAO2-ab	3.5 (0.3)	2.03 (0.01)	0.0086 (0.001)

used to filter out the Ti and La fluorescence. A Si(111) double crystal monochromator provided an energy resolution of about $\Delta E/E = 1.4 \times 10^{-4}$. The energy was calibrated using Co metal with the peak in the derivative set to 7708 eV. $CoTiO_3$ and CoO were measured in absorption as Co^{2+} standards, and to calibrate the FEFF 7 [6] calculations used to analyze the data.

The films grow with their c-axis normal to the surface. Measurements were made with the X-ray polarization in the ab-plane and along the c-axis. All of the samples except for LAO1 were measured with the samples spinning about the surface normal to minimize Bragg peak interference. Sample LAO1 seemed to have fortuitous alignment and did not need spinning. Figure 1 shows the near edge results compared to the standards. The films on STO in Fig. 1(b) show clear evidence for Co metal ranging from approximately 30–70%. In contrast the LAO films show no evidence for Co metal, and have a near edge similar to $CoTiO_3$. The edges to not look like CoO, which has been suggested as a component of some pulsed laser deposited films [7].

Since they contain significant Co metal, we did not attempt to analyze the EXAFS from the STO samples. Fig. 2 shows the extracted k^2 weighted EXAFS for the two LAO samples. The EXAFS was extracted using the autobak method as implemented in IFEFFIT [8]. The EXAFS dies off quickly indicating significant disorder about the Co site. There is a relatively small contribution from higher shells. There are small differences between the two films with the amplitude for the LAO2 film consistently smaller for both polarizations.

3. Analysis and Discussion

IFEFFIT was used to fit the first shell data. Table I compares the Co or Ti environment for TiO_2-anatase, $CoTiO_3$ and CoO. For each polarization dependent measurement, we expect a single Co-O distance if the Co is substituting for Ti. However, the distance for the two polarizations could be different. A typical single shell fit is shown in Fig. 3, and the results for all the samples are given in table I. Also, shown in Fig. 3 is a fit to a model for an interstitial site calculated using density functional theory [9]. This site has two

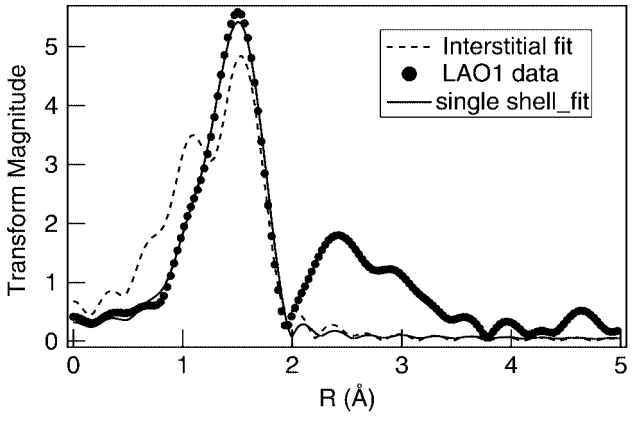

Fig. 3. Fitting for sample LAO1. The transform range is 2–11 Å^{-1}, and the fitting was carried out over the r-space range of 0.8–1.9 Å, giving approximately 7 independent data points. A single shell fit is compared to the interstitial model discussed in the text.

short Co-O bonds and four long bonds all at different distances. For the fitting an overall Δr was varied, along with an overall σ^2. If a separate σ^2 was used for the short and long bonds, the short bond value fit to a large value effectively removing them from the model. It is obvious that the interstitial model does not fit the data.

The fitting results in table I show that the Co-O bond lengths in the films are intermediate between the Co-O bond length in the typical Co compound and the Ti-O bond lengths in Anatase. This is to be expected if the larger Co ion is substituting for the Ti in anatase. In general the disorder has increased. Again this is expected due to the strains introduced into the lattice by the larger Co ion. Note that the bonds lengths along the c-axis are equal to or smaller than the ab-plane bonds. In anatase the c-axis bonds are longer. However, in the anatase structure the Co (or Ti) oxygen bonds form a linear chain along the c-axis while in the ab plane the oxygen atoms are alternately slightly above or below the plane. It is reasonable that the oxygen atoms in the plane can more easily accommodate the larger Co atom by changing the amount of buckling. The c-axis oxygen atoms are more constrained from moving away from the Co atoms.

The higher shell structure in anatase is fairly complicated, and the measured EXAFS from the higher shells is relatively weak. Therefore, detailed fitting of the higher shells was not attempted. A comparison was made with a calculated model for Co in anatase, and it does appear the measurements are consistent with disordered anatase-like higher shell structure.

The coordination numbers for the CoLAO samples are somewhat lower than for anatase. The numbers in table I are given assuming the Co is in the Ti site. For this case the two oxygens along the c-axis would give the same EXAFS amplitude as the four bonds distributed in the ab-plane. From charge neutrality we expect an oxygen vacancy is produced for each Co^{2+} ion substituted for a Ti^{4+} ion. In addition, excess oxygen vacancies are required to make the material semiconducting. The question is whether these oxygen vacancies are correlated with the Co sites. Such vacancy correlation could provide a mechanism for strain relief.

If all of the vacancies are next to the Co sites then there should be a deficit in coordination of at least one atom. This does not seem to be the case for the LAO1 film, but a partial correlation is indicated. The measured reduction in coordination is similar to our uncertainties but appears in measurements for both polarizations. A larger reduction in O neighbors is indicated for the LAO2 film. The total reduction is about 1 atom. In neither sample is there a large preference for location of the O vacancy in the c-axis or ab-plane sites.

4. Summary

The results show that XAFS is a powerful tool for looking at Co-anatase films. The near edge is very sensitive to the presence of Co nanoparticles. For films grown using OPAMBE on $LaAlO_3$, no metallic Co was detected and all of the Co was found to be in the 2+ valence. The use of atomic oxygen was less successful in avoiding metal formation, and the films studied had Co metal particles accounting for 30–70% of the total Co. In contrast to surface sensitive techniques, this XAFS result is a true average of all the Co in the film.

For the films without metal, the extended fine structure provided strong evidence for the Co occupying the Ti sites in the anatase lattice. An interstitial model is definitely ruled out, and the Co-O bond lengths are significantly shorter than typical Co^{2+} bonds with oxygen in standard compounds. This is expected if the Co is substituting for the smaller Ti atoms. Comparison of films with and without Co-rich particles found very similar results. Both results showed indications of reduced oxygen coordination with a larger reduction for the particle rich film. Oxygen vacancies are required for charge balance and to dope the films n-type. A reduced coordination indicates that there is some correlation of the O vacancies with the Co sites. This correlation might be a strain relief mechanism. The larger Co ions are undoubtedly inducing significant strain into the lattice, which could be partially relieved by an oxygen vacancy moving close to a Co. The lattice strain is indicated in the measurements by an increased Debye-Waller factor, and by a much reduced higher shell contribution as compared to the pure materials.

Abstract

A systematic study of the X-ray magnetic circular dichroism at the L_3 edge is presented for Gd and Tb single crystals in the extended energy range (MEXAFS). The investigation of the dichroic signal in this energy range is especially interesting for rare earth metals because the relative intensity of the magnetic EXAFS to the near edge signal (XMCD) is much larger compared to 3d transition metals. This is because the MEXAFS for the rare earth elements is essentially proportional to the total 4f magnetic moment, whereas the XMCD is dominated by dipole transitions to the spin-dependent 5d densities of states only. The temperature dependence of the magnetic EXAFS originates both from spin fluctuations and lattice vibrations. We present a new procedure to separate these contributions by modeling the absorption coefficients $\mu^+(E)$ and $\mu^-(E)$ for right and left circularly polarized X-rays, by the energy shifted experimental spin-averaged spectra. The temperature dependence of the MEXAFS can then be described by a temperature-dependent energy shift $\Delta E(T)$ which is proportional to the temperature-dependent magnetization $M(T)$. Furthermore, multiple and single scattering contributions in the MEXAFS are separated by comparison of the experimental data to *ab initio* calculations using the FEFF8 code.

The magnetic EXAFS (MEXAFS) is the extended energy range counterpart of the near-edge X-ray magnetic circular dichroism (XMCD). Interestingly, the temperature dependence of the MEXAFS is different from the one of XMCD because in the extended energy range the dynamic disorder due to lattice vibrations adds to the effect of the spin dynamics and therefore a larger damping with temperature is found in comparison to the near-edge signal [1–4]. Hence, the temperature dependence of the MEXAFS is a superposition of both effects. Surprisingly, the contribution of the EXAFS Debye-Waller factor is often neglected in various MEXAFS works. Therefore, the results might be questionable if simply the Fourier transform intensities are compared [5] without correcting for the effect of the lattice vibrations. In this work we will present a new experimental approach to disentangle the two contributions by modeling the MEXAFS with the energy-shifted EXAFS data. This is especially important when the MEXAFS intensity for various systems is correlated to the spin moment as for instance for rare earth metals in comparison to 3d transition metals. The Debye-temperature for the rare earth elements is in the range of $\theta_D \approx 170\,\mathrm{K}$ whereas one finds $\theta_D \approx 450\,\mathrm{K}$ for the 3d transition metals. Therefore, the mean square relative displacement σ^2 is about a factor of two larger for the rare earth metals compared to the 3d metals even at 100 K. The data at the L_3 edges were recorded on Gd and Tb single crystals at the ID12 beamline at the ESRF. We made use of the so-called gap-scan technique which enabled us to combine a high photon flux with a high degree of circular polarization [6] and detected the fluorescence yield. The data were corrected for self-absorption effects (see [7] for details). The single crystals have the shape of a plate and were mounted at normal incidence to the X-rays with the magnetic field aligned along the photon k-vector. By means of element specific hysteresis loops the saturation fields at the specific temperatures were determined [4]. The EXAFS and MEXAFS oscillations were extracted with the conventional spline analysis (see [8] for details).

The procedure applied in this work to disentangle the effect of the lattice vibrations from the spin fluctuations is based on the description of the MEXAFS in various theoretical works: The MEXAFS fine structure is related to the energy derivative of the DOS which is linked to the derivative of the spin-averaged EXAFS [9–12]. Ebert and coworkers showed that the MEXAFS fine structure is connected to the spin and orbital polarization $(\mathrm{d}/\mathrm{d}E)\langle\sigma_z\rangle$ and $(\mathrm{d}/\mathrm{d}E)\langle l_z\rangle$ by analyzing sum rules in their differential form [13–16]. Even in the near-edge range similar theoretical treatments can be found [17, 18]. In a simplified picture the MEXAFS can be described as the difference of the spin-dependent scattering at the potentials which are modeled from the normal EXAFS scattering potentials being shifted in energy by an exchange-related energy $\Delta E(T)$. In this case the MEXAFS oscillations could be simulated with χ_M^{sim} by calculating the difference of the regular EXAFS oscillations χ which are shifted in energy by $\pm 1/2\,\Delta E$:

$$\chi_M^{sim}(E,T) = \chi\left(E - \tfrac{1}{2}\Delta E(T)\right) - \chi\left(E + \tfrac{1}{2}\Delta E(T)\right). \qquad (1)$$

To test this assumption we applied this procedure to the experimental Gd and Tb MEXAFS data at 10 K and simulated them with the experimental EXAFS spectra at the same temperature. The only free parameter is the energy shift ΔE which is varied until the simulated MEXAFS intensities match the experimental ones. The results are given in Fig. 1. Surprisingly, this simple approach can reproduce various fine structures of the experimental MEXAFS seen for instance at $k = 4.0\,\text{Å}^{-1}$ for Gd and at $k = 8.0\,\text{Å}^{-1}$ for Tb. Also the enveloping amplitude of the MEXAFS is correctly described. This demonstrates that the rigid-band model as suggested by Brouder *et al.* [10] holds for the modeling of the MEXAFS even up to large k-values of about $11\,\text{Å}^{-1}$. Therefore, the shift of the EXAFS by ΔE to model $\mu^+(E)$ and $\mu^-(E)$ is a way to determine the spin-dependent densities of states. It turns out that the shape of the L_3-edge MEXAFS can be described by the first derivative of the EXAFS $\mathrm{d}\chi/\mathrm{d}E$ and $\Delta E(T)$ is there to scale the intensity. Thinking in terms of a Taylor series

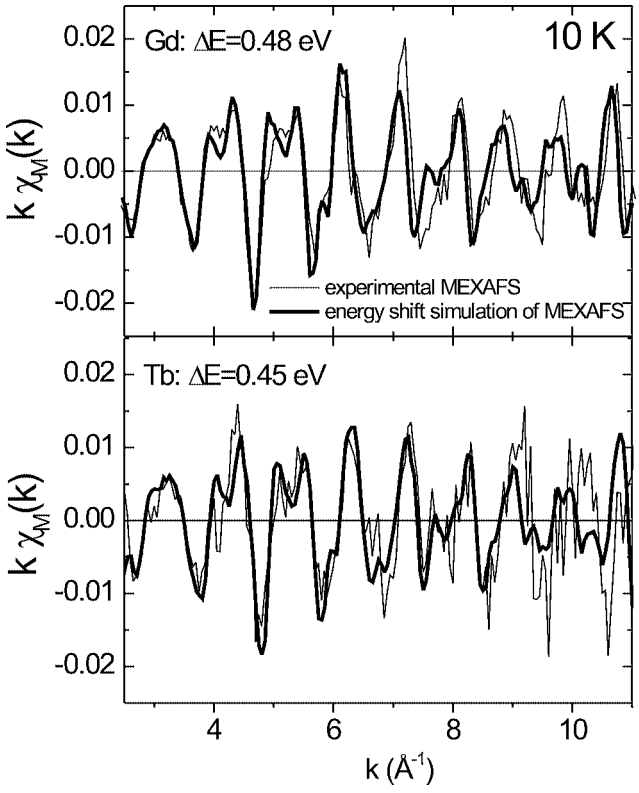

Fig. 1. Experimental MEXAFS data for Gd (top) and Tb (bottom) single crystals at 10 K in comparison to simulation of the MEXAFS with the spin-averaged EXAFS data. For the simulation the difference of the energy shifted EXAFS oscillations $\chi(E - \frac{1}{2}\Delta E) - \chi(E + \frac{1}{2}\Delta E)$ was analyzed.

the higher order terms can be neglected because of the smallness of $\Delta E(T)$. This is not the case for K-edge MEXAFS where Brouder *et al.* [10] showed that the MEXAFS is proportional to the second derivative of the EXAFS $\mathrm{d}^2\chi/\mathrm{d}E^2$ and Ebert *et al.* discussed these results on the basis of the differential form of the sum rules [15]. We also applied successfully the simple model given by eq. (1) to the MEXAFS of 3d elements (not shown). There the $L_{3,2}$ edges overlap strongly in contrast to the rare earth metals presented here, where the $L_{3,2}$ edges are well separated by several hundred eV (Tb: ∼730 eV). Furthermore, the procedure of simulating the MEXAFS at the specific temperature T with the experimental EXAFS data at the same temperature automatically takes the reduction by the EXAFS Debye-Waller factor into account. Hence, the temperature dependence of the energy shift ΔE is not due to the lattice vibrations but spin fluctuations only and therefore these two contributions can be separated.

Now, the temperature dependence of $\Delta E(T)$ will be analyzed in detail: $\Delta E(T)$ is determined by fitting the temperature-dependent MEXAFS oscillations with the procedure described by eq. (1). The experimental results for Gd are given in Fig. 2. Obviously, the temperature dependence of ΔE follows the one of the magnetization $M(T)$ [19] as it is also suggested in recent theoretical works [20]. This shows that the entire temperature dependence of the MEXAFS can be described by the factor $M(T) \cdot \mathrm{e}^{-2\sigma^2(T)k^2}$. Therefore, one has to correct not only for the amplitude reduction by the reduced temperature T/T_C but also for the EXAFS Debye-Waller factor when the MEXAFS intensity is correlated to the spin moment. In various MEXAFS works the latter effect was neglected although there is a strong influence by the factor $\mathrm{e}^{-2\sigma^2(T)k^2}$, e.g. when the MEXAFS intensity of 3d

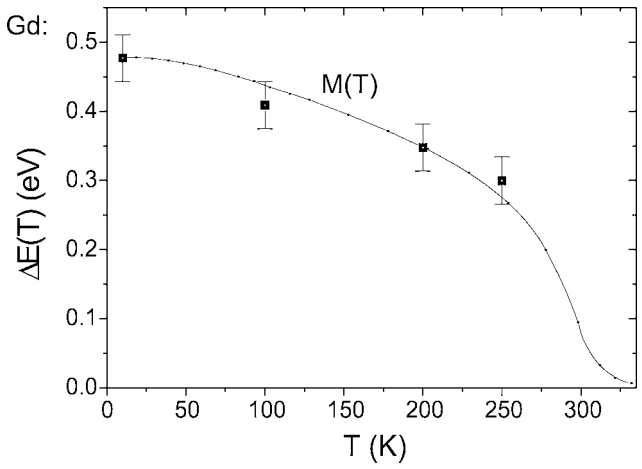

Fig. 2. Temperature dependence of the exchange related energy shift $\Delta E(T)$ for a Gd single crystal in comparison to the temperature dependence of the magnetization taken from the literature [19].

transition metals is compared to the ones of the rare earths (see above).

For a more detailed investigation of the Tb EXAFS and MEXAFS data we compared the experimental results to *ab initio* calculations using the FEFF8.2 code [21] (Fig. 3). Since the FEFF8.2 calculations are not self consistent with respect to the spin dependence, the MEXAFS data were scaled down to match the experiment. The calculations for the EXAFS and the MEXAFS agree quite well with the experiment in k-space as well as in R-space since all the fine structures are reproduced by the calculation. Interestingly, various fine structures of the MEXAFS that were already seen in the energy shift simulation in Fig. 1, e.g. at about $k = 5.3$, 6.8 and 7.8 Å^{-1}, can also be detected in the FEFF8.2 calculation. The splitting of the main peak in the Fourier transforms, which is due to a minimum in the enveloping amplitude at about $k = 9$ Å^{-1}, is accurately modeled. Even all the peaks in the Fourier transform for the EXAFS and the MEXAFS with respect to their position as well as their relative intensity are well described by the theory. In order to disentangle those peaks into their multiple- (MS) and single-scattering (SS) contributions, we used the advantage to switch on/off those effects in the theory. The result of this separation is given in Fig. 4. All the peaks up to 6.0 Å can be described by single-scattering contributions. The

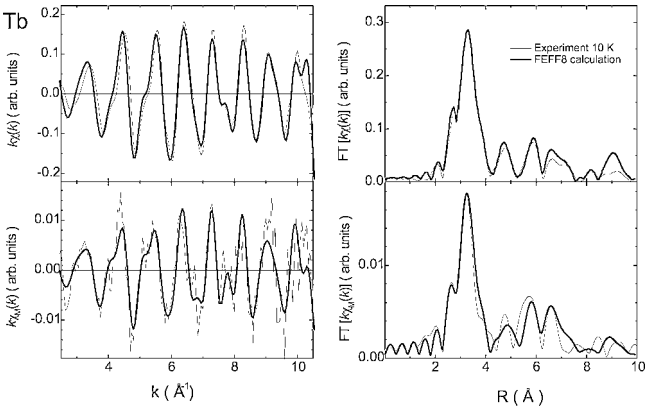

Fig. 3. Experimental Tb EXAFS (top) and MEXAFS (bottom) oscillations $k \cdot \chi(k)$ and $k \cdot \chi_M(k)$ (left) and the corresponding Fourier transforms (right) in comparison to *ab initio* calculations (FEFF8.2).

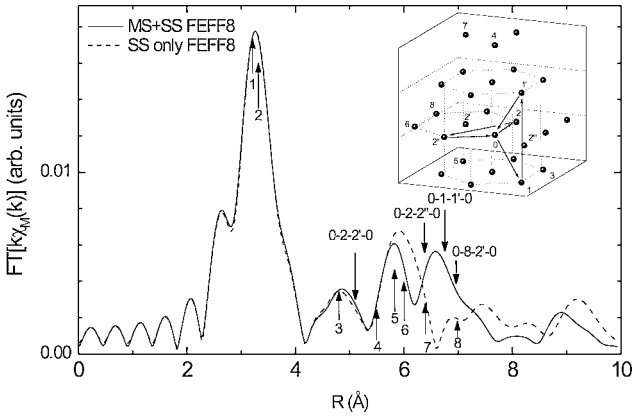

Fig. 4. Theoretical separation of multiple and single scattering contributions in the Tb MEXAFS (FEFF8.2).

triangular scattering path 0–2–2′–0 (inset of Fig. 4) at about 3.0 Å hardly contributes to the overall intensity. However, at distances larger than 6.0 Å clear contributions from various triangular paths can be found. Surprisingly, smaller intensities are found for the multiple-scattering calculation (solid line) above 7.5 Å. This demonstrates that the multiple- and the single-scattering paths interfere destructively as it was also determined for the Gd MEXAFS [22]. Contrary, such an effect was not seen for the L-edge MEXAFS of the 3d metals Fe and Co where even an enhancement of MS paths was found [2].

In conclusion, we have shown that the temperature-dependent MEXAFS can be modeled by the difference of the energy-shifted EXAFS spectra. This procedure allows to disentangle the effect of spin fluctuations from lattice vibrations. We find experimentally that the temperature-dependent energy shift follows the temperature dependence of the magnetization. This demonstrates that the MEXAFS intensities have to be corrected for the reduced temperature T/T_C **and** the effect of the EXAFS Debye-Waller factor when the MEXAFS intensities are correlated to the spin-moment. Furthermore, we find by means of *ab initio* calculations that the multiple-scattering contributions in the rare earth MEXAFS interfere destructively with the single-scattering ones in contrast to the findings for the 3d L-edge MEXAFS.

Abstract

X-ray resonant scattering experiments at (002) and (006) forbidden Bragg reflections were performed on Fe_3O_4, $MnFe_2O_4$ and $CoFe_2O_4$ single crystals. The intensity of these reflections in Fe_3O_4 shows three characteristic features as a function of energy. A pre-peak resonance related to dipolar-quadrupolar transitions coming from the tetrahedral Fe ions and a main resonance at the absorption edge and the energy-extended oscillating part ascribed to the anisotropy of the octahedral Fe ions. X-ray resonant scattering experiments on $MnFe_2O_4$ (normal spinel) and $CoFe_2O_4$ (inverse spinel) ferrites verify experimentally the origin of these resonances, the main peak is caused by the dipole transition of the octahedral site iron and the pre-edge peak is due to the dipole-quadrupole transition of the tetrahedral site iron, independently of the formal valency or chemical specie. These experimental results show that anisotropic tensor susceptibility (ATS) scattering cannot be simply considered as a direct proof of orbital ordering.

1. Introduction

X-ray resonant scattering experiments are used to find experimental proof of the existence of orbital and charge ordering in transition metal compounds. Within this framework, lots of studies have been recently reported on manganites [1–3], NaV_2O_5 [4], V_2O_3 [5] and other transition metal oxides. The interpretation of the observed X-ray resonant scattering patterns in terms of an ionic charge/orbital ordering model has been criticized by different authors who propose instead a structural origin for the observed X-ray resonant scattering reflections [6–9].

In order to investigate the charge/orbital ordering phenomena in transition metal compounds, we studied first the classical archetypical compound magnetite (Fe_3O_4). Magnetite has been considered as prototype of charge ordering systems where octahedral Fe^{3+}/Fe^{2+} iron ions are dynamically disordered above the Verwey transition temperature (Tv) and periodically ordered below Tv [10]. We carried out X-ray resonant scattering experiments at the (002) and (006) forbidden reflections, fingerpoint of the Verwey model, above and below Tv [11, 12]. Our results demonstrate that no ionic charge ordering is present in magnetite at low temperatures, at least for ionic configurations satisfying the Anderson condition [12]. Moreover, the temporal existence of localized Fe^{3+} and/or Fe^{2+} ionic states in the high-temperature phase was also completly discarded [11]. On the other hand, the experimental facts can be easily explained in terms of a structural model, based on the anisotropy of the anomalous atomic scattering factor of the octahedral Fe ions (anisotropic tensor suceptibility (ATS) scattering).

The intensities of the (002) and (006) forbidden Bragg reflections in magnetite show three clear features as a function of energy, a pre-peak resonance, a main-edge resonance and an energy-extended oscillating part. Both theoretical simulations and the q-dependence of the experimental X-ray resonant spectra indicate that the pre-peak resonance has its origin from a dipolar-quadrupolar excitation-deexcitation channel at the tetrahedral iron ions. On the other hand, the main-edge resonance and the energy-extended oscillatory part are both ascribed to 1s-εp dipolar transitions at the octahedral iron ones. The azimuthal dependence of these reflections follows a $\pi/2$-periodicity. We note that the point symmetry of the octahedral sites is not octahedral (O_h) but trigonal-distorted (D_{3d}) so anisotropy coming from this trigonal symmetry should be expected. Moreover, it also explained satisfactorily the azimuthal and q-dependencies of these reflections. The atomic scattering tensor is defined in the trigonal symmetry by,

$$\begin{pmatrix} f_\perp & 0 & 0 \\ 0 & f_\perp & 0 \\ 0 & 0 & f_\parallel \end{pmatrix} \tag{1}$$

$f_\parallel$ and $f_\perp$ being the component parallel and perpendicular to the trigonal axis, respectively. Then, we obtain that the structure factor scattering tensor is given by

$$F_{00l} = \frac{16}{3}\begin{pmatrix} 0 & (f_\parallel - f_\perp) & 0 \\ (f_\parallel - f_\perp) & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \tag{2}$$

and the respective azimuthal and q-dependencies are given by

$$I^T_{00l} \propto \left|\tfrac{16}{3}(f_\parallel - f_\perp)\right|^2 (\sin^2\theta + \cos^2\theta \sin^2(2\varphi)). \tag{3}$$

The aim of this work is to demonstrate experimentally 1) the assignation of the pre-peak resonance to atoms at tetrahedral sites and 2) the structural origin of the main-edge resonance elucidating whether it reflects or not a claimed d-orbital ordering in some way. We have performed X-ray resonant scattering experiments at the (002) and (006) forbidden reflections of two selected spinel ferrites, $MnFe_2O_4$ and $CoFe_2O_4$, at the Fe, Mn and Co K-edges. Spinel ferrites are of general formula AB_2O_4, A and B being the tetrahedral and octahedral sites, respectively. They are derived from Fe_3O_4 by partial substitution of iron ions by other divalent transition metal element such as Mn, Co, Ni, Cu or Zn. It is known that Mn^{2+} mainly substitutes the tetrahedral A-sites in the spinel structure whereas Co^{2+} mainly goes into the octahedral B-sites [13]. Considering this cation distribution between the tetrahedral and octahedral sites, no pre-peak resonance should be observed, neither at the Fe K-edge in $MnFe_2O_4$ nor at the Co K-edge in $CoFe_2O_4$. Moreover, no resonance at the Mn K-absorption edge should be detected. On the other hand, Fe K-edge spectra should show the resonance at the absorption edge in both samples.

In this paper, we will show that the measured energy and azimuthal behaviour of the (002) and (006) forbidden reflections for these spinel ferrites completely confirms our previous results

*e-mail: gloria@unizar.es

for magnetite and it adds a new experimental proof of the structural origin of resonant forbidden reflections in transition metal oxides. Finally, we note that the formal valency of octahedral iron ions in the studied (Mn, Co) spinel ferrites is +3 compared to +2.5 of magnetite. The effects of the valence state and the d-electronic configuration will be briefly discussed.

2. Experiment

X-ray resonant scattering experiments were performed at the French CRG D2AM beam line at the European Synchrotron Radiation Facility [14]. A Si(111) double crystal with an energy resolution of about 1 eV was used to monochromatize the incident σ–polarized beam. The incident polarization vector was perpendicular to the diffraction plane (σ incident geometry) and no polarization analysis to separate σ and π components of the scattering beam was performed in this case. Single crystals of Fe_3O_4, $MnFe_2O_4$ and $CoFe_2O_4$ ferrites were melt-grown by floating-zone method. (001) surfaces were cut and polished with fine diamond paste. The physical characterization has been reported elsewhere [12]. All the crystals are single phase at room temperature with lattice constants $a = 8.396$ Å, $a = 8.499$ Å and $a = 8.391$ Å for magnetite, Mn and Co ferrites, respectively.

3. Results and Discussion

The energy dependence of the intensity at the maximum of the forbidden reflections (002) and (006) of Fe_3O_4, $MnFe_2O_4$ and $CoFe_2O_4$ ferrites near the iron K absorption edge at room temperature is shown in Figure 1. A main resonance is observed at similar energies around the K edge (7125 eV) for all the samples.

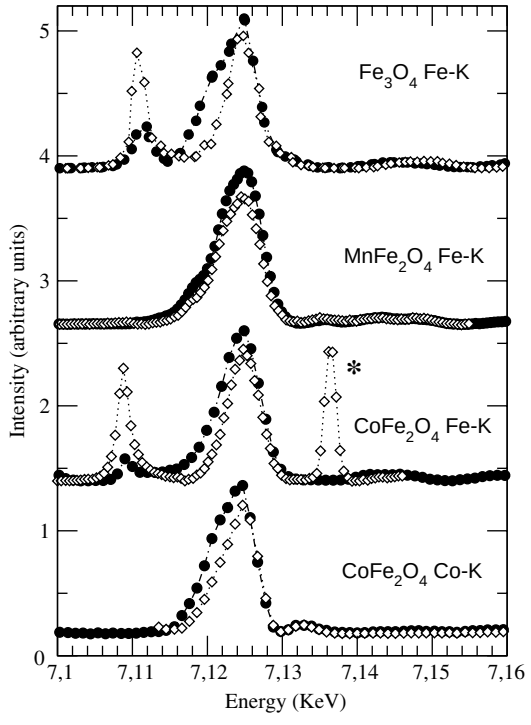

Fig. 1. Energy dependence of (002) (closed circles) and (006) (open diamonds) forbidden reflections at room temperature for Fe_3O_4, $MnFe_2O_4$ and $CoFe_2O_4$ spinel ferrites around the Fe and Co K-edges. The Co K-edge spectrum has been shifted in energy for comparison. Lines are a guide for the eye and asterisks mark spurious Renninger reflections.

This resonance was assigned to the dipolar transitions from the 1s core level to the εp bands in Fe_3O_4 due to the anisotropy of the atomic scattering factor of the octahedral Fe ion that results from the trigonal symmetry of the B-sites ($\bar{3}$m) [11]. A second resonance at about 7111 eV appears only for Fe_3O_4 and $CoFe_2O_4$ samples. This resonance corresponds to the pre-peak energy in the fluorescence spectrum and in the case of Fe_3O_4 was explained as arising from dipolar-quadrupolar excitation-deexcitation channels at the tetrahedral Fe ion by using *ab-initio* multiple scattering simulation [11]. Moreover, the intensity of this pre-peak resonance in Co ferrite shows the same q-dependence as in pure magnetite. The energy dependence of the (002) and (006) reflections at the Co K absorption edge at room temperature is also shown at the bottom of Figure 1. In this case, only the resonance at energies close to the Co K-edge (7725 eV) is observed.

The distribution of the metal ions between the tetrahedral and octahedral sites in spinel ferrites has drawn much attention in literature because of its influence in their physical properties [13]. In the case of Fe_3O_4, an inverse distribution of cations occurs; the Fe^{2+} ions are located on the octahedral B-sites and the Fe^{3+} ions are uniformly distributed over the remaining octahedral-B and tetrahedral-A sites. For Co ferrite, the inverse structure is also found where Co^{2+} ions prefer the octahedral B-site positions. On the other hand, in Mn ferrite, Mn^{2+} ions occupy predominantly the tetrahedral A-site positions. Taking into account this cation distribution between the octahedral and tetrahedral sublattice, the following conclusions can be inferred: 1) the absence of a pre-peak resonance in both the Fe K-edge spectra of $MnFe_2O_4$ and the Co K-edge spectra of $CoFe_2O_4$ (where no Fe or Co ions, respectively, occupy the tetrahedral sites) confirms that this feature comes directly from the tetrahedral ions and 2) the appearance of a resonance at the absorption edge for all the samples and K-edges considered, except for the Mn K-edge in agreement with the absence of Mn ions at the octahedral sites, confirms its dipolar origin at the octahedral B-sites. In addition, the fact that the valence state of the octahedral Fe ions in $MnFe_2O_4$ and $CoFe_2O_4$ is +3, instead of +2.5 as for Fe_3O_4, and that the resonance is observed for transition metal ions with different d-orbital occupation (Fe^{3+} is a $3d^5$ and Co^{2+} is a $3d^7$) proves that the X-ray resonant scattering intensity at these forbidden reflections arises mainly from the anisotropy of the transition metal environment, i.e. it has a structural origin.

Let us now discuss briefly the energy line shape and the azimuthal dependence of the (002) and (006) forbidden reflections in these spinel ferrites. A shift of about 2 eV to lower energies is observed for the pre-peak resonance at the Fe K-edge in $CoFe_2O_4$, indicating that the d electronic configuration of the tetrahedral Fe ions in Fe_3O_4 and $CoFe_2O_4$ are slightly different. This result also corroborates the dipolar-quadrupolar character of this resonance. Moreover, the energy line shape of the resonance at the Fe K-edge is also slightly different for the three studied samples. The dependence of the (002) and (006) scattered total intensity on the azimuthal angle φ for the Co ferrite compared to the magnetite [11] at $E = 7124.5$ eV (Fe K) and at $E = 7725$ eV (Co K) is shown in Figure 2a and 2b, respectively. The same $\pi/2$ φ-periodicity as in Fe_3O_4 is found for the Co ferrite at both Fe and Co K-edges. The dependence on the Bragg angle (θ) is clearly shown at zero azimuthal angle where the scattered intensity is about 5% of the maximum for the (002) reflection and 30% for the (006) one for both absorption edges and samples. It reasonably compares to the theoretical simulations (calculated by equation (3)) considering only the anisotropy of the atomic scattering factor

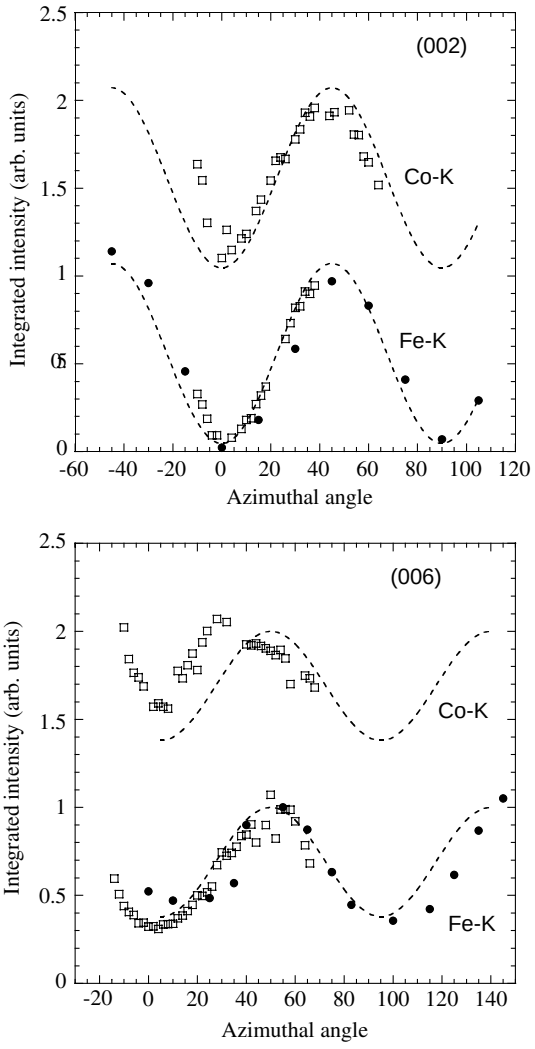

Fig. 2. (upper panel) Total integrated intensity of the (002) forbidden reflection as function of the azimuthal angle φ at the maximum of the resonance at the Fe(Co) K absorption edge. Closed circles: Fe_3O_4 sample and open squares: $CoFe_2O_4$ sample. Dashed lines show theoretical simulations calculated by equation (3). Co K-edge data have been artificially shifted by 1 unit in the vertical scale as a matter of illustration. (lower panel) Total integrated intensity of the (006) forbidden reflection as function of the azimuthal angle φ at the maximum of the resonance at the Fe(Co) K absorption edge. Closed circles: Fe_3O_4 sample and open squares: $CoFe_2O_4$ sample. Dashed lines show theoretical simulations calculated by equation (3). Co K-edge data have been artificially shifted by 1 unit in the vertical scale as a matter of illustration.

of the Fe (or Co) ions at the octahedral *B*-sites due to the trigonal distortion (dipolar transitions). Inhomogeneities in the mosaic structure of the samples at different azimuthal angles may cause the dispersion in the scattered intensities. Moreover, the energy-dependent spectra of $CoFe_2O_4$ at both Fe and Co K-edges, taken at different azimuthal angle values, are almost identical to each other except for a scale factor.

4. Conclusions

X-ray resonant scattering experiments at the respective transition metal K-edges of Fe_3O_4, $MnFe_2O_4$ and $CoFe_2O_4$ have been reported providing *direct* experimental evidence of the theoretically predicted origin for the several resonances observed in these materials: **1)** the resonance at energies corresponding to the prepeak of the fluorescence spectrum is clearly demonstrated to arise from dipolar-quadrupolar contributions from the tetrahedral iron ions and **2)** the main resonance associated to the 1s-εp dipolar transition is confirmed to be mainly of structural origin due to the anisotropy of the local symmetry at the octahedral *B*-sites.

We note that the energy and azimuthal dependence of the scattered intensity for the dipole transition does not depend on the formal valency of the octahedral *B*-site atom (Fe atom has a formal valency of +2.5 in magnetite and +3 in the other two spinels) or on the type of transition metal atom which occupies this octahedral site (the Co K-edge resonance shows similar behavior as the resonance at the Fe K-edge). On the contrary, the pre-peak resonance coming from the tetrahedral atom seems to be sensitive to the atomic specie and the chemical composition.

In conclusion, these results imply that the dipolar X-ray resonant scattering cannot be simply viewed as a *direct* observation of orbital ordering as it has been claimed for transition-metal oxides. Moreover, the lack of sensitivity of the dipolar resonant scattering signal to the formal 3d electronic configuration points out that a band description approach is the best option to explain the electronic, magnetic and transport properties in spinel ferrites.

Abstract

Permanent magnets based on Sm_2Co_{17} are of significant technological interest due to their high coercivities and elevated Curie temperatures. In this paper we examine the local environment of Zr-doped Sm_2Co_{17}. The presence of Zr in Sm_2Co_{17}-based magnets causes the formation of hexagonal Sm_2Co_{17} lamellae in the microstructure in the commercial materials. These lamellae serve as diffusion paths, enabling the development of good magnetic properties. While it is presumed that the Zr enters the lattice into either the Sm or Co dumbbell sites, there is, to date, no direct evidence of this assumption. In this paper, we present evidence of how the Zr does substitutes into the Sm_2Co_{17} lattice. We discuss the implication of this result on the magnetic properties and grain structure of the Zr-doped material.

1. Introduction

Magnetic materials of the nominal stoichiometry Sm_2Co_{17} are attractive for applications requiring high temperature, permanent magnets due to their high coercivity and Curie temperature above 900 K [1]. As engineered for commercial application, Sm_2Co_{17}-type magnets possess complex microstructures resulting from the addition of various dopants and the application of multiple heat treatments. The microstructure of a typical $Sm(Co, Fe, Cu, Zr)_z$ sample consists [1] of a cellular structure with $\sim$100 nm cells separated by fairly thick (4–10 nm) cell walls. Superposed over this structure are thin, parallel lamellae which are a few nm thick and permeate the cellular structure. Upon proper heat treatment, the dopants segregate [2] into different regions of the microstructure. The Cu migrates to the cell walls which are stabilized in the hexagonal $SmCo_5$ structure. The cells in $Sm(Co, Fe, Cu, Zr)_z$ are Fe rich and stabilize in the rhombohedral Sm_2Co_{17} structure. The lamellae are Zr rich and of the hexagonal Sm_2Co_{17} structure.

The magnetic properties result from domain-wall pinning at the cell boundaries, which is made possible by the Cu-rich 1–5 structure of the cell-walls. With low Cu content, only small sample volumes can be stabilized in the 1–5 phase and so the cell walls [3] remain thin. The addition of Zr to the sample promotes a uniform cellular microstructure as well as the formation of the Zr-rich lamellae. It is understood that the formation of the lamellae provide a path for the migration of Cu to the cell walls during thermal processing, thus promoting uniformity of the cellular structure as well as significantly increased coercivity.

While the microstructural phenomena discussed above are well established empirically, the underlying physical mechanisms remain poorly understood. Although the addition of Zr is known to promote the growth of the desired microstructure, very little is known about how Zr incorporates into the lattice of the lamellar portion of the $Sm(Co, Fe, Cu, Zr)_z$ microstructure or about the energetics of that substitution. In this work we investigate Zr-doped Sm_2Co_{17} in order to begin addressing this question. Because of the complexity of the $Sm(Co, Fe, Cu, Zr)_z$ microstructure and the presence [2] of small Zr concentrations in the cell region, we chose to focus on the Sm_2Co_{17} material in the absence of this complex microstructure by preparing samples with a few percent Zr to fall along the Sm_2Co_{17} line of the Sm–Co–Zr phase diagram [4]. In this report, we present results of EXAFS measurements on Zr-doped Sm_2Co_{17} and their structural implications.

There is scant investigation in the Sm–Co magnet literature into the details of the structure of Zr-doped material. Ray has long suggested [6, 7] that Zr enters the Sm_2Co_{17} lattice by substituting either for the Sm atom or for the Co dumbbells. Derkaoui, *et al.* [4] suggest the same on the strength of microscopy and X-ray diffraction measurements. Neither author, however, presents any direct evidence of the sort offered by an EXAFS experiment. The one report of EXAFS [8] on Zr-doped Sm_2Co_{17} presents data and conclusions at odds with our findings.

2. Sample Preparation and Data Collection

Samples of Zr-doped Sm_2Co_{17} were prepared by arc-melting stoichiometric ratios of high-purity metals under an argon atmosphere and in a water-cooled copper vessel. A few atomic percent additional Sm was added to each sample to compensate for loss of Sm during melting and annealing. In this paper, we present results on two samples prepared in this manner. Sample A was sealed in a quartz ampule under vacuum and annealed for 24 hours at 1050 °C and cooled to room temperature at a rate of 5 °C per minute. The stoichiometry of this sample was determined by inductively coupled plasma optical emission spectroscopy to be $Zr_{2.33}Sm_{8.62}Co_{89.05}$. Sample B was sealed in a quartz ampule under argon and annealed for 96 hours at 1150 °C and quenched to room temperature by immersion of the sealed ampule in water. Its stoichiometry was found to be $Zr_{3.36}Sm_{9.86}Co_{86.78}$. Purity of phase for each sample was checked by x-ray diffraction. Neither sample was pure of phase. Evidence for both the hexagonal and rhombohedral forms of Sm_2Co_{17} was seen, although both samples appeared to be predominantly hexagonal Sm_2Co_{17}. Neither sample showed significant evidence of the $SmCo_5$ phase.

EXAFS data were measured in fluorescence at NSLS beamline X11A using ionization chambers to measure both the incident and fluorescent flux. The bulk samples were mounted on a copper sample holder on the cold finger of a Displex two-stage helium compressor cryostat for low temperature measurement. Data were collected at 15, 100, 200, and 300 K. Measuring data at multiple temperatures allows us to better characterize our fitting models by verifying the temperature dependence of the fitting parameters. For example, we expect that parameters such as S_0^2 and E_0 will be independent of temperature while others, like σ^2, should be monotonically increasing in temperature.

For all data, the background removal was performed using the ATHENA [9] program, which uses the AUTOBK algorithm [10]. Data analysis was made using theoretical standards computed by FEFF6 [11]. The fits were performed using the ARTEMIS [9] program, which uses IFEFFIT [12] for all numerical operations.

3. EXAFS Results

There was significant structural variation between these two samples, as is clear from the data presented in Figures 2 and 3. The data from sample A are much larger in amplitude than from sample B and the main peak in $\bar{\chi}(R)$ is at a larger value of R, indicating a longer near-neighbor distance.

For our fits to these data, we considered the possibility that the Zr might substitute for any site in the Sm_2Co_{17} lattice. For each data set, the possibility of Zr substituting for any of the Co sites comprising the ring structures seen in Figure 1 was rejected. The nearest-neighbor distance for each of the ring sites is too short – about 2.45 Å – to be supported by either data set. The previous EXAFS report [8] reported the Zr to be in one of these sites, thus is at odds with the current results. The remaining possibilities, substitution into the Sm site or into a dumbbell Co site, are both consistent with the suggestions of Ray and of Derkaoui, *et al*. [4, 6, 7].

For sample A, the most successful model has Zr substituting for Sm but slightly displaced from the Sm site of symmetry by 0.065(9) Å. This sample also shows evidence of a small oxide component. 6.5(3)% of the Zr atoms are in an oxide environment. E_0 and the various σ^2 parameters were all reasonable and displayed reasonable temperature dependences.

The most striking result from these data was a significant statistical preference for the Zr atom to be in a local environment consistent with the rhombohedral Sm_2Co_{17} structure rather than the hexagonal. The main difference, as seen in Figure 1, is the presence of a dumbbell Co atom at 2.84 Å in the $\hat{z}$ direction in the rhombohedral structure. Excluding this scatterer from the fit, i.e. placing the Zr atom at the hexagonal Sm site, results in a statistically significantly worse fit, as seen in the lower panel of Figure 2. This result seems to be at odds with the XRD, which shows that the sample is predominantly hexagonal, and suggests that the presence of Zr in the lattice may serve to stabilize the rhomobohedral local structure under certain sample preparation conditions.

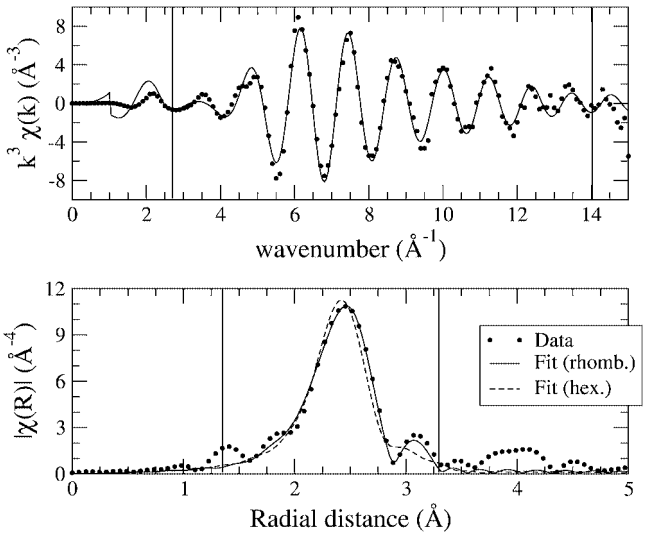

Fig. 2. Fit to the data measured on sample A using the model which places the Zr atom near a Sm site in rhombohedral Sm_2Co_{17} structure. The upper panel shows the fit in k-space with k^3 weighting. The vertical lines denote the extent of the Fourier transform. The lower panel shows the Fourier transform of the data in the upper panel. The vertical lines denote the fitting range in R. The fit with the hexagonal structure fails to fit the full width of the main peak.

The only structural model which yielded acceptable fit results for sample B places the Zr atom near the position of one of the dumbell Co atoms, although slightly farther displaced from the plane containing the ring of Co atoms surrounding the dumbbell site. The fit finds the Zr atom displaced from that plane by 1.789(61) Å as compared to the Co distance of 1.704 Å, according to the crystal data.

Although none of the other fitting models considered proved successful, the model described above is not entirely satisfying. The misfit on the high-R side of the peak in Figure 3 is significant

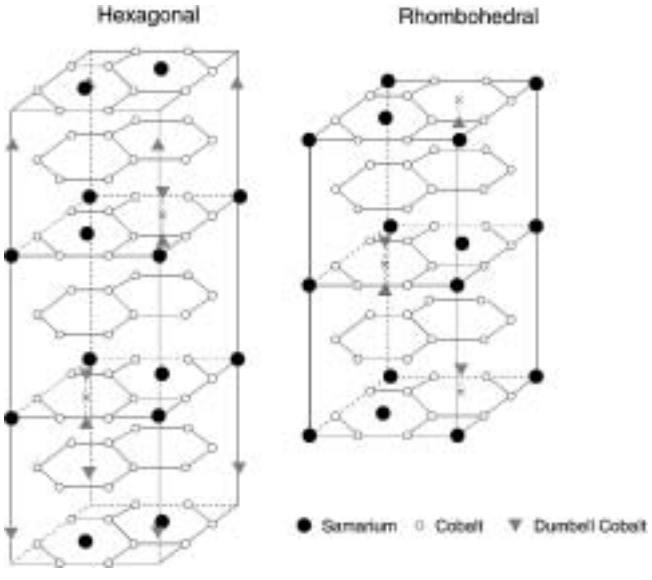

Fig. 1. Structures of hexagonal (left) and rhombohedral (right) Sm_2Co_{17} [5]. The Sm atoms (•) are at the centers of some Co (○) ring structures. Others have Co "dumbbells" at their centers.

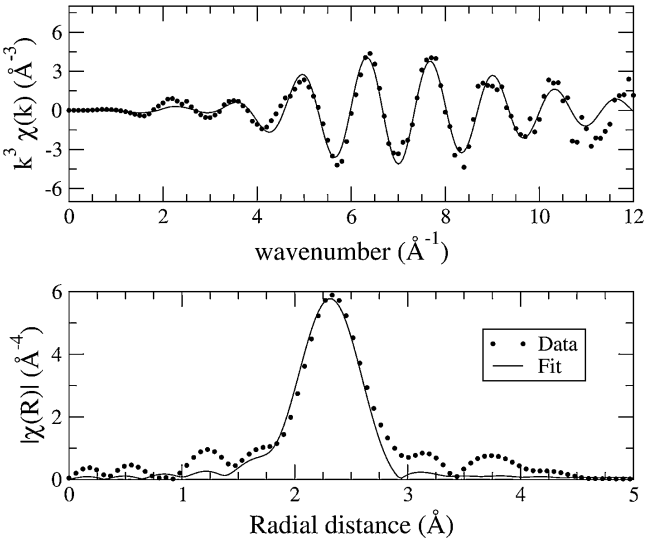

Fig. 3. Fit to the data measured on sample B using the model which places the Zr atom near a Co1 site in the hexagonal Sm_2Co_{17} Structure. The upper panel shows the fit in k-space with k^3 weighting. The vertical lines denote the extent of the Fourier transform. The lower panel shows the Fourier transform of the data in the upper panel. The vertical lines denote the fitting range in R.

and the small peak above 3 Å is not fit at all. We considered the possibilities of Zr oxide, Zr metal clusters, higher shells around the Col site, and the presence of a scatterer at the other dumbbell position. The data support none of the possibilities. Furthermore, the measured σ^2 values are large, ranging from 0.0098(33) Å^2 at 10 K to 0.0118(45) Å^2 at 300 K. Together these results suggest either that the placement of a Zr atom at a dumbell Co site introduces significant local disorder or that the model of Zr at the dumbbell site is suspect.

4. Conclusions

For sample A, the best fit to the data was obtained by placing the Zr atom near the Sm site in the rhombohedral Sm_2Co_{17} structure. For sample B, the best fit corresponds to a Zr atom near a copper dumbbell site in the hexagonal Sm_2Co_{17} structure. Both results confirm the speculations of previous authors [4, 6, 7] that Zr would replace a Sm atom or a Co dumbbell in this lattice and contrast the previous EXAFS report [8] on Zr in Sm–Co magnets.

The purpose of measuring the ternary alloy was to avoid the complexities introduced by the microstructure of the commercial $Sm(Co, Fe, Cu, Zr)_z$ materials. This did not prove to be a wholly successful strategy. Small differences in the heat treatment of our two samples lead to significant differences in structure about the Zr atom. It seems that the fabrication of the ternary alloy is, itself, a formidable materials science problem.

We plan much future work in this area. Future EXAFS studies of the ternary alloy prepared under various conditions are needed to fully elucidate the role of Zr in the Sm_2Co_{17} lattice. Clearly sample conditions lead to variations in local structure about the Zr atom. It is important to understand this variability, particularly in the temperature range in which the lamellar structure forms in the commercial alloy. Also important will be to study the role of Zr in the Sm_2Co_{17} lamellae in the commercial $Sm(Co, Fe, Cu, Zr)_z$ magnet. Electron nanoprobe energy loss studies [2] show that the Zr is concentrated in the lamellae, although some Zr remains in the cell regions of the $Sm(Co, Fe, Cu, Zr)_z$ microstructure. From those results, we estimate that about 80% of the total Zr atoms lie in the lamellae, thus making it possible to consider deconvolving the lamellar Zr portion of an EXAFS spectrum measured from the commercial magnet. These future studies on the ternary and commercial alloys will clarify the structural aspects of the Zr substitution into the Sm_2Co_{17} lattice. Detailed structural knowledge should deepen our understanding of the poorly understood physical mechanisms leading to the rich microstructure and outstanding magnetic properties of the commercial magnets.

Abstract

Spin-dependent X-ray absorption near edge structure (XANES) spectra measured by selectively monitoring of the Mn K-beta emission while scanning the excitation energy through the Mn K absorption edge were analyzed. The method of calculation is based on a combination of self-consistent spin-polarized calculation of muffin-tin potential and a full multiple scattering theory for interpretation of X-ray absorption. This approach allows to separate influence of dipole transition matrix elements and density of empty electronic states on spin-dependent XANES. It is found that matrix elements affect the splitting between spin-up and spin-down spectra only near the absorption threshold, while differences in densities of states slightly shift spectra in the region 35–55 eV above the main edge. Effects of multielectron term dependent broadening of spin-dependent XANES spectra and different mean free paths of photoelectrons with spin-up and spin-down in ferromagnetic phase were taken into account. It is shown that these factors also contribute to the splitting of spectra with different spin directions near the absorption threshold.

1. Introduction

Recent progress in construction of synchrotron sources and X-ray fluorescence detectors opened new possibilities for development of X-ray absorption measurements. By selectively monitoring one of the fluorescence components and scanning the incident photon energy through the absorption edge one can then do X-ray absorption measurements in Raman mode (or inelastic X-ray scattering mode). This experimental technique has several advantages if compared with traditional methods of X-ray absorption spectroscopy. One of them is a possibility to measure spin-dependent X-ray absorption fine structure. This method does not require long-range magnetic order and can therefore be applied to paramagnetic, antiferromagnetic as well as ferromagnetic systems. As a result of the exchange interaction between the 3p and 3d electrons in the final state (in the case of 3d-transition metals), the fluorescence spectrum shows pronounced satellite structure. On the base of multiplet splitting calculations it has been found that the spectra measured with fluorescence energy fixed on the main emission peak and on the satellite corresponds to the spin-polarized XANES spectra. After the pioneer publication of Hamalainen [1] such method was applied to the Mn K-edge in MnP [2], $LaMnO_3$ [3], complexes of Mn(II) with octahedral arrangement of metal ion [4] and Fe K-edge in protein rubredoxin [5] and Fe porphyrins [6].

Simultaneously with development of experimental techniques, theoretical methods explaining the spin-dependent X-ray absorption spectra were developed. In our preliminary paper [7] we reported first multiple scattering calculations of spin-polarized X-ray absorption fine structure (SPXANES) of MnF_2 and MnO. Besides the SPXANES the spin effects have been found to be very important in X-ray magnetic circular dichroism [8], magnetic extended X-ray absorption fine structure [9] and calculation of X-ray absorption under spin transitions in protein active centers [10]. Influence of spin-orbital interaction of final states on SPXANES is negligible (in contrast with magnetic circular dichroism), therefore using non-relativistic theory, but with inclusion of exchange splitting of final states, is appropriate for the interpretation of SPXANES.

Beside combination of multiple scattering theory with self-consistent field (SCF) calculations of potential, other methods to obtain SPXANES were proposed. Dufek [11] interpret MnF_2 SPXANES using linearized-augmented-plane-wave approximation. Taguchi and Kotani [12] reported multiplet splitting calculations of MnO and MnF_2 spectra based on empirical densities of unoccupied states.

In the present paper we report multiple scattering calculations of SPXANES of MnP.

2. Method of calculation

In order to obtain two sets of potentials for spin-up and spin-down configurations we performed self-consistent spin-polarized calculation of the electronic structure of small MnP_6 cluster that is a fragment of MnP crystal. The method we used is based on self consistent field scattered waves (SCF X_α-SW) technique with Slater X_α local density approximation (LDA) [13]. The charges of Mn and P ions were chosen according to the formal oxidation levels. Furthermore we have assumed that three 3d-electrons of Mn^{3+} are spin-up and one electron is spin-down. This correlates with recent results [14]. It has been found, that the difference between charges with various spin directions and d-character within the Mn muffin-tin spheres is 2.12 electrons.

Two sets of potentials, corresponding to the different spin states, obtained in the spin-polarized self-consistent calculations of small MnP_6clusters, were used to calculate partial phase shifts of the photoelectron, scattering on these potentials and dipole transition matrix elements. Then we performed full multiple scattering XANES calculations using these spin-dependent phase shifts and transition matrix elements in the same manner as in our previous work [7]. The algorithm of full multiple scattering method was described earlier [15]. Cluster containing 7 nearest to absorbing atom shells were chosen according to the convergence criterion.

3. Results and discussion

The spin dependence of the X-ray absorption is a result of interplay of two effects: different densities of spin-up and spin-down states and different transition matrix elements. Using multiple scattering formalism it is possible to separate these two factors. As one

*e-mail: Soldatov@rsu.ru

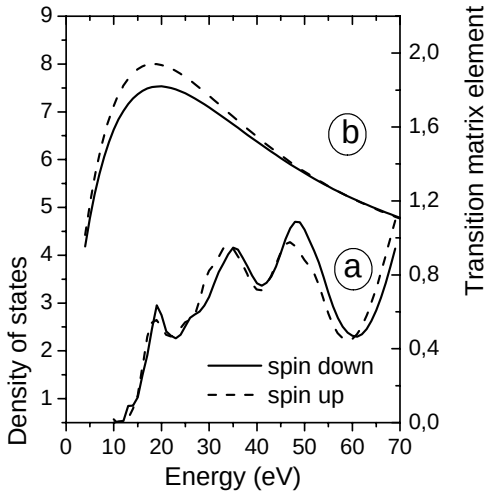

Fig. 1. (a) Spin-dependent densities of Mn unoccupied states with p-symmetry and (b) normalized squared dipole transition matrix elements as a function of photoelectron energy.

can see in fig. 1a there is an overall shift of spin-up density of states (DOS) towards low energy and a small decrease of intensity of peaks A and E. The relative shift of spin-up and spin-down DOS is due to the exchange interaction of 3d electrons with the photoelectron. It is clearly visible in the experimental spectra near the minimum F, where spin-dependence of transition matrix element is negligible. Such trend is observed also in other Mn and Fe SPXANES [1–6].

In Fig. 1b we present calculated matrix element of dipole transition. Its spin dependence influences XANES in the energy range 5–45 eV. Difference between matrix elements is significant (more than 10% in maximum). Therefore the assumption used by Taguchi [12] for MnF_2, that matrix elements for spin-up and spin-down states are equal is not valid. Besides spin dependence, the matrix element also shows considerable energy dependence. It can not be treated as a constant (as it was done for MnF_2 [11]) because it will result in wrong relative intensities of the low energy features.

In order to directly compare theoretical and experimental spectra one must take into account the broadening of the experimental spectrum according to the finite mean free path of a photoelectron, experimental resolution and spin-dependent factor equal to the width of 3p level for spin down and 3p + 1s for spin-up spectra. Recently it has been shown both experimentally [16] and theoretically [17], that for ferromagnetic samples the mean free path of photoelectrons is also spin-dependent. To test the influence of this factor on SPXANES we have performed calculations with non-spin-polarized energy-dependent broadening function obtained by Muller [18] and spin-polarized function from [17]. Results of such simulations are presented in fig. 2. Broadening factor as a function of energy is also shown. As one can see, the spin dependence of the mean free path influences the intensity of pre-edge feature and peak A. Another broadening factor mentioned above, partially compensates the differences between broadening of pre-edge peaks.

A novel method of data processing to exclude the effect of multiplet dependent broadening has been reported [2]. Probably, during this empirical data analysis the average differences between energy-dependent broadening functions were also taken into account. In fig. 3 we compare our calculations with these spectra. As one can see, good agreement with experiment was obtained.

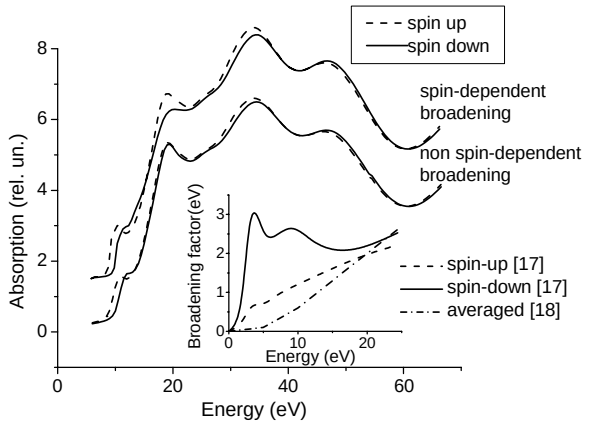

Fig. 2. Theoretical spin-dependent spectra calculated with non-spin-polarized energy-dependent broadening function [18] and spin-polarized function from [17]. The inset shows broadening factor as a function of energy.

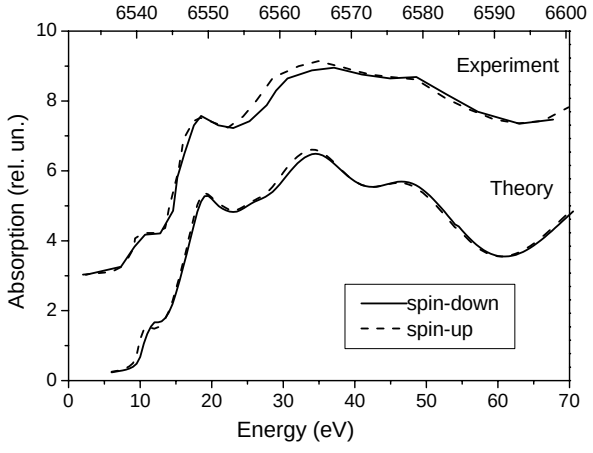

Fig. 3. Experimental Mn K-edge spin-dependent X-ray absorption of MnP after data processing [2] compared with theoretical spin-polarized X-ray absorption.

Abstract

Soft X-ray magnetic circular dichroism (MCD) and absorption spectra (XAS) were measured at the Fe $L_{2,3}$-edges and the Dy $M_{4,5}$-edges for a family of dysprosium iron garnets. The Fe ions sit in either O_h symmetry sites or T_d symmetry sites in $Dy_3Fe_5O_{12}$. Only Fe ions in the O_h sites are substituted with In ions in $Dy_3Fe_{4.25}In_{0.75}O_{12}$ and only Fe ions in the T_d sites are substituted with Ga ions in $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$. The XAS spectrum profiles of the three-dysprosium iron garnets are very similar. The MCD signals of both the Fe $L_{2,3}$-edges and the Dy $M_{4,5}$-edges of $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ are similar to that of $Dy_3Fe_5O_{12}$, but $Dy_3Fe_{4.25}In_{0.75}O_{12}$ is remarkably different. The results directly show that the spin moment of Fe in the T_d sites play a major role in determining the total magnetization of $Dy_3Fe_5O_{12}$.

1. Introduction

$R_3Fe_5O_{12}$(Rare Earth Iron Garnet: RIG) is a typical ferri-magnet composed of a rare earth element (R) and iron. The iron and rare earth valences are both positive trivalent, while oxygen is negative divalent. RIG has a crystal structure called "garnet structure". In RIG, an Fe^{3+} ion is surrounded by O^{2-} ions and has either O_h symmetry or T_d symmetry [1, 2]. It was found that the Fe^{3+} ions sit in tetrahedral and octahedral sites and the R^{3+} ions sit in dodecahedral sites. The ratio of the T_d sites to the O_h sites is 3 : 2.

The magnetic properties of RIG can be interpreted based on a collinear Neel model. In the formula $R{\downarrow}_3Fe{\downarrow}_2\ Fe{\uparrow}_3O_{12}$ (up (down) arrow represents the majority (minority) spin), the magnetic moments of the T_d and O_h sites of the iron sublattices are anti-parallel yielding a net moment of one Fe^{3+} ion, which corresponds to $5\mu_B$ directed towards the tetrahedral sites. The magnetization of the rare earth sublattice is anti-parallel to the net iron.

Dysprosium iron garnet ($Dy_3Fe_5O_{12}$: DyIG) belongs to the RIG family. $Dy_3Fe_{4.25}In_{0.75}O_{12}$ is made by site-selectively replacing 37.5% of the Fe ions in the O_h symmetry sites in $Dy_3Fe_5O_{12}$ with In ions. On the other hand, site-selectively replacing 25% of Fe ions in the T_d sites in $Dy_3Fe_5O_{12}$ with Ga ions makes $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$. The ordinal magnetic property measurements macroscopically represent the overall magnetic property of the system. On the other hand, the core level absorption spectroscopy measures the electronic and spin states in a conduction band for selected elements and orbitals. For example, when an Fe 2p electron is excited, the soft X-ray absorption spectrum (Fe $L_{2,3}$ XAS) reflects the 3d electron state following the dipole moment selection rule. (When a Dy 4f electron is excited, the spectrum is a Dy $M_{4,5}$ XAS.) The difference between the right- and left-handed circular polarized X-ray excited XAS is called circular dichroism. The spectrum reflects the spin state in a magnetic material. Kawamura *et al*. reported Dy $L_{2,3}$ magnetic circular dichroism (MCD) spectra [3].

The MCD signal direction is dependent on the ion, Dy ions or Fe ions either in T_d symmetry and O_h symmetry, that has the majority spin moment. In this study, the substitution effect of Fe on MCD spectra in $Dy_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ at the Fe $L_{2,3}$-edges and the Dy $M_{4,5}$-edges was directly measured to investigate the magnetic properties of Fe in the T_d and the O_h symmetry site.

2. Experiments

MCD and XAS spectra at the Fe $L_{2,3}$ and the Dy $M_{4,5}$-edges for the DyIG compounds were measured using synchrotron radiation at the soft X-ray beamline BL23SU at SPring-8, Japan [4, 5, 6]. An APPLE2-type undulator was the light source and a varied space plane grating type monochromator was installed at the beamline. The obtained energy-resolution $E/\Delta E$ was higher than 7000 around the Fe $L_{2,3}$-edges [7]. The XAS spectra were recorded in total electron yield (TY) mode. It is empirically known that the TY spectrum well represents the photo absorption spectrum in the core-level excitation region. The sample current (I_1) is normalized by the incident photon intensity (monitored current (I_0)) and the normalized absorption intensity (I) is determined by $I = I_1/I_0$. The XAS intensities using parallel and anti-parallel photon helicity to the magnetic field are denoted by I_+ and I_-, respectively. The XAS of isotropic polarization is defined as $I_{iso} = (I_+ + I_-)/2$, and the MCD intensity is denoted as $I_{MCD} = (I_+ - I_-)$. The most unique performance of the APPLE2-type undulator is that shifting the phase of the magnet rows of the undulator switches the photon helicity in a few seconds from right-handed to left-handed circularly polarized X-rays. During MCD measurements, the undulator and the monochromator were synchronously controlled, *i.e*., the photon helicity was switched at each photon energy point. This method is advantageous for avoiding the energy disparity between the two different circularly polarized X-rays, caused by the repeatability of a monochromator [8].

$Eu_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ powder samples were uniformly pasted on a sample holder using carbon tape. A static magnetic field of 0.4 Tesla was applied to the sample at room temperature (about 300 K). The magnetic moment of DyIG was saturated at $H = 0.4$ Tesla. The incident angle of the photon beam was set parallel to the magnetic field.

3. Results and Discussion

Figure 1 shows the XAS spectra of $Dy_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ at the Fe $L_{2,3}$-edges. Spectra of I_{iso}, I_+, and I_- are shown as solid, dashed, and dotted curves, respectively. The inset shows the detailed spectra at the L_3-edge.

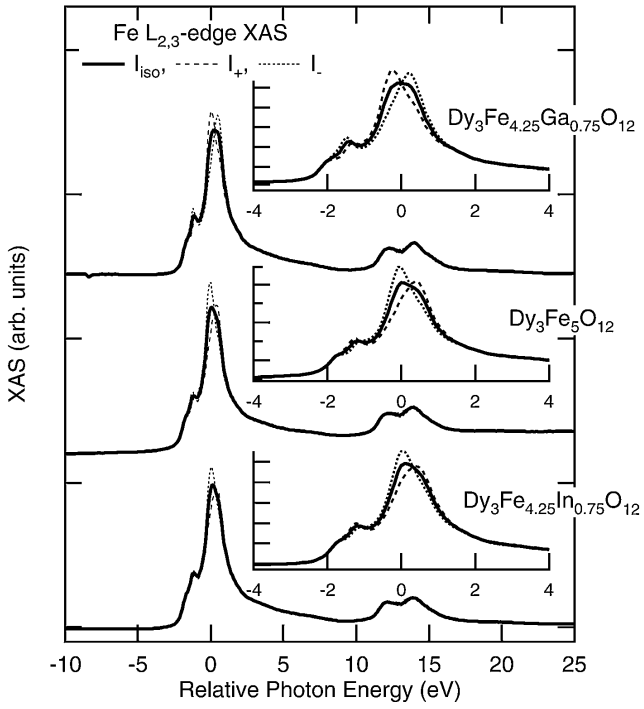

Fig. 1. Fe $L_{2,3}$ XAS of $Dy_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ in a magnetic field of 0.4 Tesla at room temperature in a relative energy scale. The L_3 peak is set to 0 eV and the edge jump is set to 1. Spectra of I_{iso}, I_+ and I_- are shown in as solid, dashed, and dotted curves, respectively. The inset shows detailed spectra at the L_3-edge.

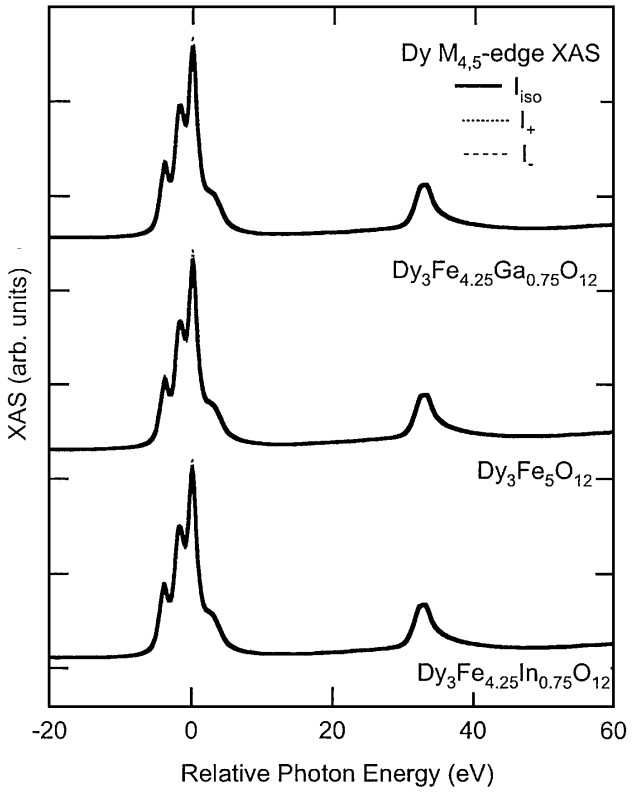

Fig. 2. Dy $M_{4,5}$ XAS of $Dy_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ in a magnetic field of 0.4 Tesla at room temperature in a relative energy scale. The M_5 peak is set to 0 eV and the edge jump is set to 1. Spectra of I_{iso}, I_+ and I_- are shown in as solid, dashed, and dotted curves, respectively.

Here the photon energy of the Fe L_3 peak of I_{iso} is nominally set to 0 eV and the edge jump of I_{iso} is normalized to be 1 for each specimen. The white lines of L_3 and L_2 are clearly observed. There is a small shoulder at the lower energy side of the L_3 peak, which originates from orbital mixing of Fe 3d and O 2p that is found in Fe oxides such as a ferrite and an ilmenite [9, 10]. Figure 2 shows the XAS spectra of $Dy_3Fe_5O_{12}$, $Dy3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ at the Dy $M_{4,5}$-edge. The spectra of I_{iso}, I_+, and I_- are shown as solid, dashed and dotted curves, respectively. Here the photon energy of the Dy M_5 peak is nominally set to 0 eV and the edge jump of I_{iso} is normalized to 1 for each specimen. The white lines of M_5 and M_4 are clearly observed. The fine structure of the M_5 peak is due to the multiplet effect.

All three samples have similar Fe $L_{2,3}$ XAS and the Dy $M_{4,5}$ XAS line shapes. These results imply that the displacement of the Fe ion does not substantially change the Fe 3d and the Dy 4f electronic states. I_+ and I_- of the Fe $L_{2,3}$-edges show differences between samples.

Figures 3 and 4 show MCD spectra (I_{MCD}: solid curves) of $Dy_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ at the Fe $L_{2,3}$-edges, and at the Dy $M_{4,5}$-edges, respectively. The photon energy of the Fe L_3 peak and the Dy M_4 peak are nominally set to 0 eV and the zero level of the Fe $L_{2,3}$ MCD and the Dy $M_{4,5}$ MCD spectra are shifted by 0.3 and 0.15, respectively.

The MCD signal signs are the same for the Fe $L_{2,3}$-edges and the Dy $M_{4,5}$-edges of $Dy_3Fe_5O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$, but $Dy_3Fe_{4.25}In_{0.75}O_{12}$ has the opposite sign. The Dy $M_{4,5}$-edges MCD signal is in opposite direction of the Fe $L_{2,3}$-edges. For all the samples, the net Fe spin moment is opposite the net Dy spin moment. The Fe ions in O_h sites decrease when the Fe ions are replaced with In ions, but the MCD signal of $Dy_3Fe_{4.25}In_{0.75}O_{12}$ and $Dy_3Fe_5O_{12}$ are the same. The MCD signal of $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_5O_{12}$ are in opposite

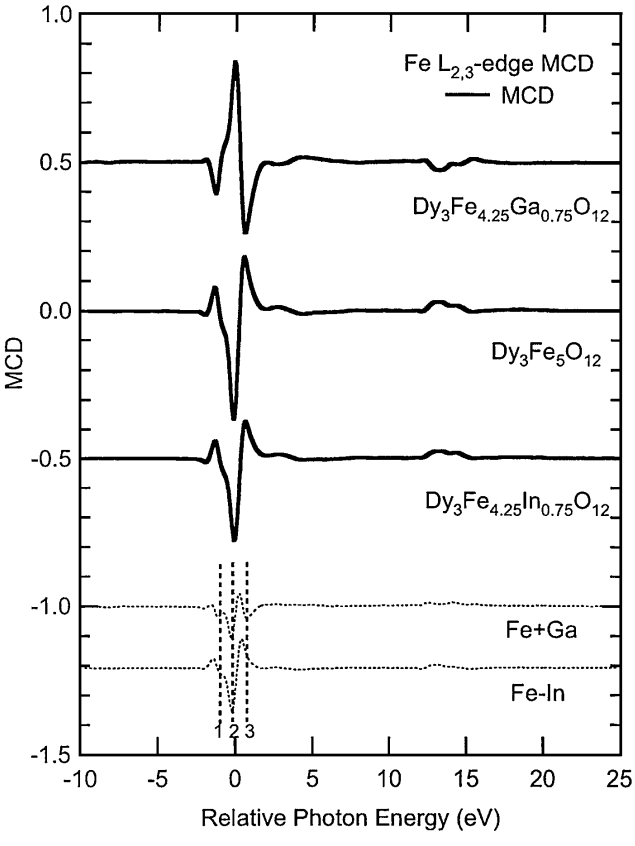

Fig. 3. Fe $L_{2,3}$ MCD of $Dy_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ in a magnetic field of 0.4 Tesla at room temperature in a relative energy scale.

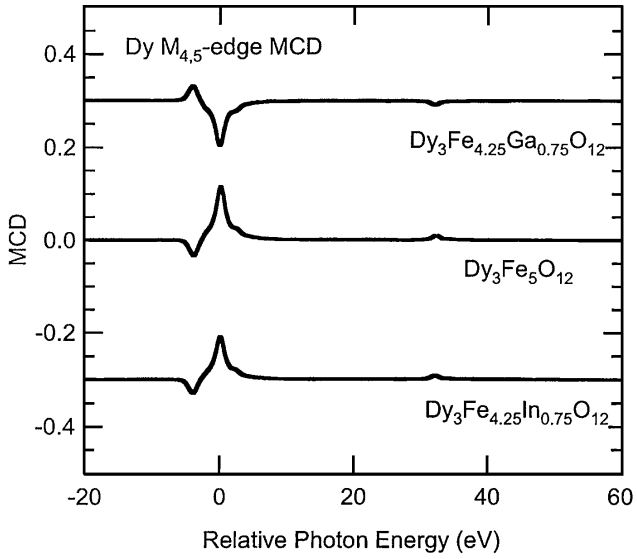

Fig. 4. Dy $M_{4,5}$ MCD of $Dy_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ in a magnetic field of 0.4 Tesla at room temperature in a relative energy scale.

directions and the majority spin moment in $Dy_3Fe_5O_{12}$ is changed from that in $Dy_3Fe_5O_{12}$. Here, the magnetic moments of Fe and Dy are defined as M_{Fe} (about $5\mu_B$) and M_{Dy}. The number of Fe ions in O_h and T_d sites is defined as N_{Oh} and N_{Td}, respectively. The macroscopic magnetic moment is written as $(N_{Td}\text{-}N_{Oh})\ M_{Fe}\text{-}3M_{Dy}$. $Dy_3Fe_5O_{12}$ has a positive moment, by $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ has a negative moment. The magnetic moment of the Dy ions itself is large, but they disordered at room temperature and the total magnetic moment of Dy is estimated to be $0.42\mu_B < M_{Dy} < 1.67\mu_B$.

In Fig. 3, the dotted curves show the difference spectra of $Dy_3Fe_{4.25}In_{0.75}O_{12}$ from $Dy_3Fe_5O_{12}$ MCD spectra and to make the number of Fe ions the same, the intensity of $Dy_3Fe_{4.25}In_{0.75}O_{12}$ (I_{Fe-In}) is reduced by a factor 0.85. For the $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ spectra (I_{Fe+Ga}), the difference specra is achieved by adding the spectra of $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_5O_{12}$. Again, the intensity of $Dy_3Fe_{4.25}In_{0.75}O_{12}$ is reduced to 0.85 to scale the number of Fe ions in an unit. In the I_{Fe+Ga} spectrum, the signal from the O_h sites is enhanced and in the I_{Fe-In} spectrum, the T_d signal is enhanced. The line shapes of the XAS and MCD spectra are strongly dependent on the electronic states or the electronic configuration of the atom. In order to provide a better qualitative description of the spectral feature, the line shapes of the XAS and MCD spectra were further investigated by calculating by the ionic model [11]. Figure 5 shows the corresponding calculated Fe $L_{2,3}$ MCD spectrum (I_{MCD}) for Fe^{3+} (d^5) in the T_d symmetry

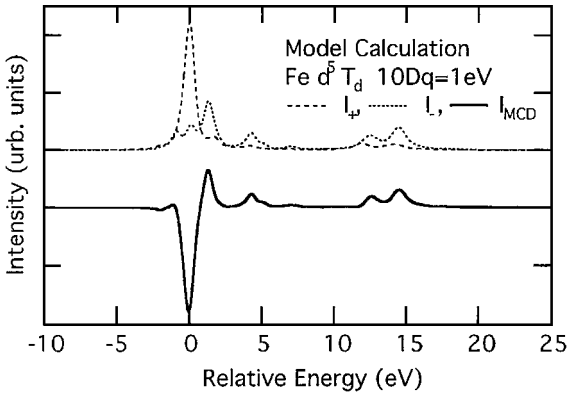

Fig. 5. Calculated XAS and MCD spectra using the ionic model, at the Fe $L_{2,3}$-edge for Fe^{3+} ion in a T_d symmetry crystal field for $10Dq = 1$ eV.

crystal field (I_+ and I_-) and where the crystal field energy from the ligand state to the 3d level $10Dq = 1$ eV. The claculated spectrum reproduces the line shape of the I_{Fe-In} spectrum. Comparing Fig. 5 and Fig. 3, it is assumed that in Fig. 3 the O_h site structures are observed at 1 and 3 and the T_d site structure is observed at 2.

In summary, the substitution effect of Fe on the total magnetic moment direction of $Dy_3Fe_5O_{12}$ was directly investigated. The XAS and MCD spectra were measured at the Fe L and the Dy M-edge of $Dy_3Fe_5O_{12}$, $Dy_3Fe_{4.25}Ga_{0.75}O_{12}$ and $Dy_3Fe_{4.25}In_{0.75}O_{12}$ with element selectivity. The Fe ions in the T_d symmetry sites play an important role in determining the direction of the total magnetization.

Abstract

In this work, geometric structures for *TM*-doped (*TM* = Mn and Fe) ZnO film grown by combinatorial laser molecular beam epitaxy (CLMBE) were investigated using fluorescence EXAFS measurement. The EXAFS analysis has revealed that the majority of *TM* ions heavily doped in ZnO ([Mn] ∼ 20% and [Fe] ∼ 1%) substituted the Zn atoms in ZnO lattice.

1. Introduction

Diluted magnetic semiconductors have attracted much interest as materials with both optical and magnetic properties. Recently, ZnO-based diluted magnetic semiconductor (DMS) with high Curie temperature above room temperature has been predicted by mean field theory [1]. High *Tc* is beneficial in utilizing ZnO-based DMS for novel magneto-electronic devices.

In the present work, Fe- and Mn-doped ZnO thin films grown by combinatorial laser molecular beam epitaxy (CLMBE) were investigated by fluorescence extended X-ray absorption fine structure (EXAFS) measurements using synchrotron radiation. We have successfully fabricated 3d transition-metal-doped (TM-doped) ZnO films by CLMBE [2, 3]. However, the geometric structures for the heavily TM-doped ZnO has not been clear yet. The fluorescence EXAFS measurement is a powerful technique for investigating local structures around a specific element and is suitable for evaluating the geometric and electronic structures around TM ions in the present study [4, 5].

2. Experimental

Mn- and Fe-doped ZnO films were grown on sapphire (0001) substrate by CLMBE. Details of the film growth procedure are described in ref. [2]. Concentration of Fe and Mn ions were determined by electron probe microanalysis (EPMA).

EXAFS measurements were performed at the beam line BL12C at the Photon Factory in Tsukuba using the SR from the 2.5 GeV storage ring with a Si(111) double crystal monochromator and a bent cylindrical mirror [6]. The EXAFS spectra were measured in the fluorescence-detection mode at a temperature of 70 K. The intensity of incident X-ray beam was monitored by a nitrogen-filled ionization chamber, while the fluorescence X-ray signals were detected by 19 elements Ge solid-state detector (SSD).

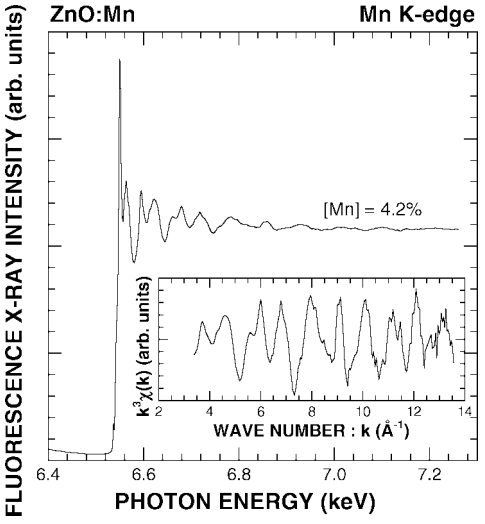

Fig. 1. Fluorescence X-ray intensity of Mn-doped ZnO film (Mn concentration : [Mn] = 4.2%) at Mn K-edge. Inset shows Mn-K-edge EXAFS oscillation function spectrum $k^3\chi(k)$.

3. Results and discussion

Figure 1 and 2 display the fluorescence X-ray intensities for Mn- and Fe-doped ZnO thin films at Mn and Fe K-edge, respectively. EXAFS oscillations were clearly observed for each sample. Figures 3 and 4 represent the Fourier transformed Mn and Fe ions K-edge EXAFS spectra $k^3\chi(k)$ for Mn- and Fe-doped ZnO thin films and the theoretical EXAFS spectra $k^3\chi(k)$ for substitutional Mn and Fe ions on the Zn site in the ZnO lattice are compared. Theoretical EXAFS spectra were generated by FEFF6 program [7]. Despite the high level of *TM* ions doped in the ZnO, several peaks are clearly observed at a longer radial distance, indicating that the local structures around the *TM* ions are well-ordered with respect to short-range ordering. In addition, the experimental spectra correspond well to the theoretical ones. Thus, it is expected that *TM* ions in heavily doped ZnO substitute the Zn-site in the ZnO lattice.

In order to analyze the details of the measured spectra, curve-fitting for the EXAFS spectra was carried out with theoretically calculated spectra using FEFF6 [7]. For all the samples, species of neighboring atoms and coordination numbers show good agreement with those of the ZnO film. Although we also carried out curve-fitting for models of various TM oxides, reliable parameters for such models were not obtained. We therefore

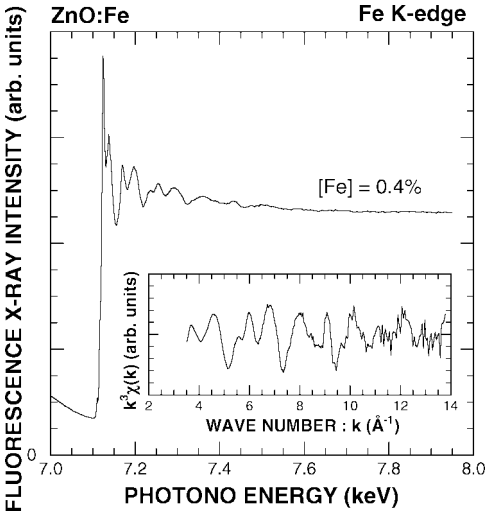

Fig. 2. Fluorescence X-ray intensity of Fe-doped ZnO film (Fe concentration: [Fe] = 0.4%) at Fe K-edge. Inset shows Fe-K-edge EXAFS oscillation function spectrum $k^3\chi(k)$.

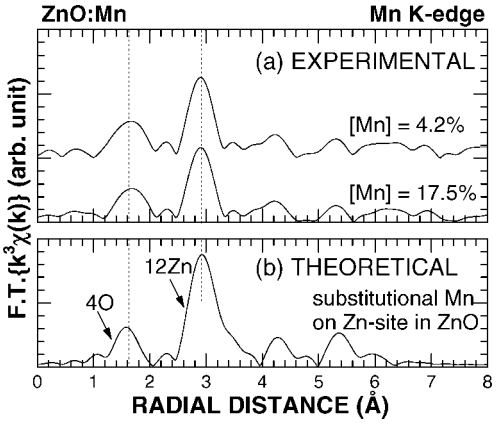

Fig. 3. Fourier transform of Mn K-edge EXAFS oscillation function spectra $k^3\chi(k)$ of (a) Mn-doped ZnO film and (b) theoretical EXAFS spectrum for the substitutional Mn ion on the Zn site in the ZnO lattice. The Fourier transformation was performed in the k range of 4.0–13.0 Å^{-1}. The Debye-Waller factor was assumed as 0.05 Å for bond length below 3.5 Å and 0.075 Å for bond length above 3.5 Å. The theoretical EXAFS spectra were generated by FEFF6 [7].

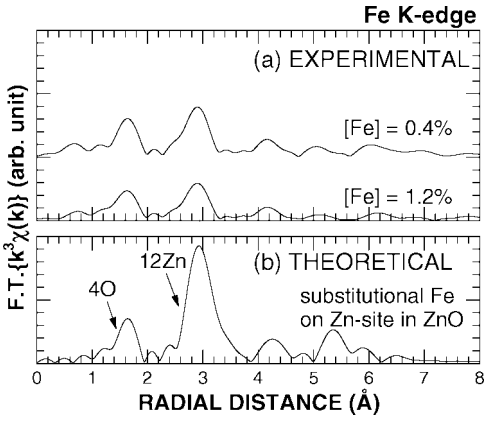

Fig. 4. Fourier transform of Fe K-edge EXAFS oscillation function spectra $k^3\chi(k)$ of (a) Fe-doped ZnO film and (b) theoretical EXAFS spectrum for the substitutional Fe ion on the Zn-site in the ZnO lattice. The Fourier transformation was performed in the k range of 4.0–13.0 Å^{-1}. The Debye-Waller factor was assumed as 0.05 Å for bond length below 3.5 Å and 0.075 Å for bond length above 3.5 Å. The theoretical EXAFS spectra were generated by FEFF6 [7].

conclude that the majority of *TM* ions (above 80% of the total *TM* ion amounts) in all the samples substitute the Zn-site in ZnO, which indicates the formation of a ZnO-based DMS layer. For the Mn-doped ZnO thin films, Mn-O bond lengths were determined to be 2.01–2.02 Å, and for the Fe-doped ZnO thin films, the Mn-O bond length is 1.97–1.98 Å.

Abstract

We studied the feasibility of magnetic circular dichroism (MCD) in the hard X-ray region for determining 4f magnetic moments by measuring the temperature dependence of MCD spectra at rare earth L_2-edge in systems of rare earth iron garnets (R-IG) for R = Gd, Dy and Sm. Two components arising from the magnetization of the Gd and Fe sublattices, which were combined into the MCD spectrum of Gd-IG, were separatively deduced. For Dy- and Sm-IG, we successfully obtained the temperature dependence of the MCD component that comes from only R sublattice magnetization under the assumption that the MCD spectra of the series of R-IG contain the same contribution of the iron sublattice.

1. Introduction

Since the first theoretical prediction of magnetic circular dichroism (MCD) in X-ray absorption spectra (XAS) by B. T. Thole in 1985 [1], a lot of MCD measurements have been preformed for various ferromagnetic and ferrimagnetic materials [2–5] using synchrotron radiation sources, which produce high brilliant X-rays with good tunability of the circular polarization. The physical origin of MCD can be understood qualitatively by the excitation of partially spin-polarized photoelectrons from an unpolarized initial core state to spin-split empty final states [6–8]. The interest in the use of MCD is well understood by its ability to provide highly selective information: (1) the absorption process is atomic selective and (2) owing to the selection rules, it is possible in principle to determine independently the magnetic contribution of all open shells in an atom. These advantages of MCD are encountered in not only macroscopic magnetization measurements such as VSM or SQUID but also microscopic measurements using polarized neutrons or electrons.

The MCD in the region of hard X-rays has feasibility in some experimental aspects; a little surface sensibility which gives information of bulk magnetism, and good transmission through substances which can collect good statistical accuracy, and no necessity of high vacuum chambers. The first stage of the MCD measurements using hard X-ray was brought in the late 1980s by G. Schütz *et al.* [3]. Subsequently, extensive studies at the K-edge of transition metals ($1s \rightarrow 4p$) or at the L-edge of rare earths ($2p \rightarrow 5d$) has been reported [4–7] with experimental data and theoretical calculations. Unfortunately, however, the explanation of the MCD spectra at these edges were not so straightforward because we do not directly observe the shells that mainly contribute to the magnetization. On the contrary we measure at L-edges of transition metal ($1s \rightarrow 3d$) or M-edges of rare earths ($3d \rightarrow 4f$) in the soft X-ray region. Especially, the MCD spectra of rare earth L-edges in 4f-3d magnetic materials, in which more than two magnetic elements exist, have complicated structures. This complexity is interpreted as a consequence of the following effects. (a) There is an unignorable effect of E2 (quadrupole) transition, which contaminates the spectra produced by E1 (dipole) transition. (b) The polarization of 5d electrons is due to both the 4f-5d *inter*-atomic interaction and (c) the 5d-3d *intra*-atomic interaction with the adjacent transition metal. Quantitative and systematic calculations of MCD in the series $R_2Fe_{14}B$ were performed by Fukui *et al.* including the above effects [8]. K. Asakura and H. Ogasawara have proceeded the calculation with the hybridization effect of R 5d and Fe 3d in $R_2Fe_{14}B$ [9] and $CeFe_2$ [10]. They pointed out the importance of the additional effects to the 4f-5d interaction caused by the contraction of 5d orbital in the real space. This effect of '5d-contraction' may reverse the sign of the MCD signal in some cases [11, 12]. The spectra reproduced from their calculations were in good agreement with experimental results. The significance of the effects described above for other materials is, however, still unclear for a lack of empirical inspections.

In this paper we report the temperature dependence of MCD spectra at the R L_2-edge of rare-earth iron garnets (R-IG, $R_3Fe_5O_{12}$; R = Gd, Dy, and Sm). In R-IG, there exist two ferric sites; one contains three Fe^{3+} in tetrahedral symmetry and the other contains two Fe^{3+} in octahedral symmetry per formula unit. Magnetic moments of iron at these two sites align antiparallel by super-exchange through oxygen atoms. The R^{3+} ions are antiferromagnetically coupled to the net moment of the iron ions in the case of heavy rare earths and ferromagnetically in the case of light rare earths, but this coupling is much weaker than that among iron ions. The sublattice magnetization of R-IG was studied by means of the subtracting method [13, 14], in which the magnetization of the R sublattice was estimated from the subtraction of the magnetization of Lu-IG from that of R-IG under the assumption that the Fe sublattice has almost the same value of the magnetic moment in the series of R-IG. Lu has a filled 4f shell which has no magnetic moment and the whole magnetic moment of Lu-IG originates in the Fe sublattice. The magnetic moment of Gd and Dy at low temperature were estimated as 21.0 μ_B and 21.9 μ_B in this subtracting method [14], and the temperature dependences of these magnetic moments were well explained by the molecular field theory [15]. A reliable result for Sm sublattice magnetization was, however, not obtained because the magnetic moment of Sm is too small to be determined correctly by the subtracting method [16].

The purpose of this study is to investigate the temperature dependence of MCD spectra in R-IG, and to evaluate the validity of the *element specific* measurement of MCD in the hard X-ray region comparing with the R sublattice magnetic moment estimated from macro magnetization by the subtracting method.

2. Experiments

MCD measurements were made on SPring-8 BL39XU. A detail description of the optical configuration at this beamline was reported in [17]. The energy resolution of the incident X-rays was about 1.5 eV at the absorption edges measured in this study. The degree of circular polarization, about 90%, was switched between right and left at 30 Hz by using a diamond phase retarder [18]. The powdered samples, which were put uniformly on a scotch tape, were mounted in a magnetic field of 2 T. The magnetic field was generated by a super-conducting magnet for measurements at temperature below 30 K, and by an electromagnet at higher temperature. The intensities of the incident and of the transmitted X-rays were converted to voltage, V_0 and V, using ion chambers are in the front and back of the sample position. The photo absorption, $\mu(\omega)$, is measured as the time-average of V/V_0, and MCD, $\Delta\mu(\omega)$, is measured as the output of a lock-in signal which averages V/V_0 with modulation of the circular polarization of X-rays. In this scheme, we define

$$\text{XAS:} \quad \mu(\omega) = \frac{\mu_+(\omega) + \mu_-(\omega)}{2}, \tag{1}$$

$$\text{MCD:} \quad \Delta\mu(\omega) = \mu_+(\omega) - \mu_-(\omega). \tag{2}$$

Here $+$, $-$ means right and left circular polarization of the incident X-ray when the external magnetic field is parallel to the X-ray direction. The spectra of $\mu(\omega)$ and $\Delta\mu(\omega)$ were measured in the energy range of 40 eV around the absorption edges at temperatures between 2 K and 300 K with a step of about 10 K. The MCD spectra in this study have been normalized by the 'edge jump' of XAS spectra, which was estimated as the difference of $\mu(\omega)$ at ± 20 eV from the absorption edges. The MCD peak due to the effect for the quadrupole transition has been undetected in the L_2-edge of these compounds, so no considerations or procedures for its effect were needed. The MCD spectrum of Gd-IG and Dy-IG flips its sign below and above the compensation temperature, T_{comp}, so we have adapted the sign of MCD below this temperature and have reversed MCD spectra that were measured above T_{comp}.

3. Results and discussion

The Gd L_2-edge MCD spectra of Gd-IG measured at 2, 50, 100, 200 and 300 K are shown in Fig. 1. The temperature dependence of these spectra shows continual changes of both the shape and the magnitude of MCD. The reduction of the intensities of MCD with the rise of temperature evokes analogous with the depression of the magnetization of Gd sublattice. The change of the spectral shape, however, means that the MCD value at each energy point has different temperature dependence. In order to understand the behavior of these spectra, we have taken the proposition as follows. MCD at Gd L_2-edge contains two components. (1) First, $\Delta\mu_{Gd}(\omega)$, which is the direct spectrum reflecting the magnetic states of Gd sites, that is, the magnetization of the 4f shell. This component varies corresponding to the 4f-5d *intra-atomic* interaction. (2) Next, $\Delta\mu_{Fe}(\omega)$, which comes from the magnetization of the iron sublattice through 5d-3d *inter-atomic* super-exchange interaction. The observed MCD spectrum is a linear combination of these components.

$$\Delta\mu_{exp.} = \Delta\mu_{Gd}(\omega) \cdot m_{Gd}(T) + \Delta\mu_{Fe}(\omega) \cdot m_{Fe}(T), \tag{3}$$

here, $m_M(T)$ means the magnetization of the M atom sublattice. Both terms in the right side of the equation change only their size according to the magnetization of each sublattice, which depends

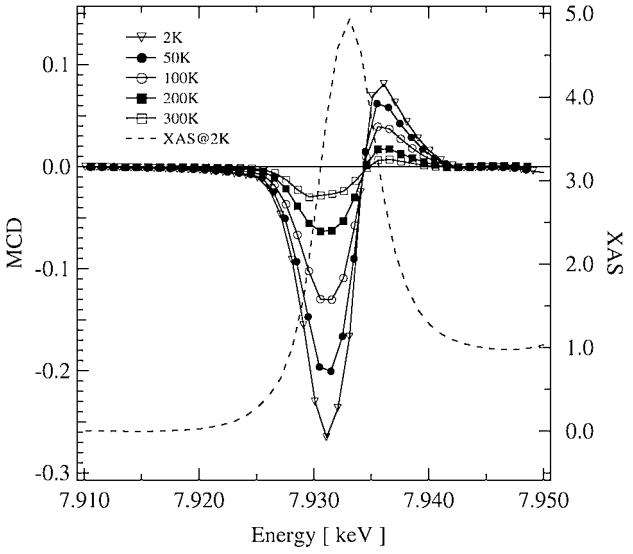

Fig. 1. MCD spectra of Gd L_2-edge in Gd-IG measured at 2 K, 50 K, 100 K, 200 K and 300 K. All spectra have been normalized by the edge jump of XAS.

to temperature, and do not change shape. The shape of $\Delta\mu_{exp.}$ is determined as the ratio between $m_{Gd}(T)$ and $m_{Fe}(T)$ at each temperature.

In order to extract $\Delta\mu_{Gd}(\omega)$ and $\Delta\mu_{Fe}(\omega)$ independently from obtained MCD spectra, we set them as parameters and preformed a fitting at each energy. For $m_{Gd}(T)$ and $m_{Fe}(T)$, the sublattice magnetic moments for Gd and Fe were used, which were estimated by means of the subtracting method of the macroscopic magnetization measurements of Gd-IG and Lu-IG.

In Fig. 2, the obtained two components are plotted. These fitting results can reproduce the experimental MCD spectra, $\Delta\mu_{exp.}$, at each temperature with good precision. The Fe components in Fig. 2 are very similar in shape to the MCD spectrum of Lu L_2-edge in Lu-IG, measured by N. Kawamura [19]. The 4f shell in Lu has no hole and no magnetic moment; therefore 5d spin polarization reflects only the magnetization of the Fe sublattice. This means that the $\Delta\mu_{exp.}$ of Lu-IG contains only the second term

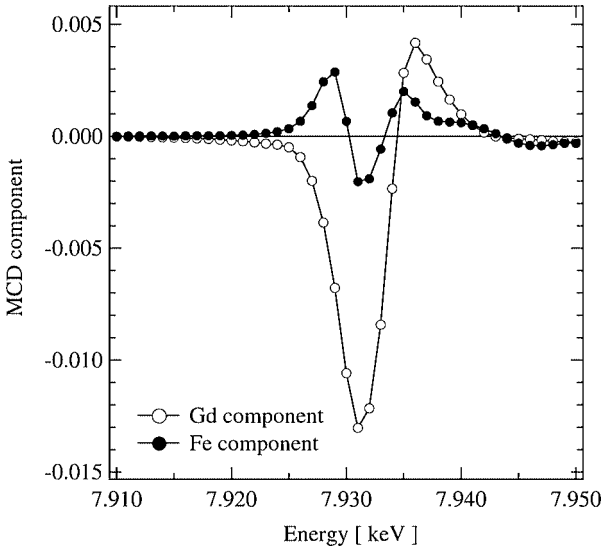

Fig. 2. The components of Gd (open) and Fe (filled) that contribute to MCD of Gd-IG L_2-edge. Both components are plotted as the size as the each sublattice has the magnetic moment 1 μ_B.

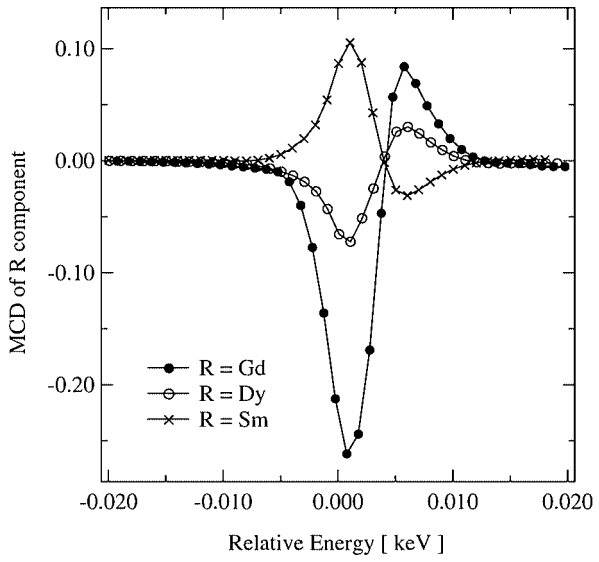

Fig. 3. The rare earth components in the MCD spectra of Gd-IG (filled), Dy-IG (open), and Sm-IG (cross) at 2 K. The magnetic moments of all R sublattices are parallel to the applied field in these samples.

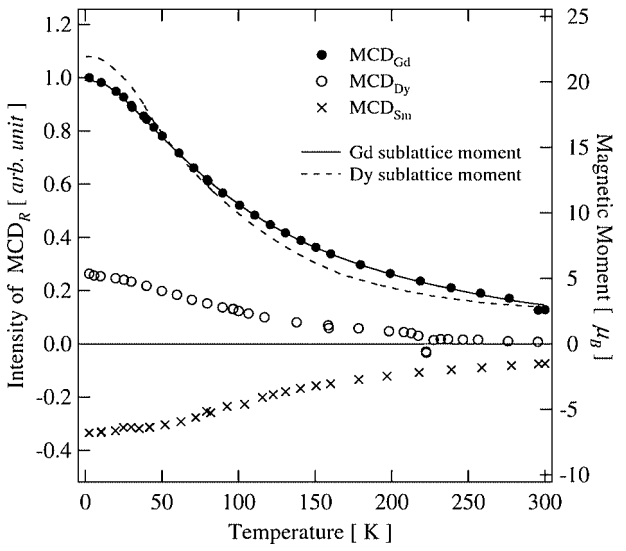

Fig. 4. The temperature dependence of the MCD components of Gd (filled), Dy (open), and Sm (cross), normalized by the value of Gd at 2 K. The magnetic moments of sublattice R estimated by means of the subtracting method are also plotted with the right axis as a solid line and a dashed line for Gd-IG and Dy-IG, respectively.

in Eq. (3). The similarity of the MCD spectrum in Lu-IG and the Fe component in Gd-IG supports the validity of the fitting analysis in this study and also demonstrates the possibility that $\Delta\mu_{Fe}(\omega)$ in Fig. 2 is appropriable to other R-IGs.

The measured MCD spectra of L_2-edge in Dy-IG and Sm-IG have the same trend of the temperature dependence as that of Gd-IG; the value for those decreases with increasing temperature, changing the shape of spectra. From these spectra, we have extracted the rare earth component, $\Delta\mu_R(\omega) \cdot m_R(T)$, which corresponds to the first term in Eq. (3), on the assumption that the component from the magnetization of the iron sublattice is also included in MCD spectra of Dy-IG and Sm-IG. In this procedure, we needed to shift the energy of $\Delta\mu_{Fe}(\omega)$ to the absorption edge of Dy or Sm. These energy-shifts were estimated as the differences of the first inflection points of XAS and were tuned finely to create the experimental spectra most closely.

The obtained spectra of Dy and Sm components at 2 K are shown in Fig. 3. In Fig. 3 are also plotted Gd component deduced from the fitting analysis in Gd-IG. With increasing temperature, these components change sizes according to the magnetization of the R sublattice, $m_R(T)$, being invariable in shape. In Fig. 4, the thermal variation of these R components in Dy-IG, Sm-IG and Gd-IG are shown where these are normalized so that of Gd equals 1 at $T = 2$ K. The magnetization-temperature curves of R sublattice estimated by means of the subtraction method of macro measurements are also in the same figure as a solid line for Gd and a dashed line for Dy. In Fig. 4, the right axis and the left axis are scaled approximately as the Gd sublattice magnetization should superpose to the MCD component of the Gd sublattice.

For Gd-IG and Dy-IG, the rare earth MCD components in Fig. 3 are similar in shape; they show a prominent minimum at $E = 1$ eV followed by a maximum located at about $E = 6$ eV, and the ratio between these peaks is about 1 : 3. The spectrum of the Sm component has also the same similarity with reversed sign. It is expected that the shape of these components may apply to the L_2-edge MCD spectra of other rare earth iron garnets.

The temperature dependence of the Dy component in Fig. 4 is consistent with the sublattice magnetization estimated from macroscopic measurements. Its value is, however, too small. The result of the MCD component of Sm, which is larger than that of Dy in absolute value and has a minus sign through the measured temperature, shows the discrepancy that the magnetic moment of Sm estimated from macroscopic measurement is expected to be small compared to that of Dy, and to have a plus sign versus the applied field. From this result, it is inferred that the L_2-edge of MCD at the rare earth reflects a value that is proportional to the total magnetization of the R sublattice, but it is not easy to compare among the samples that have different R elements. The reason seems to be the degree of 4f-5d interaction or an effect of the contraction of the 5d shell. Further investigations of MCD in the hard X-ray region for various 4f-3d compounds are needed. It is noteworthy that the temperature dependence of the Sm magnetic moment in Sm-IG, which is difficult to estimate by means of macroscopic measurement for its small 4f magnetic moment, is clearly obtained in this study as shown in Fig. 4.

4. Conclusion

We presented a verification of the *element specific* magnetic measurement of rare earth L_2-edge MCD spectra in R-IG comparing to the magnetization of the R sublattice, which is deduced from macroscopic magnetization measurements of R-IG and Lu-IG by means of the subtraction method. All measured MCD of Gd-IG, Dy-IG, and Sm-IG contain the same component from Fe sublattice magnetization, and the contribution of the R sublattice has been simply obtained by subtracting the Fe component from the measured spectra. The R component of MCD spectra in R-IG indicates a thermal variation similar to the estimated magnetization of the R sublattice from the macroscopic measurements, but the sign and the magnitude of MCD signals includes an uncertainty, which is expected to be related to the 4f-5d interaction with the effect of the spatial contraction of the rare earth 5d shell. The temperature dependence of the Sm sublattice magnetization in Sm-IG has been obtained without contamination from the Fe sublattice.

Abstract

Polarization-dependent X-ray absorption fine structure together with X-ray diffraction have been used to study the local structure in $SrTiO_3$ thin films grown on Si(001). Our data indicate that an interfacial polarization of the $SrTiO_3$ layer by the Si substrate results in a tetragonal distortion of the $SrTiO_3$ unit cell.

At room temperature, $SrTiO_3$ (STO) exemplifies the ideal, cubic perovskite structure [1]. It is formed by placing Sr^{+2} atoms at the corners of a cube, a Ti^{+4} atom at the cube center, and O^{-2} atoms at the face centers, in perfect octahedral coordination with the Ti^{+4} atom, as shown in Figure 1a. STO is often referred to as an "incipient" ferroelectric because it exhibits quantum paraelectric behavior below 4 °K in which the ferroelectric phase transition is suppressed by the non-vanishing zero-point motion of the ions [2]. It also possesses a competing, antiferroelectric distortion at 105 °K that involves the rotation of the oxygen octahedra coupled with a small, <0.01%, tetragonal c/a distortion [3]. Additionally, it is well known that strain induces ferroelectricity in STO at liquid-helium temperatures [4], and a recent theoretical study has suggested that the "mismatch" strain imposed on a thin STO layer when grown on a substrate with a dissimilar lattice constant can lead to ferroelectricity at room temperature [5].

To examine the effects of epitaxial strain on thin STO films, films with thicknesses of 40 Å, 60 Å, 80 Å, and 200 Å were grown on Si(001) substrates using molecular-beam epitaxy. Details of the sample preparation have been given elsewhere [6]. Near and extended X-ray absorption fine-structure data were collected at the Ti K edge. All data were recorded at room temperature. The data were recorded by monitoring the Ti K fluorescence using a single-element SiLi detector. The absorption data were collected with the polarization vector of the synchrotron radiation aligned both parallel and perpendicular to the Si(001) surface. In addition, the X-ray absorption spectrum from finely ground STO powder was recorded in transmission; it was used as the phase and amplitude standard to determine the Ti–O bond lengths within the films.

In order to characterize the strain state of the STO films, high-resolution X-ray diffraction measurements were performed. Figure 2 shows the results of the diffraction experiment for both the parallel (in-plane) and perpendicular (out-of-plane) lattice constants of the STO films. Notably is the observation that the lattice constant in the in-plane direction; i.e., the lattice constant parallel to the STO/Si interface, is significantly larger than the bulk STO lattice constant. This effect is due to the different thermal expansion coefficients of STO and Si. It has been observed for GaAs on Si hetero-epitaxy and results from the relaxation of the film at growth temperature [7]. Even more surprising, however, is that the out-of-plane lattice constant of the thinner films becomes larger than the corresponding in-plane lattice constant with a c/a distortion approaching ∼0.33. This distortion is close to the c/a distortion observed for the tetragonal, ferroelectric phases of $BaTiO_3$ (∼1%) [8].

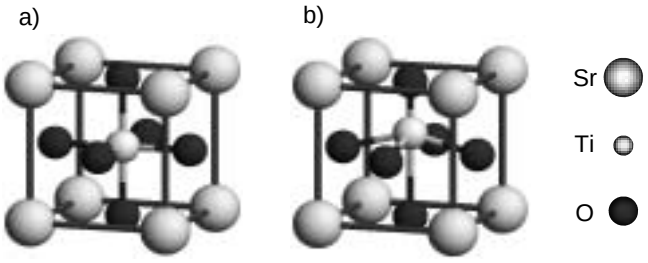

Fig. 1. STO unit cell. a) Cubic. b) Tetragonal.

Figure 3 shows the Ti K X-ray absorption near-edge spectra from the thin films studied. The main edge occurring near 4980 eV is associated with dipole transitions from the Ti 1s to the Ti 4p conduction-band levels. The first two features occurring below the edge are associated with dipole-forbidden transitions from the Ti 1s to the crystal-field split Ti 3d states that have a splitting of ∼2.1 eV, as we have indicated in the figure [9]. Our data show a

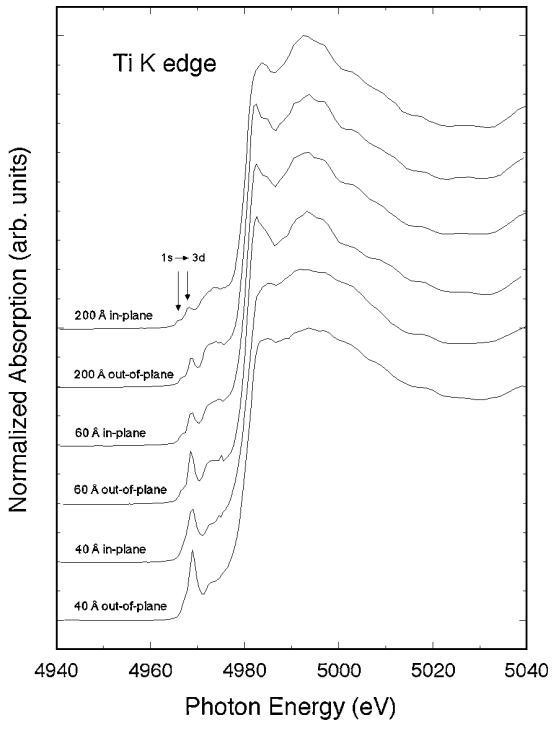

Fig. 3. Ti K pre-edge spectra from the thin STO films recorded with the polarization vector in-plane and out-of-plane. The data have been normalized to equal edge jump.

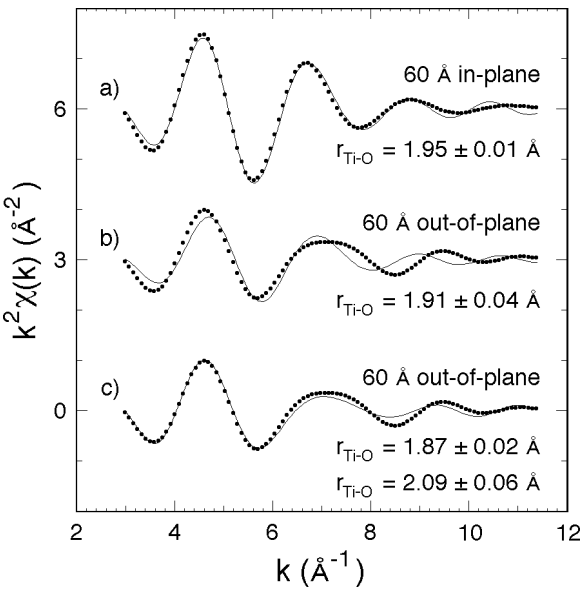

Fig. 4. Fits to the Fourier-filtered, first-shell contributions to the k^2-weighted fine structure from the 60 Å film using the phase and amplitude functions obtained from the STO powder. The dots are the data points of the backtransform, and the solid lines are the fits. a) In-plane data using one Ti-O distance. b) Out-of-plane data using one Ti-O distance. c) Out-of-plane data using two Ti-O distances.

large increase in the intensity of the second but not the first Ti K pre-edge feature with increasing strain. In crystals that possess an inversion center, the d states that are even with respect to inversion are symmetry forbidden from mixing with the p states that are uneven. In crystals that lack an inversion center, this symmetry restriction is lifted, and the p states are allowed to mix with the d states making 1s transitions to the second of the two pre-edge features dipole allowed [9, 10]. The intensity of the second pre-edge feature therefore has been correlated with the loss of inversion symmetry that accompanies ferroelectricity in the perovskite structure [11]. Consequently, these data suggest that the presence of the STO/Si interface results in the polarization of the STO layer. As evidenced by the data from the thicker films, this polarization decreases away from the interface, and it is likely caused by the ionic rearrangement of the first STO layer.

To quantify the extent of this distortion, we now examine our extended X-ray absorption fine-structure data. The Ti-O radial shell was modeled with the phase and amplitude standards obtained from the STO powder. The results of the modeling for the 60 Å film are shown in Figure 4. The top panel (a) shows the fit to the data from the film recorded with the polarization vector in-plane, and the middle panel (b) shows the fit to the data recorded with the polarization vector out-of-plane, both assuming a single Ti-O bond length. Clearly, a beat occurs in the out-of-plane data near $k = 7\,\text{Å}^{-1}$ that is not modeled by a single Ti-O distance. Our analysis using two Ti-O distances (c) finds the Ti-O bond length to be split by 0.22 ± 0.06 Å along the Si[001] surface-normal direction. (We note that due to the limited data range attainable from such thin films, only the coordination numbers and bond lengths were fit.)

It is interesting to compare our determination of the splitting of the Ti-O distance to that determined by neutron scattering for the tetragonal, ferroelectric phase of $BaTiO_3$ [12]. This distortion results in three distinct Ti-O bond lengths, one within the contracted a plane, $r_{\text{Ti-O}} = 2.00$ Å, and two along the elongated c axis, $r_{\text{Ti-O}} = 1.83$ Å and $r_{\text{Ti-O}} = 2.20$ Å. These bond lengths compare with our determination of the in-plane, $r_{\text{Ti-O}} = 1.95 \pm 0.01$ Å, and out-of-plane, $r_{\text{Ti-O}} = 1.87 \pm 0.02$ Å and $r_{\text{Ti-O}} = 2.09 \pm 0.06$ Å, Ti-O bond lengths within the strained STO film.

Our model of the strained STO tetragonal unit cell is shown in Figure 1b. The model possesses three distinct Ti-O bond lengths (one within the contracted a plane and two along the expanded c axis) concomitant with the loss of inversion symmetry around the central Ti ion. The intrinsic relationship between strain, polarization, and chemical hybridization had been observed experimentally.

Abstract

Films of cobalt-doped titanium dioxide ($Co_xTi_{1-x}O_{2-\delta}$) can be stabilized in the thermodynamically unfavorable anatase phase if they are grown on appropriate substrates. We performed X-ray Absorption Spectroscopy (XAS) measurements at the oxygen, titanium, and cobalt edges of PLD grown samples. Our data shows the success of this substrate-induced stabilization of the anatase phase occurs only at elevated temperatures (~700 °C or more) and elevated oxygen partial pressures (~1×10^{-5} Torr or more). The effects of post annealing in vacuum are also considered.

1. Introduction

Magnetic semiconductors have recently received considerable attention because of their potential applications in combining conventional semiconductor technology and spin transport electronics. Spin polarized current injection in semiconductors is an obstacle of particular concern that may be overcome by the development of a suitable ferromagnetic semiconductor. When injecting spin polarized electrons from ferromagnetic metals into traditional semiconductors, scattering can occur because of band structure mismatch [1]. Ferromagnetic semiconductors, if successfully synthesized, could solve this problem.

Cobalt doped anatase TiO_2 has been shown to have a hysteretic signature at and above room temperature [2–4]. However, it is thermodynamically unfavorable [5] and will, at elevated temperatures, revert to the more stable rutile structure [6]. For most spin transport electronics applications, it is essential that these materials be grown as thin films. As has been well demonstrated in other systems, it is possible to stabilize the anatase phase by growing it on an appropriate substrate. Two substrates have been identified by the scientific community as good candidates to stabilize the anatase phase: $SrTiO_3(001)$ and $LaAlO_3(001)$ [5, 7, 8]. The lattice match between the cubic $SrTiO_3$ ($a = 3.905$ Å) and the tetragonal anatase TiO_2 ($a = 3.784$ Å, $c = 9.515$ Å) helps promote the growth of anatase with the c axis perpendicular to the film plane. The rutile structure of TiO_2 is also a tetragonal crystal but with a poor lattice match ($a = 4.585$ Å, $c = 2.953$ Å) [9].

The Co-doped anatase is properly described by $Co_xTi_{1-x}O_{2-\delta}$, where the "δ" represents oxygen vacancies, which must exist to maintain charge neutrality of the sample by compensating for the cobalt (valence 2+) substituted titanium (valence 4+) atoms. It is therefore not surprising that the sample's structure depends strongly on the oxygen partial pressure during growth. Note additionally that oxygen vacancies are necessary for conductivity. According to Chambers *et al*. [1], oxygen vacancies make TiO_2 an n-type semiconductor; it would otherwise be an insulator. They also suggests the ferromagnetic coupling between cobalt atoms is electron mediated and would not be possible without oxygen vacancies in excess of those required for charge neutrality.

2. Experimental

In this study, $Co_xTi_{1-x}O_{2-\delta}$ films ($x = 1\%$ and 7%) were grown on $SrTiO_3$ by pulsed laser deposition (PLD) at various temperatures and partial pressures of oxygen (PO_2). Rutherford backscattering, X-ray diffraction, and vibrating sample magnetometry measurements on some of the samples have been published elsewhere (see Shinde *et al.* [3]). The samples were shown to exhibit ferromagnetism at high temperatures and high temperature treatment was found to dramatically enhance Co incorporation in the matrix. Subsequent XAS results (this study) allowed us to determine the necessary conditions that enable the substrate induced stabilization of the desired anatase structure. We used X-ray Absorption Spectroscopy (XAS) to measure the $L_{2,3}$ edges of cobalt and titanium, and the K edge of oxygen. Measurements were performed at the MSU Materials X-ray Characterization Facility located at beamline U4B of the National Synchrotron Light Source at Brookhaven National Laboratory.

Rutile and anatase TiO_2 have been studied extensively. The XAS intensity profiles of oxygen and titanium, in rutile or anatase, are available for comparison with our spectra. Our spectra are in fair agreement with calculations by F. M. F. de Groot [10, 11] and in very good agreement with XAS spectra measured by Ruus *et al*. [12] and Soriano *et al*. [13]. By comparing our oxygen and titanium XAS spectra with previously measured spectra we can determine whether our Co-doped samples are in the anatase, rutile, or some other TiO_2 structure.

3. Results

To make the structure identification, the revealing feature is a double peak at around 460 eV. For the anatase structure the left peak dominates while for the rutile structure the right peak is the larger of the two. Similarly, the oxygen spectral shapes reveal whether the probed oxygen is in an anatase or rutile structure. Having both oxygen and titanium spectra for comparison allows us to determine our sample's structure with confidence.

3.1. *Substrate growth temperature dependence*

Titanium and oxygen XAS measurements on samples grown at various substrate temperatures (see Fig. 1) reveal a lower limit to the temperature at which films can be stabilized in the

*E-mail: lussier@physics.montana.edu

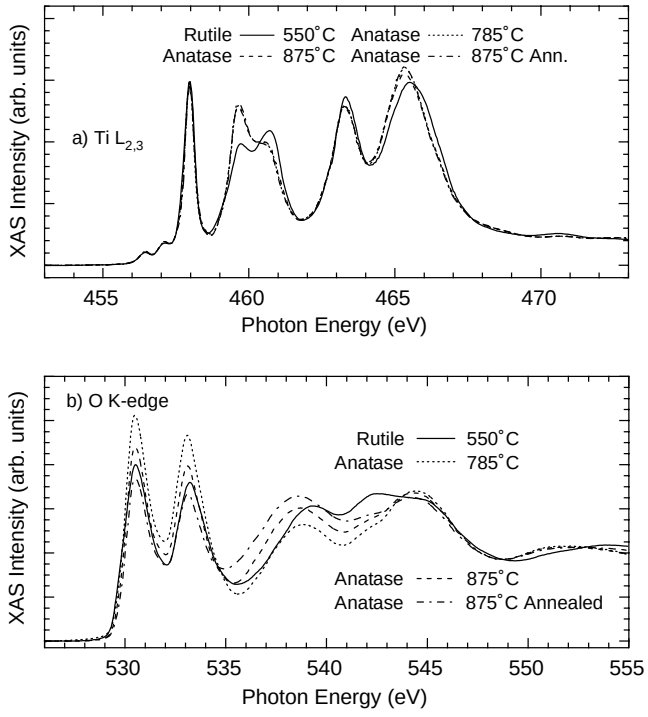

Fig. 1. The titanium $L_{2,3}$ XAS (a) for 7% cobalt doped TiO_2 films grown at various substrate temperatures. Only the lowest growth temperature yielded the rutile structure while all others resulted in anatase. Annealing the sample resulted in no significant difference in the titanium spectra. The oxygen K edge spectra (b) confirm the titanium results. Spectra from all samples have the same general features except for that of the sample grown at 550 °C, which is characteristic of the rutile structure.

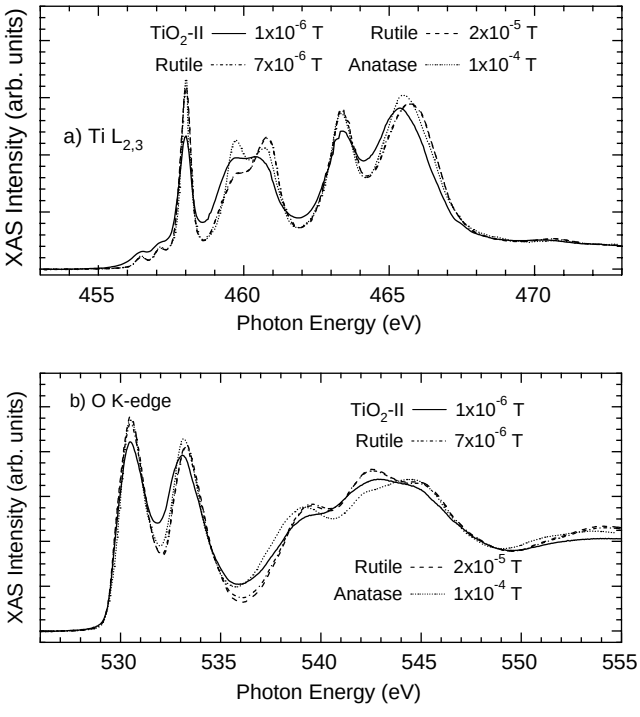

Fig. 2. Titanium spectra (a) for 1% Co samples grown at various PO_2. Oxygen partial pressures above 1×10^{-4} are necessary to ensure growth in the anatase structure. The oxygen spectra (b) for the same samples confirm the conclusions reached from the titanium spectra. For partial pressures below approximately 5×10^{-6} Torr we obtain a spectrum similar to that of the $CoTiO_2$-II structure.

anatase structure for Co-doped TiO_2. For successful substrate induced stabilization, the titanium, cobalt, and oxygen atoms must have a minimum mobility, allowing them to conform to the substrate. At low temperatures the reduced mobility causes the substrate induced anatase structure growth to be lost and the films then revert to the more thermodynamically stable rutile structure.

3.2. *Dependence on oxygen partial pressure during growth*

The oxygen partial pressure (PO_2) dependence was determined for two sets of samples grown at 700 °C with 1% and 7% cobalt doping. There is a minimum PO_2 required to obtain the anatase structure (see Fig. 2). Indeed, below a certain PO_2 the films grow in the rutile structure, or at very low PO_2, they may adopt the so-called TiO_2-II structure. Although the TiO_2-II XAS spectral shape resembles a mixture of anatase and rutile, this structure is an entirely different (orthorhombic) structure [12]. We understand the PO_2 effect by recognizing that oxygen has a lower sticking coefficient on a fully oxidized surface. Titanium then, likely dictates film growth kinetics and anatase growth must occur at an overpressure of oxygen (well above stoichiometric ratios). Oxygen deficiency will again compromise the substrate induced anatase structure stabilization. Interestingly, at the threshold oxygen partial pressure between the formation of anatase and rutile there appears to be a region of mixed phase. This was revealed by the sample grown at the threshold PO_2 of 2×10^{-5} T, for which the surface region is in the rutile structure while the bulk appears to be in the anatase structure (as revealed by XRD measurements by Shinde *et al*. [3]). The titanium spectra and oxygen spectra share the same general features whether samples are grown with 1% or 7% cobalt doping so the 7% spectra were omitted in Fig. 2. The conclusions we draw concerning PO_2 effects on growth are by and large independent of cobalt doping concentration.

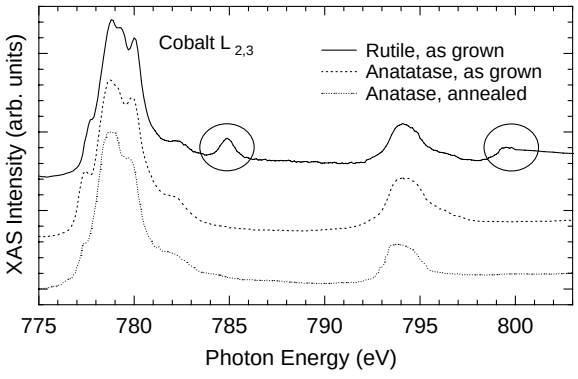

Fig. 3. Cobalt $L_{2,3}$ spectra. Samples that were shown to be in the rutile phase from the oxygen and titanium spectra have additional features that are circled in the figure. The effect of annealing on the cobalt spectra of 7% Co-doped samples is also shown. The sharpening, and partial loss of shoulder features suggests a partial transformation to metallic cobalt.

3.3. *Cobalt Spectra*

The cobalt $L_{2,3}$ XAS spectra shown in Fig. 3 are in agreement with those published by Chambers *et al*. for Co doped anatase TiO_2 [1]. They very closely resemble $CoTiO_3$ spectra, providing evidence that cobalt atoms take on substitutional lattice sites [4]. The spectral shapes display minimal change with varying growth conditions or resultant structure. Nevertheless, we identified an additional sharp feature above both the L_2 and L_3 edges in the Co spectra from samples that were determined to be in the rutile phase (by inspection of the oxygen and titanium scans). The origin of this spectral feature (circled in Fig. 3) is still

unknown but is currently being investigated by band structure calculations.

Also included in Fig. 3 is the cobalt $L_{2,3}$ XAS spectrum for a sample that was post annealed in vacuum at 875 °C to create conductivity enhancing oxygen vacancies and disperse clustered cobalt atoms in the film [3]. Although cobalt clusters in a semiconducting matrix exhibit macroscopic ferromagnetism, an intrinsic ferromagnetic semiconductor is necessary to achieve successful interfacing with traditional semiconductors. Cluster dispersal is therefore desirable. The present work shows that annealing also causes out-diffusion towards the surface. This is substantiated by the sharpening and loss of shoulder features of the L_3 edge of the annealed spectrum in Fig. 3, which both suggest a partial transformation to metallic cobalt. Because XAS is surface sensitive, and previous work shows dispersal in the bulk [3], we conclude that metallic clustering occurs near the surface. Our conclusions apply to our sample which was annealed in vacuum. Other studies show that annealing in an oxygen environment leads to similar results [14] and annealing in argon caused dispersal but no clustering [3].

4. Conclusion

We have determined suitable oxygen partial pressure and substrate temperature conditions that allow for substrate induced stabilization of cobalt doped anatase TiO_2 grown by PLD. The phase diagram shown in Fig. 4 best describes our conclusions. High enough growth temperatures are necessary to induce mobility of deposited atoms and epitaxial conformation to the substrate. A minimum PO_2 ensures enough oxygen is present during growth in spite of oxygen's higher volatility compared to titanium and cobalt. Post-annealing leads to out-diffusion of cobalt and metallic surface clustering. Finally, we have identified a new feature in the cobalt scans of Co-doped rutile TiO_2 that is absent for samples in the anatase structural phase.

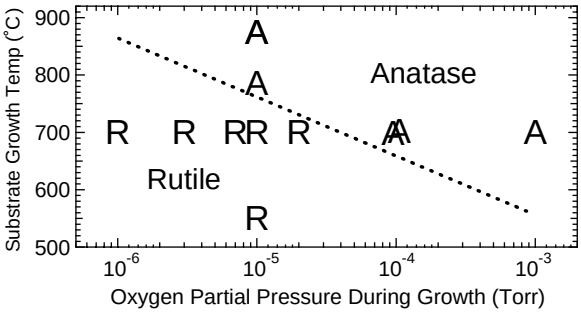

Fig. 4. Phase diagram for partial oxygen pressure and substrate growth temperature requirements that allow for substrate induced anatase structure stabilization on $SrTiO_3$.

Abstract

We use XMCD at the $L_{2,3}$ edges of iron to analyze the site-specific magnetic contributions of ions in nanoparticles of maghemite, γ-Fe_2O_3. Maghemite is the oxidized form of magnetite Fe_3O_4. We report results of the study of the magnetic order on tetrahedral and octahedral magnetic sublattices in γ-Fe_2O_3 nanoparticles as a function of the applied magnetic field. Magnetic contributions of Fe^{3+}_{Oh} and Fe^{3+}_{Td} are determined using the Ligand Field Multiplet theory. It is found that when the external field decreases, the magnetic contribution of Fe^{3+} ions on octahedral sites is significantly reduced by comparison to the contribution of Fe^{3+} ions on tetrahedral ones. This shows that a higher degree of canting exits on octahedral sites.

1. Introduction

Size reduction of ferrimagnetic spinel oxides results in modifications of their magnetic properties. For instance, particles of some nanometer are superparamagnetic at room temperature. Furthermore, when there is no appreciable relaxation of the magnetization, the value of the non-relaxing magnetization of ferro- and ferrimagnetic particles is lower than the saturating magnetization of the bulk material. Cationic disorders and atoms located at the surface are responsible for this lowering of the non-relaxing magnetization.

Maghemite is the oxidized form of magnetite. It has the following crystallographic structure: $(Fe^{3+}_{Td})[Fe^{3+}_{5/3}\square_{1/3}]_{Oh}O_4$ ($Fd\bar{3}m$), where $\square$ stands for a vacancy, *Td* for the tetrahedral crystallographic sites of spinel and *Oh* for the octahedral ones. Moments on octahedral and tetrahedral sites are coupled antiferromagnetically. Magnetic disorders in nanoparticles of maghemite have been widely investigated by means of zero- and in-field Mössbauer spectroscopy, magnetization measurements under high and moderate field and AC susceptibility [1]. Many experimental results indicate that spin disorder arises from surface spins, that experience fewer magnetic exchanges with the neighboring atoms. There is also opposite results, assigning the magnetic disorder to the existence of chemical defects in all the volume of a particle [2].

Site-specificity of X-Ray Magnetic Circular Dichroism (XMCD) makes it a powerfull tool to analyze the magnetic contributions of the different atoms in nanoparticles of spinel oxides. This piece of work focuses on the case of small maghemite nanoparticles of average diameter 3 nm. These particles are synthetized using soft chemistry in a two-step process. Aqueous co-precipitation of Fe^{2+} and Fe^{3+} ions at room temperature yields to magnetite particles. Magnetite is oxidized to maghemite under acidic conditions. Details of the synthesis can be found in reference [3]. This synthesis gives well-crystallized monodisperse particles. SQUID magnetometry measurements and Mössbauer spectroscopy have been carried out previously on these particles [4]. We use XMCD at the $L_{2,3}$ edges of iron to study the magnetic order on tetrahedral and octahedral sites in those particles at 4,2 K, as a function of the external magnetic field.

2. Experimental and calculations

Isotropic absorption spectra (XAS) and XMCD signals have been recorded at the Elettra synchrotron source (Trieste, Italy) on the BACH beamline [5]. The experimental end-station is a UHV chamber cooled thanks to a pumped ^{4}He cryostat. A superconducting coil allows to apply a magnetic field up to $+/-$ 7 T on the sample. The sample is a power of γ-Fe_2O_3 nanoparticles. A copper sample holder ensures electrical and thermal conductions. The absorption is measured by total electron yield. Exit and entrance slits are set to 20 µm. The beam is monochromatized using a plane mirror and a spherical grating of groove density 400 lines.mm^{-1}. The resulting resolving power is of $E/\Delta E \simeq 2000$. The photon flux on the sample is larger than 10^{11} photons.s^{-1}. The XMCD signal is extracted from four absorption spectra, recorded reversing both the phase of the high-energy APPLE II undulator and the magnetic field applied along the X-ray propagation direction. The absorption cross-sections for a right-circularly polarized beam and for a magnetic field applied paralled and antiparallel to the propagation vector $\boldsymbol{k}$ are denoted as $\sigma^{\downarrow\uparrow}$ and $\sigma^{\downarrow\downarrow}$. In the same manner, for a left-circularly polarized beam, the corresponding cross-sections for parallel and antiparallel fields are denoted as $\sigma^{\uparrow\uparrow}$ and $\sigma^{\uparrow\downarrow}$. The XMCD signal is obtained following $\sigma_{\mathrm{XMCD}} = \frac{(\sigma^{\downarrow\uparrow}+\sigma^{\uparrow\downarrow})}{2} - \frac{(\sigma^{\downarrow\downarrow}\, n+\, \sigma^{\uparrow\uparrow})}{2}$.

XAS and XMCD signals are simulated by Ligand Field Multiplet calculations. Multiplets calculations are multi-electronic calculations taking into account the ground $2p^63d^5$ configuration and the excited $2p^53d^6$ configuration. The inter-electronic interactions (e.g. the Slater integrals) and the spin-orbit coupling on the 2p (ζ_{2p}) and 3d shell (ζ_{3d}) are calculated using Cowan's atomic Hartree-Fock code [6]. Furthermore, in a solid, Slater's integrals are scaled by a reduction factor κ, to account for the electronic delocalization. The Hamiltonian also contains crystal field and Zeeman terms. Reduced matrix elements are calculated by Th. Thole's code, using Butler's group subduction theory in the ground and the excited configurations [7, 8]. The transitions are calculated in the electric dipole approximation for right- and left-circularly polarized radiations. Transition lines are convoluted by a Lorentzian function ($\Gamma(L_3) = 0.2$ eV and $\Gamma(L_2) = 0.4$ eV), accounting for the core-hole broadening, and by a

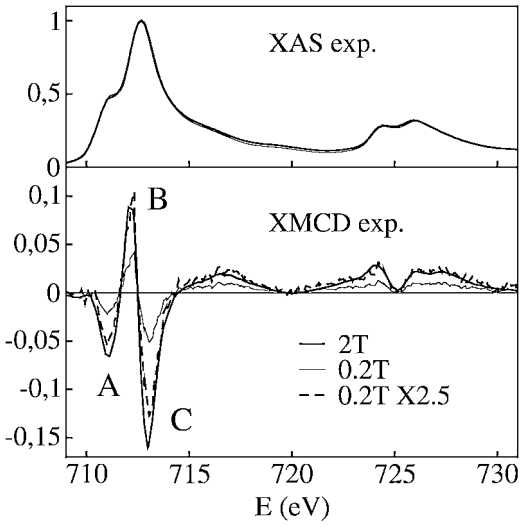

Fig. 1. Experimental isotropic absorption (XAS) and XMCD signals of γ-Fe_2O_3 nanoparticles of average size 3 nm for $H_{ext} = 2$ T and $H_{ext} = 0.2$ T.

Gaussian function ($\sigma = 0.25$ eV), accounting for the experimental broadening.

3. Results and discussion

XAS and XMCD obtained for external fields of 0.2 and 2 T are reported on figure 1. There is a reduction of the dichroic intensity, evaluated as the integral of $|\sigma_{\mathrm{XMCD}}|$. This reduction reflects the dependence of the magnetization of nanoparticles on the external field. At 4,2 K, the ratio of the XMCD intensity between 2 T and 0.2 T is $(M(2\,\mathrm{T})/M(0.2\,\mathrm{T}))_{\mathrm{XMCD}} = 2.5$. This value can be compared to magnetization measurements at the same temperature: $M(2\,\mathrm{T}) = 60\,\mathrm{A.m^2.kg^{-1}}$ and $M(0.2\,\mathrm{T}) = 29\,\mathrm{A.m^2.kg^{-1}}$, yielding $(M(2\mathrm{T})/M(0.2\,\mathrm{T}))_{\mathrm{SQUID}} = 2.0$. In addition to the variation of intensity, the shape of the XMCD signal is also modified when the magnetic field decreases. Figure 1 also presents the XMCD signals recorded at 0.2 T multiplied by 2.5, so as to have equal intensities for the positive B peaks at 0.2 and 2 T. From the rescaled signal, it appears that the intensities of the two negative A and C peaks at 0.2 T are reduced comparatively to their value at 2 T. The A peak is decreased by 12% and the C peak is decreased by 20%. In the following, it is shown using Ligand Field Multiplet calculations that the A and C peaks are due to the magnetic contribution of Fe^{3+}_{Oh} ions and that the B peak is due to the magnetic contribution of Fe^{3+}_{Td} ions. As moments of Fe^{3+}_{Oh} and Fe^{3+}_{Td} ions are coupled antiferromagnetically, their contributions to XMCD are of opposite sign.

The calculations are performed separately for Fe^{3+}_{Oh} and Fe^{3+}_{Td} ions. The XAS and XMCD signal arising from each site are presented on figure 2. The value of crystal field parameters can be inferred from optical spectra for tetrahedral [9] and octahedral [10] Fe^{3+} ions. We used 10 Dq (Fe^{3+}_{Oh}) = 1.5 eV and 10 Dq (Fe^{3+}_{Td}) = 0.7 eV. The reduction of Slater's integrals gives a Racah B parameter of 88 meV, that is close to the experimental Racah B parameter of 72 meV for maghemite [10, 11]. The total magnetic field experienced by Fe^{3+} ions is simulated by the Zeeman hamiltonian with $\mu_B g H = 20$ meV in $\hbar$ units. As the crystallites are oriented at random with respect to the external field, the dichroic spectra are calculated for three crystallographic orientations of the applied field: $H_{ext}//[111]$, $H_{ext}//[110]$ and $H_{ext}//[100]$ (see figure 2). The average over space

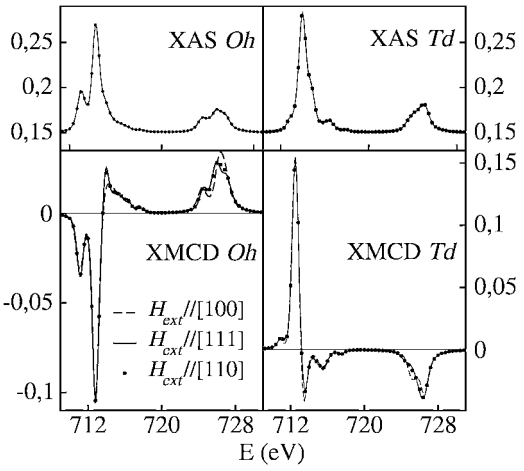

Fig. 2. Calculated XAS and XMCD for $H_{ext}//[111]$, $H_{ext}//[110]$, and $H_{ext}//[100]$.

of the absorption cross-sections is evaluated from these three orientations according to reference [12]:

$$\sigma_{\mathrm{powder}} = \frac{100}{385}\sigma_{H_{ext}//[100]} + \frac{99}{385}\sigma_{H_{ext}//[111]} + \frac{176}{385}\sigma_{H_{ext}//[110]}$$

XMCD signals of Fe^{3+}_{Td} and Fe^{3+}_{Oh} ions are similar for $H_{ext}//[110]$ and $H_{ext}//[111]$, but they are slightly modified for $H_{ext}//[100]$. However, the effect of the orientation of the external magnetic field is weaker for Fe^{3+} ions, that have an almost pure sextet ($^6A_{1g}$) orbital non-degenerated ground state in octahedral symmetry, than for anisotropic Fe^{2+} ions for instance [13].

XAS and XMCD of γ-Fe_2O_3 are then reproduced by linear combinations of the separate octahedral and tetrahedral contributions, as shown on figure 3. The shoulder at 714 eV is too intense by comparison with the experimental signal. It is probably due to covalency effects, that influence noticeably the shape of the XMCD signal between L_3 and L_2 edges. Simulating such effects would require configurations interactions in the calculations. XMCD signals of figure 3 are obtained assuming an ideal ferrimagnetic ordered bulk structure ($Td/Oh = 3/5 = 0.6$) and a reduced magnetic contribution of Fe^{3+}_{Oh} ions ($Td/Oh = 0.65$). The former XMCD signal is rescaled to have equal intensities of the

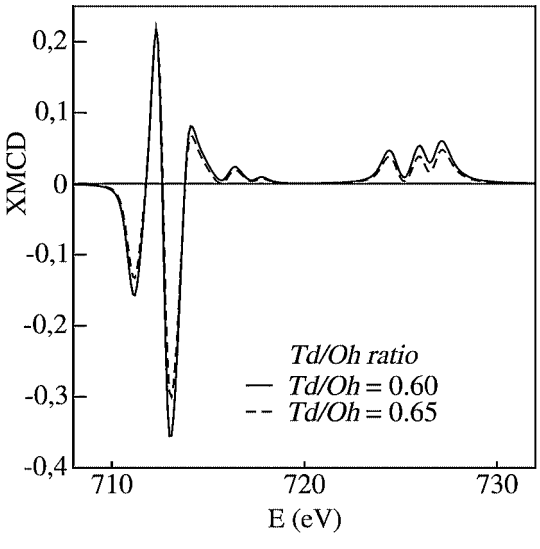

Fig. 3. Calculated XMCD (XAS normalized to 1 at the maximum of the L_3 edge) for two Td/Oh ratios.

B positive peaks in the two calculated signals. For the reduced magnetic contribution of Fe^{3+}_{Oh} ions, the intensity of the A peak is lowered by 15%, and the intensity of the B peak by 16%, which is close to the experimental evolution observed going down from 2 T to 0.2 T. The simulation agrees with an additional decreases of 8% of the magnetization on octahedral sites compared to the global lowering of the magnetization on both of the *Td* and *Oh* sublattices awaited if one considers a same degree of spin disorder for the two sublattices.

4. Conclusion

XMCD at the $L_{2,3}$ edges allows to investigate the respective magnetic contributions of Fe^{3+} ions on octahedral and tetrahedral sites in γ-Fe_2O_3. The use of multiplet calculations allows to assign the experimental field-dependence of XMCD to a greater degree of spin disorder on the octahedral magnetic sublattice relatively to the tetrahedral one. From XMCD measurements on a single size of particles, it is not possible to conclude whether this magnetic disorder is a surface or a core effect. Similar measurements have been performed on larger particles, that have a lower surface to volume ratio. A greater magnetic disorder on octahedral sites still exists when low magnetic fields are applied. But the effect is reduced compared to the 3 nm particles. Those results are consistent with a magnetic disorder located at the surface of the particles. We have also investigated particles coated with phosphate ligands. The ligands create a total magnetic disorder of the first atomic layer at the surface of the particles. The comparison of coated particles with uncoated ones evidences that magnetically disordered surface sites are mainly octahedral sites. These results stand in agreement with former in-field Mössbauer results [4]. Details of these investigations will be published in a forthcoming publication.

Abstract

We report X-ray Absorption Fine Structure (XAFS) measurements of the colossal magneto-resistance (CMR) samples $La_{0.79}Ca_{0.21}MnO_3$ and $La_{0.7}Ca_{0.3}MnO_3$ at high magnetic fields. For T near T_c, the width parameter of the pair distribution function, σ, decreases significantly as the applied magnetic field is increased. For a given magnetization, M, the decrease in σ^2 from the disordered polaron state is the same, irrespective of whether M was achieved through a change in temperature or the application of an external magnetic field. This universal behavior can be modeled as a quadratic function of magnetization, and suggests a new model for the magnetization process.

In many previous studies, σ^2, the width the Mn-O pair distribution function, decreases rapidly as the temperature (T) is lowered below the ferromagnetic transition temperature (T_c) for the CMR manganites. This has been attributed to a decrease in the amount of polaron-induced disorder in the magnetized state; similar results have also been observed in neutron pair distribution function (NPDF) analysis studies [1–7]. Furthermore, for several different CMR samples, we have shown that the change in σ^2 ($\Delta\sigma^2$) below T_c can be described by an exponential function of the magnetization, although no theoretical model predicts such behavior [1, 2]. The more extensive study presented here shows that the change $\Delta\sigma^2$ is only a function of the magnetization M, irrespective of how M is produced; it also provides evidence for a new relationship between $\Delta\sigma^2$ and M, based on a physical model.

Mn K-edge data were collected on powdered samples of $La_{0.79}Ca_{0.21}$ MnO_3 and $La_{0.7}Ca_{0.3}MnO_3$ as a function of temperature and magnetic field on beamline 7-2 (Si ⟨111⟩ monochromator crystals) at the Stanford Synchrotron Radiation Laboratory (SSRL). The data were reduced using standard procedures and Fourier transformed to r-space. The r-space Mn-O peak was then fit using the RSFIT program, using standards calculated from FEFF6 [8]. The number of neighbors was constrained to 6, and only the r-space peak position and the width parameter of the pair distribution function, σ, were allowed to vary. (S_o^2 and E_o were determined at low T and then held constant for fits to higher temperatures.) Then σ provides a single local structure parameter for comparison with M. Although one might attempt to model the system as two (or more) Mn-O peaks, there would then be two amplitudes and two σ's which are partially coupled; a local structure parameter for comparison with M is then not well defined. For each temperature, independent fits were made to four traces and the average value of σ obtained; the relative errors, the rms fluctuation about the average, is comparable to the symbol size, except where error bars are shown. The absolute errors for σ^2, which depend on S_o^2, may be of order 10%; they shift the plot vertically.

These first results indicate a significant temperature and magnetic field dependent change in σ^2, near and above T_c (∼190 K for the 21% Ca sample, and ∼260 K for the 30% Ca Sample) (see Fig. 1 and Fig. 2). At low temperatures, the sample is ordered and σ^2 is small while at high temperatures there is a large amount of polaron-induced disorder, as observed previously. Furthermore, there is a field dependent change in σ^2. Near T_c, σ^2 decreases as the applied field is increased indicating that the application of a magnetic field removes polaron disorder from the sample (see Fig. 1 and Fig. 2).

The change in σ^2 is defined as

$$\Delta\sigma^2 = \sigma^2_{\mathrm{T}} + \sigma^2_{\mathrm{FP}} + \sigma^2_{\mathrm{static}} - \sigma^2_{\mathrm{Mn-O}}, \tag{1}$$

where σ^2_{T} is the thermal contribution calculated from $CaMnO_3$ [9], $\sigma^2_{\mathrm{static}}$ is the excess (above σ^2_{T}) contribution at low temperatures, $\sigma^2_{\mathrm{Mn-O}}$ is calculated from fits to r-space data and is plotted in Fig. 1 and Fig. 2. The difference between $\sigma^2_{\mathrm{T}} + \sigma^2_{\mathrm{static}}$ and $\sigma^2_{\mathrm{Mn-O}}$ at high

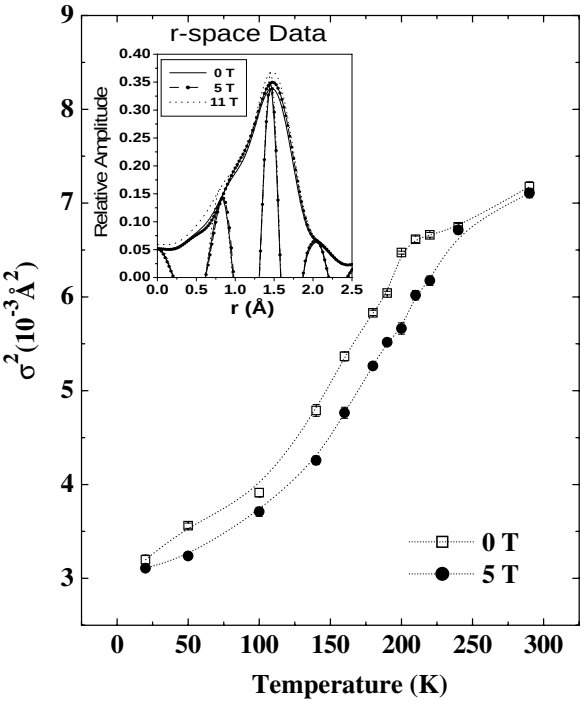

Fig. 1. σ^2 vs T for the Mn-O nearest neighbor peak for the 21% Ca sample. The dotted lines are guides to the eye. The inset shows the corresponding r-space changes in the Mn-O peak at T_c (190 K) – the amplitude increases (σ^2 decreases) with increasing field.

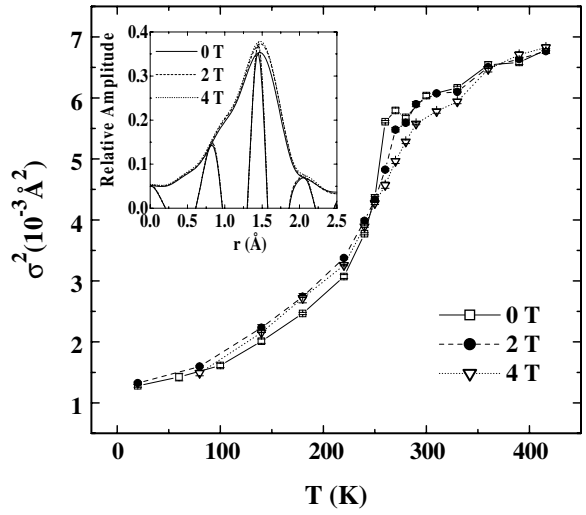

Fig. 2. σ^2 vs T for the Mn-O nearest neighbor peak for the 30% Ca sample. The lines are guides to the eye. The inset shows the corresponding r-space changes in the Mn-O peak at T_c (260 K) – the amplitude increases (σ^2 decreases) with increasing field.

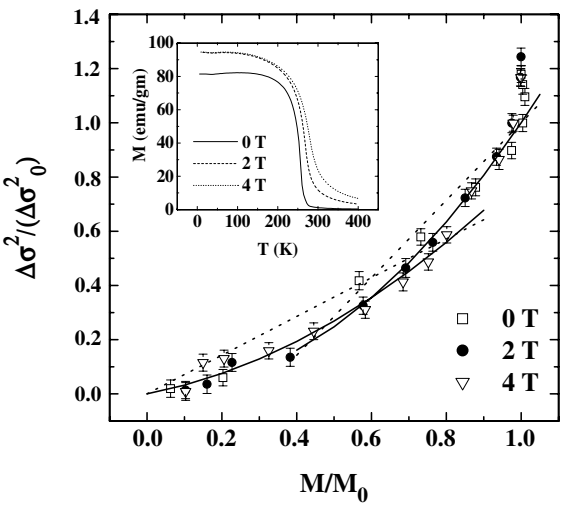

Fig. 4. $\Delta\sigma^2$ vs relative magnetization for the 30% Ca sample. $\Delta\sigma^2$ and M have been normalized to the value at 150 K, when the the sample becomes fully magnetized. The curves show the theoretical dependence of $\Delta\sigma^2$ on magnetization given by the quadratic function described in Eq. (2). The dotted lines show the dependence of a linear fit assuming the distortions are first removed in pairs of distorted Mn^{+3} and undistorted Mn^{+4} sites, as described in the text. The inset shows the magnetization curve for each field in the plot demonstrating that the sample magnetization is saturated (remains constant) below 150 K. The vertical part near $M/M_0 = 1$ is evidence that polaron distortions are continuing to be removed after the sample has become fully magnetized.

temperatures is called the full polaronic distortion, σ^2_{FP} in Eq. (1) above [1, 2].

In Fig. 1, we show that for the 21% sample, σ^2 decreases as the applied B-field is increased at constant temperature. A similar dependence on B-field can be seen for the 30% sample at temperatures near T_c. However, at lower temperatures for this sample, the change in σ^2 is independent of field and $\Delta\sigma^2$ continues to increase as T is lowered after the magnetization saturates which occurs at ∼150 K (compare magnetization data in Fig. 4 inset and Fig. 2).

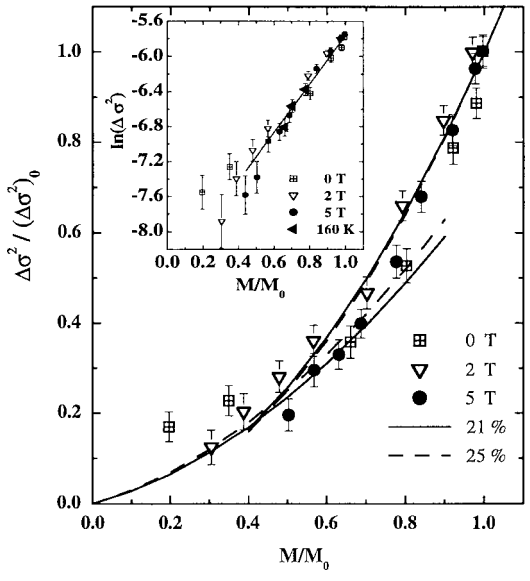

Fig. 3. $\Delta\sigma^2$ vs relative magnetization for the 21% Ca sample. $\Delta\sigma^2$ and M have been normalized to the maximum value for each field. $\Delta\sigma^2$ is the decrease in σ^2 as T is lowered below T_c that is attributed to the loss of polaronic distortion. The curves show the theoretical dependence of $\Delta\sigma^2$ on magnetization given by the quadratic function described in Eq. (2). The inset shows a logarithmic plot of $\Delta\sigma^2$ vs normalized magnetization; it shows that over this available range in M, a semi-log plot describes the data quite well. In both plots many of the data points are at a different temperature (i.e. for fixed field, varying T). To show more clearly that one can keep T fixed and vary M (via a change in B-field) several points are plotted for $T = 160$ K. These points lie along the same line in the semi-log plot indicating a universal dependence on M.

The observed changes in $\Delta\sigma^2$ can be modeled by either an exponential function or a polynomial function of magnetization where there are regions of differing behavior see Fig. 3 and Fig. 4. A semi-log plot for the 30% sample is similar to the inset for the 21% sample. The magnetization has been normalized to the saturation value while $\Delta\sigma^2$ has been normalized to the value at which the sample becomes fully magnetized; this occurs at the lowest temperature for the 21% sample, but at ∼150 K for the 30% sample. The relatively slow change in $\Delta\sigma^2$ at low M indicates that the lowest-distortion sites must become magnetized first. Since the "Mn^{+4}" site is thought to be essentially undistorted, the magnetization process may proceed in pairs – an undistorted "Mn^{+4}" site and a distorted "Mn^{+3}" site; this allows an electron to hop back and forth between two Mn sites as required in the double exchange model but only required that one of the distorted sites become undistorted. Once all the "Mn^{+4}" sites become magnetized (60% of the sample is magnetized for the 30% sample), further increases in M require that every additional Mn site must become undistorted. Since a significant cluster must be magnetized in ferromagnetic systems it is likely that the magnetized clusters form filaments through the sample and the magnetic and non-magnetic regions are intertwined. For the 30% sample, the vertical part near $M/M_0 = 1$ in Fig. 4 is evidence that polaron distortions are continuing to be removed after the sample has become fully magnetized, which indicates that the Mn sites can be magnetized but still have a small local distortion. A possible explanation is that the polarons are still partially localized at 150 K. Only at the lowest temperatures are the polarons essentially delocalized.

The magnetization process described above can be described by the following model. Let the smallest polaron distortions removed be α_0, and assume that there is a distribution of distortions that are removed with the largest distortions removed when $M \sim M_o$. The distortion that is removed at various states of magnetization (f is the fractional magnetization (M/M_o)), can be

described as $\alpha = \alpha_o(1 + \gamma f)$, where γ is a measure of the range of distortions. Below the critical value of f (twice the Calcium concentration, $2x$) the distortion removed per pair is only α; above this value of f the distortion removed per pair is 2α. This leads to the following normalized expressions which were used to fit the $\Delta\sigma^2$ data:

$$\frac{\Delta\sigma^2}{\Delta\sigma_0^2} = \begin{cases} \frac{1}{2}Af(1+\gamma f) & \text{for } f \le f', \\ \frac{1}{2}Af'(1+\gamma f') + A(f-f')(1+\gamma f) & \text{for } f > f', \end{cases} \quad (2)$$

where f' is the critical value of f (twice the Calcium concentration, $2x$), and A is a normalization constant equal to $\frac{1}{\Delta\sigma_0^2}$, where $\Delta\sigma_0^2$ is value of $\Delta\sigma^2$ when $f = 1$. $\gamma = 2$ gives good agreement with the data in Figs. 3 and 4.

We have extended our previous results [1, 2] to show that the relationship between σ^2 and magnetization, is more universal. Changing the sample magnetization by either varying the applied field or varying the temperature produces similar changes in σ^2. Further analysis needs to be done to investigate the full nature of this relationship.

Acknowledgments

The experiments were carried out under NSF grant DMR0301971 and were performed at SSRL, which is operated by the U.S. DOE, Division of Chemical Sciences, and by the NIH, Biomedical Resource Technology Program, Division of Research Resources.

Abstract

We have measured Mn K-edge magnetic EXAFS for $Ni_{0.76}Mn_{0.24}$ alloy. The 2nd peaks in the Fourier transform attributed to Mn-Mn pairs in the ordered phase are enhanced in comparison with those in non-magnetic EXAFS. This result suggests that some Ni atoms in the 2nd shell are replaced by Mn atoms, which have large magnetic moment in comparison with Ni atoms, due to heat-treatment induced atomic ordering. Semi-relativistic theoretical calculations well explain the observed magnetic EXAFS. We estimate the ratio of the magnetic moments of Ni to Mn atom in Ni-Mn alloy, within a single scattering limit.

1. Introduction

The correlation between the structure and magnetism of 3d transition metal alloys has long been an important topic in condensed matter physics. Among the 3d transition metal alloys, the Mn based alloys have recently attracted special attention because of their potential applications in magnetic recording technology. Ni_3Mn alloy has been an interesting example of such alloys and can undergo a structural phase transition where the magnetic behavior is sensitive to the atomic arrangement [1]. Cable and Child studied the magnetic moment distributions in disordered Ni_xMn_{1-x} ($x = 0.80$–0.95) alloys by polarized-neutron diffuse-scattering [2]. They showed that the magnetic moment of isolated Mn atom in $Ni_{0.95}Mn_{0.05}$ alloy is 3.50 μ_B, which decreases with Mn concentration. Two possible explanations are proposed: (1) The ferromagnetic component of Mn moment decreases by becoming randomly oriented or antiferromagneically coupled. In this case the local magnetic moment of Mn atom is conserved even in the disorder state. (2) Averaging over up-spin and down-spin magnetic configurations on Mn atoms. In this case, the net local moment of Mn atom decreases. They concluded that the magnetic distribution is complicated and not specifically defined by the neutron-cross-section measurement, since the neutron scattering technique is based on long-range order.

On the other hand, magnetic XAFS is a powerful tool for the investigation of local magnetic structures with short-range order in alloys, and uses circular polarized X-ray beam from a synchrotron radiation source [3–7]. The interpretation of magnetic EXAFS is clear and direct for the study of local magnetic structures, although the signal is much smaller than that of magnetic XANES. Recently, some theoretical approaches have been developed for magnetic EXAFS analyses [8–10]. Recent measurements of magnetic XAFS have been reported for alloys [11] and theoretical analyses have been applied to FeCo and FePt alloys [9] and disordered GdCo alloys [12].

In this paper, we experimentally and theoretically study magnetic EXAFS for ordered $Ni_{0.76}Mn_{0.24}$ alloys prepared by heat treatments.

2. Experimental and Theory

A 21 μm foil sample of $Ni_{0.76}Mn_{0.24}$ was prepared by polishing carefully and annealing for 100 hours at 693 K under Ar atmosphere in order to make certain an ordered state. The reason why we study this concentration is that the ordered phase of $Ni_{0.76}Mn_{0.24}$ alloy is easily obtained by the shorter heat treatment time than that of $Ni_{0.75}Mn_{0.25}$ alloy, in which the residual oxygen can oxidize the sample. The saturation magnetization of this sample is 56.4 emu/g and the degree of order S is deduced to about 0.74. Magnetic EXAFS of Mn k-edge (6.4–7.2 keV) for $Ni_{0.76}Mn_{0.24}$ foil was measured at BL28B of Photon Factory in KEK (2.5 GeV) with circularly polarized X-rays that were generated by an ellipsoid multi-pole wiggler and monochromatized using a Si(111) double-crystal monochromator [13, 14]. The absorption spectra were measured in transmission mode at 30 K. Instead of switching helicity of the incident photons, the applied magnetic field, about 0.6 T which is still enough to saturate the magnetization of the sample, was reserved every 4 seconds to obtain MCD effect.

We perform semi-relativistic theoretical calculation of the magnetic EXAFS for binary alloy as the ordered model of Ni_3Mn including up to 4th shell atoms (∼5 Å). In the case of the binary system, it is important to determine the electronic state for each atom. To calculate the phase shift for magnetic EXAFS, we refer to the electronic structures obtained from FLAPW method [15]. The details of the present theoretical approach are discussed elsewhere [15, 16]. In this calculation, multiple scattering effect, the amplitude reduction factor by Debye-Waller factor and many-body effects are not taken into account.

3. Results and Discussion

First we discuss the result for non-magnetic EXAFS. Figure 1 (a) shows the non-magnetic EXAFS oscillation function, $k\chi(k)$, for experimental Mn K-edge for $Ni_{0.76}Mn_{0.24}$ foil sample (solid line) and theoretical calculation by a model of ordered *fcc* Ni_3Mn (dashed line). For experimental spectra the magnetic EXAFS signal is normalized by the edge jump of the non-magnetic X-ray absorption spectrum to be unity. Similar experimental spectrum was observed in a previous paper [15]. However, the present result is much better than the previous one. As the figure shows, the main oscillating parts for experimental and theoretical calculation are coinciding. On the other hand, a more fine oscillation is found in the experimental spectrum. Figure 1 (b) shows a comparison between experimental and theoretical Fourier transforms (FT) of the non-magnetic EXAFS $k\chi(k)$ shown in Fig. 1 (a). For the data processing we use the XANADU code [17]. The k-range of the Fourier transform is $2.0 \sim 10.8\,\text{Å}^{-1}$. Solid line (dashed line) shows the result for the experimental (theoretical) EXAFS. Vertical arrows in Fig. 1 (b) denote the crystallographic positions

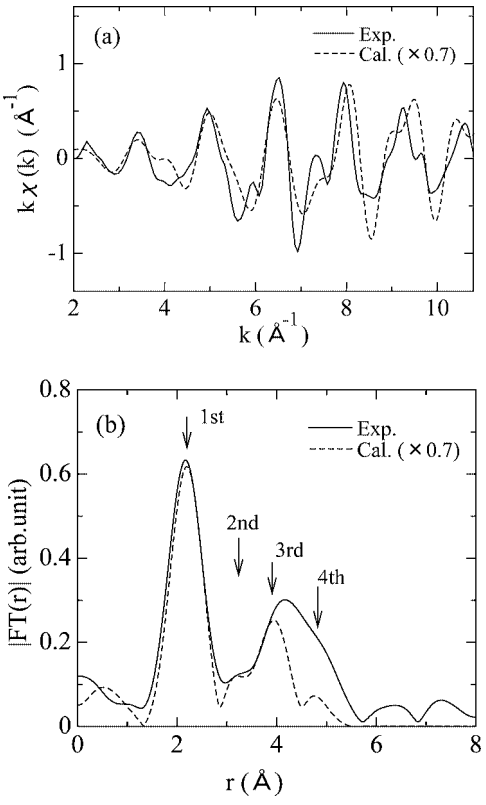

Fig. 1. (a) Non-magnetic EXAFS $k\chi(k)$ spectra for the Mn K-edge of experimental data for $Ni_{0.76}Mn_{0.24}$ alloy (solid line) and theoretical calculation as a model of ordered Ni_3Mn (dashed line). (b) Fourier transforms of non-magnetic EXAFS $k\chi(k)$ shown in (a).

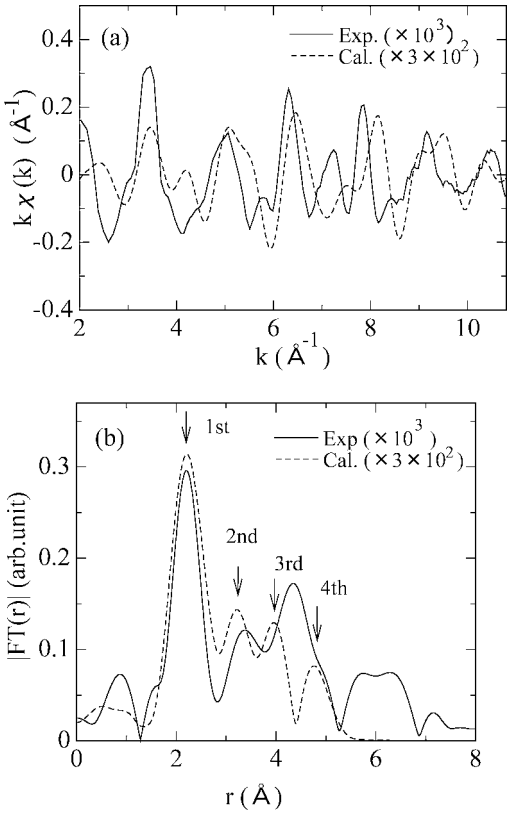

Fig. 2. (a) Magnetic EXAFS $k\chi(k)$ spectra for the Mn K-edge of experimental data for $Ni_{0.76}Mn_{0.24}$ alloy (solid line) and theoretical calculation as a model of ordered Ni_3Mn (dashed line). (b) Fourier transforms of the magnetic EXAFS $k\chi(k)$ shown in (a).

of nearest neighbor atoms in Ni-Mn *fcc* lattice from the central Mn atom. First nearest neighbor atoms are located at 2.54 Å, second at 3.59 Å, third at 4.5 Å and fourth at 5.08 Å. In Fig. 1 (b), the phase shift correction is not considered, so the peak position is not equal to these crystallographic data. The amplitude of the calculated EXAFS is larger than that for the experimental one, since we neglect thermal vibration, electron mean-free and many-body effects in the present analyses (the factor is about 0.7). The FT of the first and second peak for the theoretical calculation almost overlapp the experimental one. However, deviation is found between theoretical calculation and experimental spectrum for the third and fourth peaks (experimental peaks is enhanced in comparison to theoretical). This phenomenon is considered as a multiple scattering effect; especially a focusing effect is expected in the fourth shell atoms. In the present theoretical calculation, multiple scattering is not taken into account. Since our present calculation cannot reproduce such an effect, we discuss mainly the results for the first and second shells.

Next we discuss the result for magnetic EXAFS. Figure 2 (a) shows a comparison between experimental magnetic EXAFS $k\chi(k)$ spectrum and theoretical one. The main oscillating part almost coincides with that of non-magnetic EXAFS. On the other hand, the fine oscillating structure is more pronounced than in the case of non-magnetic EXAFS. Figure 2 (b) presents a comparison between experimental and theoretical calculation for the FT of magnetic EXAFS shown in Fig. 2 (a). Deviation is found in the third and fourth peaks between experimental and theoretical. This is considered as multiple scattering or focusing effect as for non-magnetic EXAFS. For the first and second peaks, we can find clear enhancement of the second peak in magnetic EXAFS in comparison to non-magnetic one (Fig. 1 (b)). This result can be interpreted as follows. After appropriate heat treatment, the Ni-Mn alloys are ordered. In the ordered phase, Mn atoms with large magnetic moment ($\sim$3.5 μ_B from neutron diffraction [2]) are exchanged to Ni atoms that are located in the second shell around an X-ray absorbing Mn atom. Therefore the second nearest Mn atoms strongly contribute to the magnetic EXAFS.

Another important effect we should consider is a strong multiple scattering effect, which was reported in the higher shell of magnetic EXAFS by Ahlers & Shutz [6] and Wende *et al.* [7]. Wende *et al.* have shown the quite interesting result that the multiple scattering effect is enhanced in magnetic EXAFS and the FT peak for the second shell overlaps the triangle multiple scattering path for *bcc* structure [7]. In their case, if the first nearest distance is 2.49 Å (as a typical model for Fe), the distance for the third shell is 4.06 Å and the corresponding triangle path is 3.92 Å, in which it is difficult to distinguish them with the FT method [7]. On the other hand, in the present *fcc* Ni_3Mn case, the distance for the second shell is 3.59 Å and the corresponding triangle path is 3.81 Å (the difference is 0.22 Å). We carefully checked the simulation of FT (k-range is 2–10.8 Å^{-1}) for various situations and certify that the peaks of 3.59 Å and 3.81 Å do not overlapped and can be distinguished from each other. The peak of the triangle path (3.81 Å) should be included at longer distance than the second peak. However, since the second peak position is slightly shifted in Fig. 2 (b), a small portion of the triangle path effect may be mixed into the second shell contribution. Unfortunately our present calculation cannot take the multiple scattering process into account. So we have to consider a single scattering limit.

ptIn the theoretical calculation for magnetic EXAFS, we can handle the electronic configuration and also magnetic moments of each Ni and Mn atom. For the ordered Ni_3Mn model, the 1st and

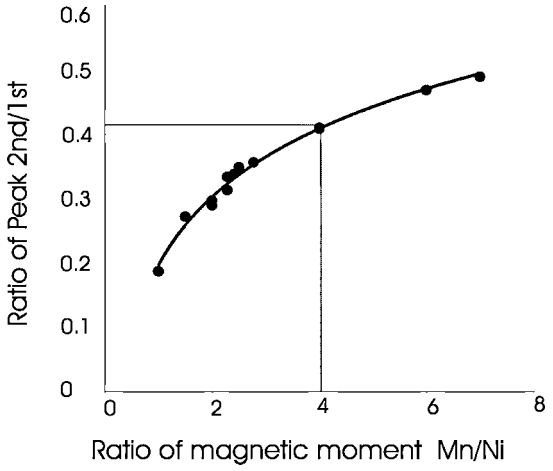

Fig. 3. The ratio of the calculated Fourier peak intensity Mn/Ni as a function of the ratio of magnetic moments Mn/Ni atom used for the theoretical calculation.

2nd peak in the Fourier transform are attributed to the Ni and Mn atom. The ratio of the peak intensities of the 1st to 2nd peak in the FT of the magnetic EXAFS depends on the magnetic moment of Ni and Mn atoms. Figure 3 shows calculated Fourier peak intensity Mn (2nd peak)/Ni (1st peak) as a function of the ratio of magnetic moments of Mn and Ni atom used for the theoretical calculation.

From the FT in Fig. 2 (b), we obtain the ratio of 2nd/1st peaks 0.41. Using the theoretical curve shown in Fig. 3, we estimated the ratio of the magnetic moment Mn/Ni ~ 4.0 (as shown in Fig. 3). This value is much smaller than that obtained from neutron study (Mn/Ni ~ 10) [18], however it is fairly close to the result derived from a recent band calculation using FLAPW method (Mn/Ni ~ 4.8) [15]. As a reason for the small value of the ratio of magnetic moments Mn/Ni, the ordered Ni_3Mn model is not adequate for the present $Ni_{0.76}Mn_{0.24}$ sample ($S \sim 0.74$). The electronic states used in the theoretical calculation are still inaccurate or the multiple scattering effect cannot be neglected in the contribution of second shell peak. While there are still problems we should solve in this simple method to derive the ratio of the magnetic moments of each atom, this method has a potential for disordered magnetic systems in which neutron diffraction cannot be applied. To improved this method, more accurate analyses of magnetic EXAFS, *e.g.* multiple scattering process [7], thermal vibration and spin disorder [5] and many body effect, are necessary to take into account.

4. Conclusion

We measure the Mn K-edge magnetic EXAFS for $Ni_{0.76}Mn_{0.24}$, where the 2nd peaks in the Fourier transform are enhanced in comparison with those in non-magnetic EXAFS. This result suggests that some Ni atoms in the 2nd shell are replaced by Mn atoms with larger magnetic moment than Ni atom, due to heat-treatment induced atomic ordering. Semi-relativistic theoretical calculation well explains the observed magnetic EXAFS. We propose a simple method to evaluate the ratio of the magnetic moments for each atom in Ni-Mn alloy from magnetic EXAFS, which is applicable to disordered systems, even within a single scattering approximation.

Abstract

Fe_8 clusters are molecules which show quantum spin tunneling at very low temperature. They have eight iron ions that are six-fold coordinated and magnetically coupled through oxygen bridges. The net magnetization ($M_s = 20\,\mu_B$ per molecule) results from competing antiferromagnetic interactions between the Fe^{3+} ions ($S = 5/2$). Because of the structural anisotropy of these molecules, the magnetization curve presents a hysteresis loop with staircases below 2 K. The staircases of the hysteresis loop are due to the quantum spin tunneling, which is temperature dependent for 400 mK $< T <$ 3 K and temperature independent below 400 mK. Using a ^{3}He–^{4}He dilution refrigerator, we have recorded XMCD spectra at iron $L_{2,3}$ edges at 300 mK for this molecule. It has been possible to record an XMCD remnant signal, without magnetic field applied, on these high spin molecules. XMCD coupled with Ligand Field Multiplet calculations has allowed to determine the spin and orbit magnetizations of Fe^{3+}.

1. Introduction

High spin molecules show peculiar magnetic properties at very low temperature: remnant magnetization and spin tunneling effect below $\simeq$1 K. In order to determine the role of the anisotropy of the molecule in the remnant magnetization process and to know the contributions of the spin and orbit magnetic moments to the total magnetization, we carried out X-ray absorption spectroscopy (XAS) and X-ray magnetic circular dichroism (XMCD) experiments at the iron $L_{2,3}$ edges at 300 mK. The spectra have been simulated in the ligand field framework. A first part presents the Fe_8 high spin molecules and their properties. In the two following parts, the experimental set up that permits XMCD recordings at 300 mK and the simulation of the experimental signals are described. Then the results are presented and discussed.

2. High spin molecules

2.1. *Structure of the molecules*

Molecule – magnets present a high remnant magnetic moment at low temperature (remnant magnetization higher than $5\,\mu_B$ per molecule below 300 mK) [1]. This behaviour makes these molecules good candidates for the small memory elements searched for spintronics. The properties expected to obtain such magnetic response are high structural anisotropy and high magnetic moment. Thus, it shall contain a sufficiently high number of transition elements and particular geometry which can favour one magnetization direction among the others. The structure of the molecule $[(C_6H_{15}N3)_6Fe_8O_2(OH)_{12}]Br_7(H_2O)$ $Br–8H_2O$ (Fe_8) is shown on fig. 1. It contains 8 iron atoms (Fe^{3+}, $S = 5/2$). The iron ions are magnetically coupled through bridging oxygens. Spin-polarized neutron diffraction measurements showed that six iron magnetic moments stand in a direction and the two other ones stand in the opposite direction. The resulting spin of the molecule is $S_{tot} = 10$.

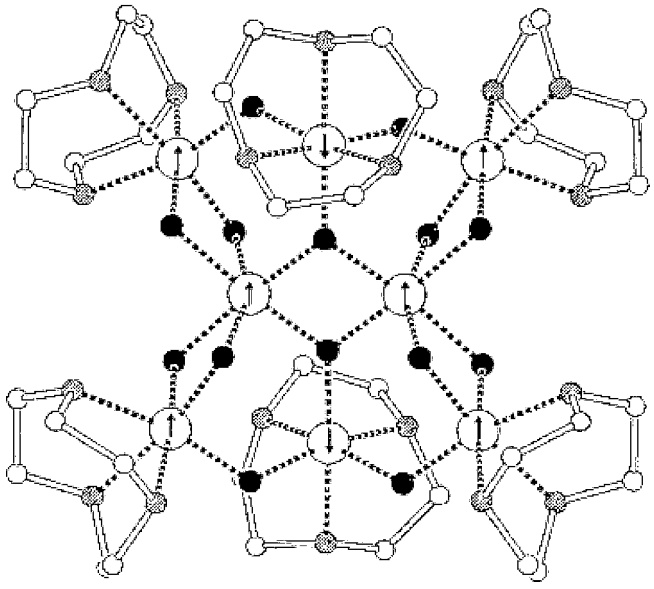

Fig. 1. Fe_8 molecule [1]. The wide circles represent iron atoms, the small black ones oxygen atoms, the small grey ones nitrogen atoms and the small white ones carbon atoms.

2.2. *Magnetic properties of Fe_8 molecules*

The temperature at which the hysteresis loop opens on the magnetization curve depends on the rate of variation of the magnetic field. When the loop opens, one observes staircases that are due to the spin tunneling effect [1]. Indeed, contrary to the majority of magnetic compounds, the magnetization of this magnet-molecule is quantized. The spin-tunneling effect and the remnant magnetization are observed only below $\simeq$1 K but the relaxation is slow enough to be studied by XMCD below $\simeq$300 mK (75% of the saturation magnetization is kept after one hour, time needed to record the XMCD signal).

3. Experimental set up

The experiments have been carried out on the SU23 beamline at LURE (Orsay, France) with a dilution refrigerator set up [3].

A liquid ^{4}He cryostat reaches temperatures no lower than 4.2 K. If one pumps on the liquid ^{4}He phase, one can reach 1 K and 0.3 K if it is ^{3}He instead of ^{4}He. To reach lower temperatures, we used a ^{3}He–^{4}He dilution refrigerator. This device is constituted of a

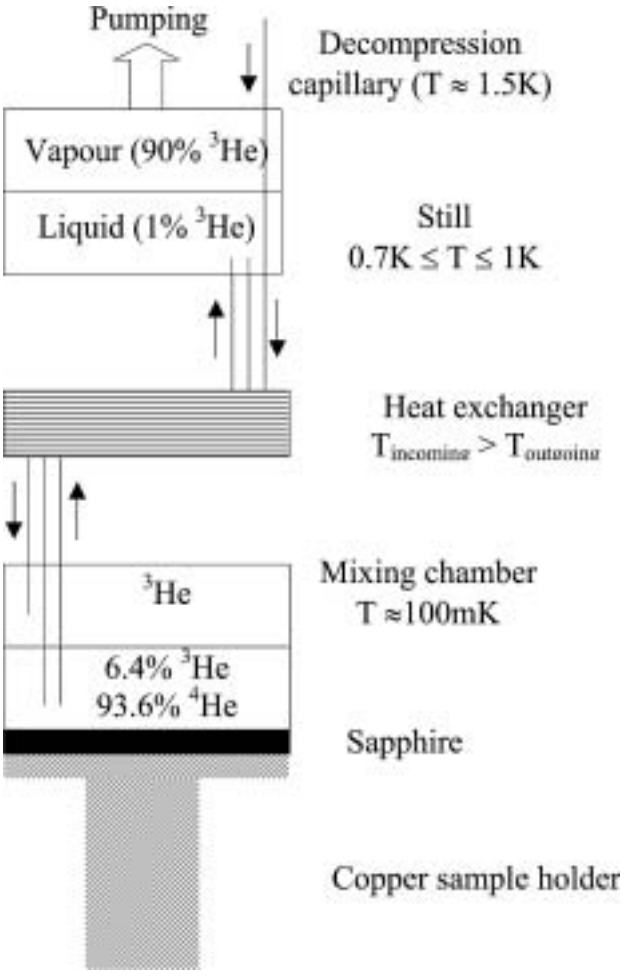

Fig. 2. Scheme of the inner part of the dilution refrigerator.

classical $^4He_{liq}$–N_{2liq} cryostat and of an inserted cooling device containing the ^{3}He–^{4}He mixture. Below 1 K, a phase separation occurs between ^{3}He and ^{4}He. The device is cooled by pumping on the two-phase mixture, inducing the transfert of ^{3}He molecules from the ^{3}He rich phase to the poor one. The cooling happens because of the large latent heat absorbed when a ^{3}He molecule crosses the interface. A sample holder is fixed to the colder part of the device through a sapphire that permits at the same time the thermal conduction and the electrical insulation necessary to the detection in the total electron yield mode.

A scheme of the experimental set up is shown on fig. 2. With this type of device, one can reach 0.1 K in a closed chamber. For XAS utilisations, the cryostat must include windows permitting the entry for the X-ray beam. This reduces the thermal insulation. Moreover, the application of the magnetic field needed for the XMCD measurements induces Foucault currents that also limit the minimum temperature. The ^{3}He–^{4}He dilution refrigerator developped at LURE reaches a stable temperature of 300 mK under the X-ray beam.

Motivations for carrying out XAS and XMCD experiments at these very low temperatures are multiple. They include the study of small particles in which the blocking temperature is very low: the smaller the particles, the lower the blocking temperature.

4. Modelisation of the spectra: multiplets calculations

We used the ligand field multiplet theory in order to simulate the isotropic and XMCD spectra at the Fe $L_{2,3}$ edges. This method takes into account the local environement of the absorbing atom through the crystal field parameters and the hybridization of the chemical bond (by the means of the Slater integrals). A trigonal distorsion of the octahedral sites have been used in agreement with the actual symmetry around Fe ions. The obtained signals are convoluted by a Lorentzian function in order to take into account the lifetime of the core hole and by a Gaussian function to take into account the instrumental broadening.

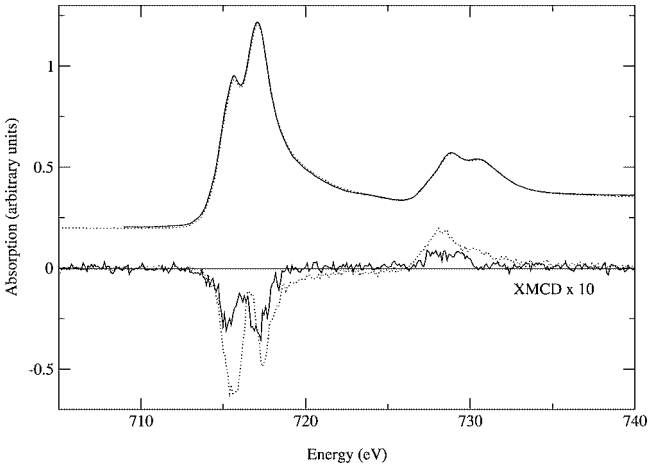

Fig. 3. Dot line: XAS and XMCD signals with T = 300 mK and H = ±5 T. Solid line: remnant XAS and XMCD signals with T = 300 mK and H = 0 T after saturation in a field of ±5 T.

5. Results and discussion

5.1. *Experimental results*

We have recorded the absorption and dichroic signals under 300 mK. Fig. 3 shows the XAS and XMCD signals obtained in a magnetic field of ±5 T and the XAS and remnant XMCD signals obtained under 0 T after saturation in a magnetic field of ±5 T. The remnant signal at 717.5 eV is attributed to Fe^{3+}. It represents only 65% of the corresponding feature observed under the 5 T magnetic field. This is the consequence of the relaxation of the magnetization. This reduction is in agreement with the values obtained by SQUID measurements [1]. However, this remnant dichroic spectrum shows that the relaxation is slow enough to acquire the remnant signal. This constitutes one of the first observations of a remnant XMCD signal on molecular systems, the other being at the Cr and Ni K-edge [4]. If one takes into account the polarization rate and the relaxation of the magnetization, the intensity of the dichroic signal has the expected order of magnitude. Nevertheless, even if these experiments were carried out on samples from the same batch as Ghigna *et al.* [2], the obtained signal is different.

Besides, one can notice that the dichroic feature at 716 eV is stronger in the spectrum recorded with magnetic field than in the spectrum recorded without magnetic field. This contribution to the spectra can be attributed to paramagnetic Fe^{2+} present on the surface of the grains and giving a dichroic signal only when the field is applied. Working in remanence sets free from the contribution of this species that is not part of the molecule. The calculations have thus been compared to the remnant signal.

5.2. *Modelisation*

The calculated signals are presented in fig. 4, compared to the experimental spectra recorded without magnetic field after

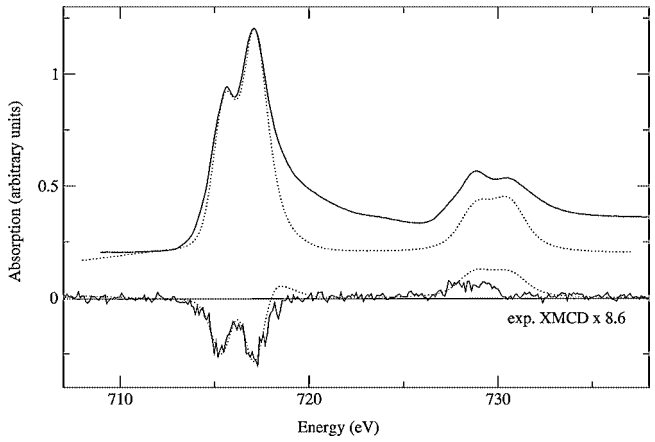

Fig. 4. Comparison between experimental and calculated signals.

application of $H = \pm 5\,\mathrm{T}$. The signal calculated with Fe^{3+} ions in distorted octahedral sites gives a good simulation of the spectra at the L_3 edge. The signal is not so well reproduced at the L_2 edge.

The values obtained for the crystal field ($10\,\mathrm{Dq} = 1.7\,\mathrm{eV}$) and for the reduction of the Slater integrals ($\kappa = 0.31$) are consistent with the values used for the simulation of Fe^{3+} signals in analogous molecular compounds.

The calculations give a spin moment of $5/2$ and no orbital moment on the Fe^{3+} ions, which is in agreement with the predicted values for an ion with the $3d^5$ configuration. The distorsion of the octahedral sites, which is necessary to the fit, does not change significantly the value obtained for the orbital moment. This zero value is not incompatible with the existence of a magnetic anisotropy in Fe_8. Indeed, Ghigna and coworkers have observed that on the Mn_{12} molecule, the orbital magnetic moment is 0 though a strong anisotropy is observed [2].

Nevertheless, the value of the L_z/S_z ratio obtained by the use of the sum rules on the experimental signal is not 0 but about 0.1, which leads to an orbital magnetic moment of $0.5\,\mu_B$. The discrepancy comes from the differences between the experimental and calculated signals at the L_2 edge.

6. Conclusion

The ^{3}He–^{4}He dilution refrigerator makes possible measurements of XMCD signals at the $L_{2,3}$ edges at very low temperature (300 mK). This method gives the dichroic signal due to the Fe^{3+} contained in the molecule and not to spurious contributions of eventual paramagnetic iron ions. Multiplets calculations tend to show that the existence of a remnant magnetization does not imply a non-zero orbital magnetic moment.

Acknowledgements

We would like to thank François Bertran and Franck Fortuna from the SU23 beamline (LURE, Orsay, France) for their help in the experimental part of the work and Sandrine Brice for her useful advice in the multiplet calculations. This is IPGP contribution No. 1925.

Abstract

The elements-specific magnetizations of Co/Cu/Ni trilayers are studied near their Curie temperature by X-ray magnetic circular dichroism. Small magnetic fields are applied during the measurements to rule out the formation of magnetic domains. The experiments confirm that the Curie temperature of the Ni magnetization is shifted up to $\Delta T_{Ni} \approx 80\,\mathrm{K}$ in presence of an interlayer exchange coupling. In agreement with *ab initio* theory, we evidence the tail of the Ni magnetization in the trilayer.

Co/Cu/Ni trilayers have been used as a prototype system to study the interlayer exchange coupling J_{inter} [1–3]. In these trilayers the ferromagnetic layers of Ni and Co are coupled through the Cu spacer. The coupling strength and the relative alignment of the Ni magnetization to the Co magnetization (parallel or antiparallel) are mainly determined by the thickness of this Cu spacer [3]. Pioneering experiments, which were carried out in remanence, revealed a separate onset of the magnetization for the different ferromagnetic Ni and Co layers [1]. In the case of 4 ML Ni and 2 ML Co the ordering temperature of Ni is below the one of Co. A remarkable increase ΔT of the lower ordering temperature was observed in the presence of J_{inter} [1, 2]. Theoretical investigations addressed this effect to enhanced 2D spin-fluctuations [4]. The exchange coupling of the Co film acts on the Ni film not only as static exchange field but it influences also by higher order contributions the dynamics of the fluctuating spins. Therefore, a tail in the temperature-dependent magnetization is expected near the ordering temperature [4, 5]. However, this tail was not observed in the earlier experiments.

Up to now, the magnetization of coupled trilayers has only been investigated in remanence. Effects that possibly arise due to the formation of magnetic domains near the ordering temperature cannot be entirely excluded. Therefore, investigations under a small applied field were carried out here. To clarify the question of a tail of the Ni magnetization in coupled trilayers small signals close to the Curie temperature have to be measured precisely with a high density of temperature points. Such a clarification contributes to the investigations of the temperature dependence of the interlayer exchange coupling, as studied e.g. in [6]. The absence of the Ni tail would imply that J_{inter} vanishes when the magnetization of one ferromagnetic component in the trilayer vanishes. The recent development of the new undulator beamlines at third generation synchrotrons has very much improved the technical possibilities.

In the present work the individual magnetizations of Co and Ni in coupled Co/Cu/Ni trilayers are studied by the virtue of the element-specific X-ray magnetic circular dichroism (XMCD) in remanence as well as in a small applied magnetic field. Hysteresis loops and temperature-dependent magnetization curves are investigated. In particular we draw our attention to the Ni magnetization near the Ni Curie temperature. New results bring new insight into the critical behavior of exchange coupled ferromagnetic thin films near their ordering temperature.

The Co/Cu/Ni trilayers were prepared *in situ* like in the earlier experiments as described for example in Refs. [1, 3]. The measurements were carried out in ultrahigh vacuum (base pressure $p < 2 \cdot 10^{-10}$ mbar) at the undulator beamline UE56/1-PGM at BESSY II. We measured the drain current while applying a positive voltage to a metallic grid near the sample to ensure the complete extraction of the emitted electrons also under a small magnetic field. The substrate crystal was oriented such that we measured along [110], which is the easy axis for Co/Cu/Ni/Cu(100) trilayers. The XMCD signal at the maximum of the L_3 edge (normalized to a constant edge jump) is proportional to the element-specific magnetization $M(T)$. For the hysteresis loops we measured the field-dependent XMCD signal at the L_3 maximum. Taking advantage of the high photon-flux together with the high circular polarization-degree at the new undulator beamlines at third generation synchrotrons small XMCD signals near the Curie temperature can be determined more precisely. Better statistics can be obtained in shorter time and therefore, measurements close to T_C^{*Ni} with a relativly high density of data points have become achievable.

Figure 1 presents the magnetization of a 6 ML Ni film covered with 5 ML Cu in the temperature range from ∼80 K up to room

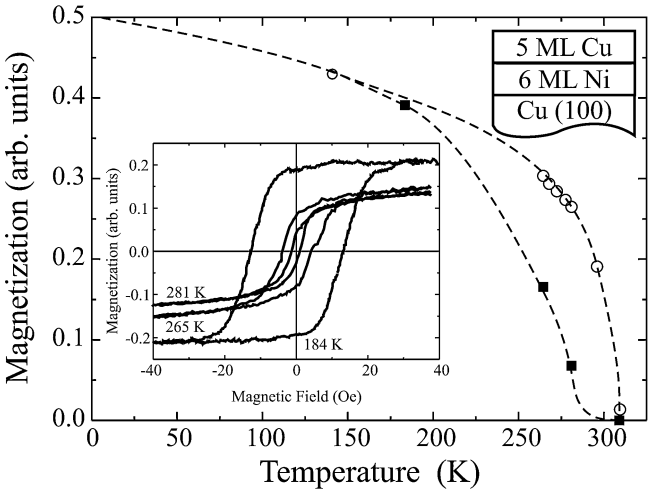

Fig. 1. Temperature-dependent Ni magnetization of a 5ML Cu/6ML Ni/Cu(100) bilayer system in a constant applied magnetic field ($H = 40$ Oe, open circles), and at remanence determined from hysteresis loops (solid squares). The dashed lines serve as guides to the eyes. The inset shows the Ni hysteresis at three different temperatures.

temperature in remanence (solid squares) and under a constant applied magnetic field of $H = 40\,\mathrm{Oe}$ (open circles). Hysteresis loops at three different temperatures are shown in the inset of Fig. 1. At $T = 184\,\mathrm{K}$ the coercitive field is $H_C = 13\,\mathrm{Oe}$ and the magnetization saturates for $H \gtrsim 30\,\mathrm{Oe}$. Above $T \approx 200\,\mathrm{K}$ the remanent magnetization decreases considerably faster than the one in the applied magnetic field. Such a behavior has been observed in ultrathin Co/Cu(100) films [7] and Ni/Cu(100) films [8] using the polar magneto-optic Kerr effect. In both cases it was addressed to the formation of magnetic domains near the Curie temperature of these films. Magnetic domains with different directions of magnetization lead to a reduction of the remanent magnetization. Applying a small magnetic field of $H \approx 30\,\mathrm{Oe}$ is, in our case, sufficient to bring the sample into a single domain state even close to the Ni ordering temperature. Only by measuring on a single domain film one will obtain the proper magnetization in vicinity of T_C. However, the applied magnetic field should be small so that it does not produce additional field-induced magnetization in the sample. It is worth while to mention that operating in very low magnetic fields of a few Oe only it is important to pay attention to small stray fields. Zero current in the electro-magnet is not equal to zero magnetic field in the sample. Already a very small magnetic field like e.g. the earth field displaces the hysteresis loops, and creates a mismeasurement of the proper magnetization.

In Fig. 2 the temperature-dependent magnetization of Ni in a coupled trilayer measured at $H = 40\,\mathrm{Oe}$ both before (open circles) and after evaporation of the Co layer (solid circles) is shown. Measuring under a small static magnetic field we ensure a single-domain state of the sample. Therefore, we can rule out artifacts that stem only from a formation of domains. At first, a 4 ML Ni film capped with 4 ML Cu was studied (open circles). For this bilayer the Ni magnetization vanishes at $T_C^{Ni} \approx 210\,\mathrm{K}$. Then we 'turned on' the coupling by evaporating 2.8 ML Co onto the same sample. The Ni magnetization in the trilayer (solid circles) vanishes at a critical temperature $T_C^{*Ni} \approx 290\,\mathrm{K}$ which is $\Delta T_{Ni} \approx 80\,\mathrm{K}$ higher than for the bilayer system. The Curie temperature of the Co film is well above room temperature and its magnetization (not shown) is nearly constant in the investigated temperature range. The large ΔT_{Ni} confirms the results of Refs. [1, 2] so that they cannot be addressed to effects of domain formation.

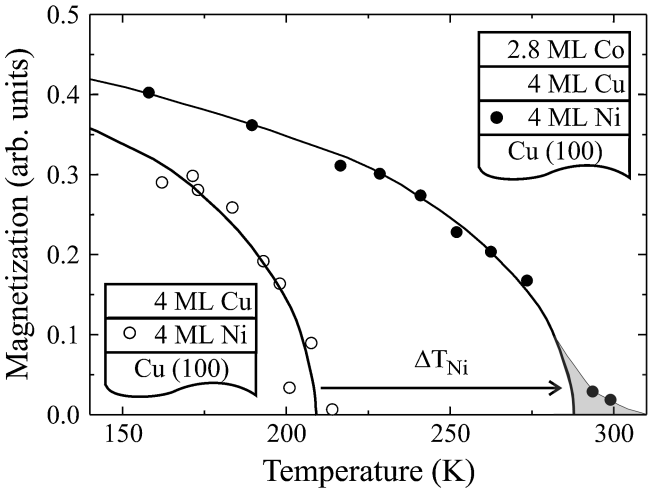

Fig. 2. Ni magnetization of a trilayer before (open circles) and after (solid circles) evaporation of the Co layer measured at $H = 40\,\mathrm{Oe}$.

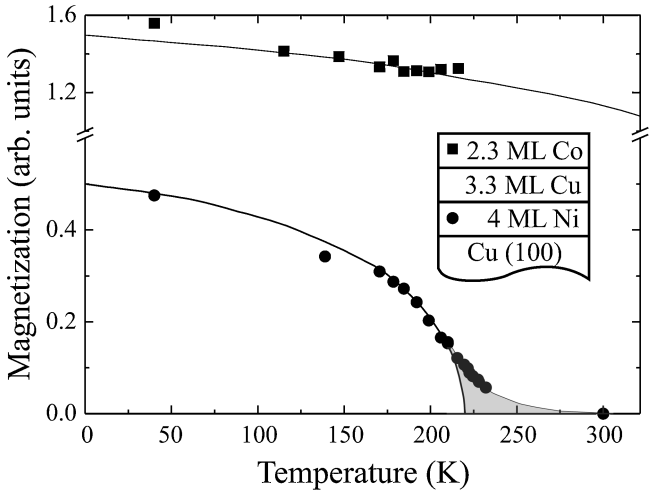

Fig. 3. Individual Ni and Co magnetization of a Co/Cu/Ni trilayer. A tail in the Ni magnetization near the ordering temperature is clearly visible.

Theoretical investigations of coupled trilayers revealed that the Curie temperature shift is related to the strength of the interlayer exchange coupling. For the description of the magnetic behavior in the ultrathin magnetic layers spin-fluctuations have to be taken into account in a localized picture [4]. In two-dimensional systems such spin-fluctuations reduce the magnetization more strongly than in bulk systems. Another theoretical study uses the so-called spectral density approach, that is within an itinerant single-band Hubbard model, to investigate coupled trilayers [5]. Although an itinerant model is more appropriate for 3d transition metals, the results of both approaches are in good agreement with the experiment yielding a strong shift ΔT_{Ni} to higher values after the Co film has been evaporated on top, i.e. after the exchange coupling has been switched on.

Figure 3 shows the individual Ni and Co magnetization curves exemplarily for a trilayer consisting of 4 ML Ni, 3.3 ML Cu and 2.3 ML Co for temperatures with $40\,\mathrm{K} \leq T \leq 300\,\mathrm{K}$. Both curves were measured under a small applied field. In our new experiments in a temperature range close to T_C, we observe a tail of the Ni magnetization which is clearly out of the noise. This tail in $M(T)$ is predicted in both theoretical investigations the itinerant approach and the localized Heisenberg model [4, 5].

In summary, we have presented the element-specific magnetizations of Co/Cu/Ni/Cu(100) trilayers close to the Curie temperature of the Ni film. For the measurements the formation of magnetic domains close to T_C has to be excluded. We have demonstrated that in our case applying a small magnetic field of $H = 30\,\mathrm{Oe}$ is sufficient. The shift ΔT_{Ni} of the Ni magnetization in the trilayer compared to the Cu/Ni bilayer is remarkably large and cannot be induced by a static magnetic field only. The existence of a tail of the Ni magnetization was evidenced. Our results are in agreement with theoretical predictions in a Heisenberg model as well as in an itinerant approach. They demonstrate that spin fluctuations, i.e. higher order contributions in the spin dynamics, are of more importance in ultrathin films than 3D bulk magnetism.

Acknowledgments

We thank the BESSY crew for the good operational conditions of the beamline and the technical assistance. This work was supported by the BMBF (05 KS1 KEB 4).

Abstract

The $LaMn_{1-x}Ga_xO_3$ series has been studied by means of X-ray absorption spectroscopy (XAS) at the Mn and Ga K-edges. The local electronic and geometric structure around Ga^{3+} barely changes along the series showing that Ga^{3+} only acts as a constructive element of the crystal structure. On the contrary, the intensity of the pre-edge structures at the Mn K-edge shows a continuous decrease as the content of Ga increases. This result indicates a strong mixing of the 3-d states among near-neighbours Mn^{3+} ions. The local geometric structure around Mn^{3+} (MnO_6 octahedron) also changes along the series. Namely, Mn^{3+} evolves from a cooperative static Jahn-Teller regime, as in $LaMnO_3$, to a non-correlated dynamic Jahn-Teller regime ($x > 0.5$). Moreover, this result points to the lack of local tetragonal distortion for isolated Mn^{3+} ions.

1. Introduction

$R_{1-x}A_xMnO_3$ (R = rare earth; A = divalent cation) compounds show a large variety of phase transitions and magnetic arrangements as result of a strong interplay among orbital, lattice, magnetism and transport properties [1, 2]. $LaMnO_3$ [3–5] with an orthorhombic unit cell and a cooperative tetragonal deformation of the MnO_6 octahedron (Jahn-Teller type) at room temperature shows antiferromagnetic (AFM) ordering of A-type below $T_N = 140$ K. The manganese moments are aligned in the [010] direction with the spins coupled ferromagnetically in the *a-b* plane and antiferromagnetically along the c axis. Variations in the oxygen stoichiometry [5] or doping [1, 2] induce ferromagnetic interactions in these compounds. The substitution of La by a divalent cation leads to ferromagnetic and conductive compounds without tetragonal deformations of the MnO_6 octahedron. This ferromagnetic (FM) interaction is ascribed to the double exchange mechanism between Mn^{3+} and Mn^{4+} [6]. FM interactions can also be induced by substitution of Mn by another transition metal [7–12]. In $LaMn_{1-x}Ni_xO_3$, ferromagnetism can be explained by a strong superexchange [11, 12] FM interaction between Mn^{4+} and Ni^{2+}. However, the replacement of Mn^{3+} by a non-magnetic trivalent ion such as Ga^{3+} or Sc^{3+} also induces ferromagnetism [8, 10].

$LaMn_{1-x}Ga_xO_3$ series was matter of our interest with the aim to determine the change of properties as a function of the dilution of manganese with a non-magnetic trivalent metal as gallium [13]. We note that substitution with gallium does not change the valence state of manganese. The replacement of Mn by Ga induces a continuous decrease of the tetragonal distortion of the MO_6 (M = Mn, Ga) octahedron being practically regular for $x \geq 0.6$. Simultaneously, a FM component appears that it is explained in terms of a canting of the A-type AFM structure. The FM component increases with the Ga content up to $x = 0.5$ where a collinear ferromagnetism is observed. For $x \geq 0.6$, the system evolves from collinear ferromagnetism into superparamagnetism. The pure A-type AFM structure only appears for the undoped sample, $LaMnO_3$, in which a complete cooperative ordering of the local tetragonal distortions occurs. The ordering degree of this tetragonal distortion, observed by the decrease of the cell distortion in the orthorhombic structure, seems to be the origin of the sign change in the magnetic interactions. Recently we have studied the local structure above the Jahn-Teller transition temperature (T_{JT}) obtaining that the MnO_6 octahedron is already distorted above T_{JT} and consequently, the change of magnetic interaction observed in this system should be due to an order-disorder transition [14].

To determine the origin of the change from antiferromagnetism to ferromagnetism with Mn dilution, an accurate characterisation of the series is needed. Previous diffraction studies give information on the average of interatomic distances and geometry for atoms, manganese and gallium. In order to obtain information on the local geometry on each individual atom, a selective technique was used in the present study. We report here, the study of the electronic and local structure around the two metals by means of X-ray absorption spectroscopy at Mn and Ga K-edges in $LaMn_{1-x}Ga_xO_3$ series. As we will show, the tetragonal distortion of the MnO_6 octahedra decreases with x and it results in a decrease of the orthorhombic distortion of the unit cell. In other words, the crystal structure and the magnetic ordering changes with increasing the content of gallium and this effect is due not only to the disorder induced by the substitution but also to the change on the local structure at the manganese atom.

2. Experimental

We have studied $LaMn_{1-x}Ga_xO_3$ samples with $x = 0$, 0.1, 0.2, 0.4, 0.6, 0.8 and 1. The synthetic route and crystallographic structure have been reported elsewhere [13]. All samples were characterised as single-phase perovskites by X-ray powder diffraction at room temperature. The oxygen content of the samples was analysed using standard redox titration with $KMnO_4$ and Mohr salt. The samples were oxygen-stoichiometric within the analysis accuracy (± 0.02).

X-ray-absorption measurements at the metal K-edge were carried out at the BM29 beam line at the European Synchrotron Radiation Facility (Grenoble, France). A fixed-exit Si(311) double crystal monochromator was used, the estimated energy resolution being $\Delta E/E = 6 \times 10^{-5}$. The absorption spectra were recorded in transmission mode at room temperature using ionisation chambers as detectors. EXAFS spectra ($\chi(k)$) were obtained by removing the smooth atomic absorption coefficient (μ_0) by means of a cubic spline [15]. The spectra were analysed using FEFF 8.10 package that allows correlating Debye-Waller factor (DW) with the interatomic distances. The structural analysis was performed

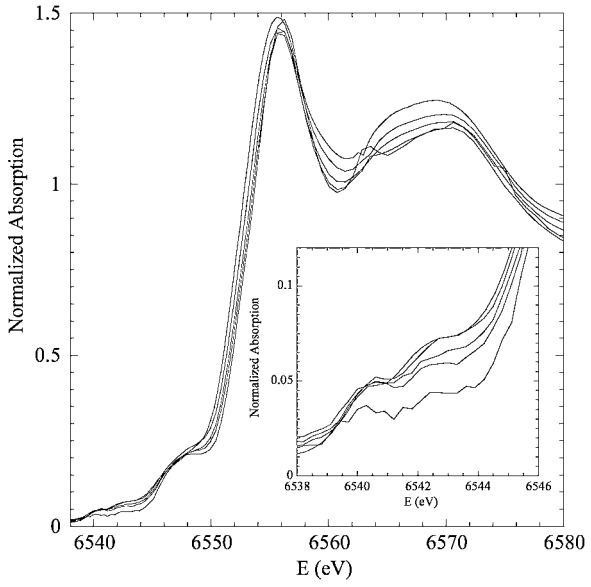

Fig. 1. Normalized Mn K-edge XANES spectra for $LaMn_{1-x}Ga_xO_3$ samples (from left to right $x = 0.0$, 0.2, 0.4, 0.6 and 0.8). Inset: Detail of the pre-peak structures.

in the R-space fitting mode including multiple scattering terms up to 4 Å [16]. XANES spectra were normalized to the high part of the spectrum (around 100 eV above the absorption edge) after a linear background subtraction [15].

3. Results

The Mn K-edge XANES spectra of $LaMn_{1-x}Ga_xO_3$ ($x = 0$, 0.2, 0.4, 0.6 and 0.8) at room temperature are shown in figure 1. The spectra are characterised by a main resonance at the edge corresponding to $1s \rightarrow \varepsilon p$ transitions and a pre-peak structure around 15 eV below the edge. The pre-peak is displayed in more detail in the inset of figure 1. All the spectra are very similar to each other as expected for compounds with a similar perovskite structure. A continuous chemical shift to higher energies is observed from $LaMnO_3$ to $LaMn_{0.2}Ga_{0.8}O_3$. The chemical shift, correlated with the valence state, between $LaMnO_3$ (Mn^{3+}) and $CaMnO_3$ (Mn^{4+}) has been determined to be 4.3 eV [11]. In the $LaMn_{1-x}Ga_xO_3$ series, a maximum shift of 0.5 eV was found. Accordingly, we can deduce a similar valency for the Mn along this series, as expected from the homovalent substitution between Mn^{3+} and Ga^{3+}.

The pre-peak structure is ascribed to $1s \rightarrow 3d$ transitions either quadrupole-allowed or dipole-forbidden. The latter becomes allowed due to a strong mixing of O 2p and Mn 3d states. It has been recently suggested [17] that the pre-peaks have their origin in the density of d-states of the neighbouring transition metal atoms, showing the mixing of d states between different atoms, through hybridisation with the oxygen p-band. The intensity of the pre-peaks decreases with increasing the content of Ga. According to the previous model [17], near neighbours Mn atoms are replaced with Ga that has 3d orbitals fully filled. Therefore, $LaMn_{1-x}Ga_xO_3$ samples have less available empty 3d states with increasing x. We also note that the pre-peak shape is unaltered after dilution indicating a similar splitting of the Mn d-band for all samples.

The Ga K-edge room-temperature XANES spectra of the $LaMn_{1-x}Ga_xO_3$ series, not shown here, are very similar to each other, indicating that the local electronic and geometrical structures around Ga^{3+} do not change along the series.

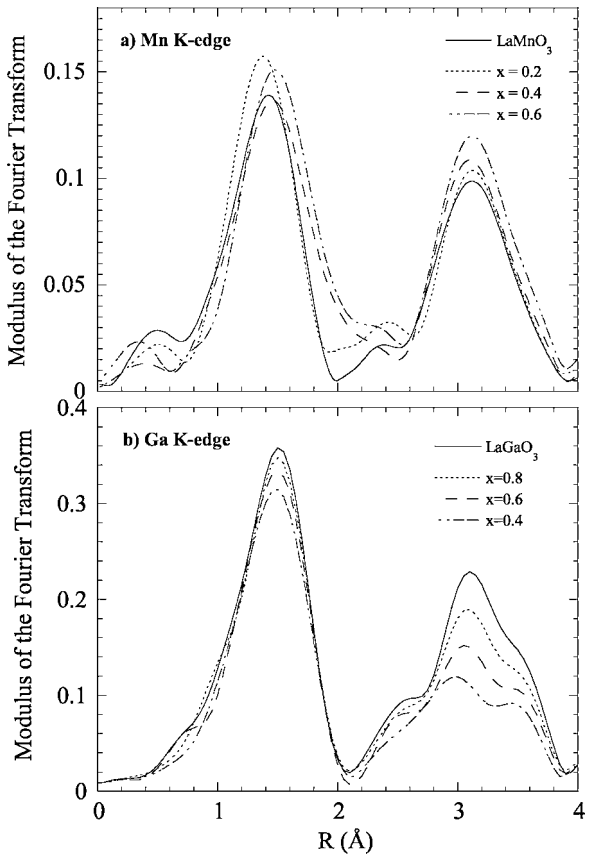

Fig. 2. Modulus of the k-weighted Fourier Transform of the EXAFS spectra of $LaMn_{1-x}Ga_xO_3$ samples at a) Mn K-edge and b) Ga K-edge.

Figure 2a shows the modulus of the Fourier transform at the Mn K-edge. The k-weighted Fourier Transform between 3.0 and 12.0 $Å^{-1}$ was calculated using a Gaussian window. Two main peaks corresponding to first (Mn-O) and second (Mn-La, Mn-Mn, Ga and Mn-O) coordination shells are noticeable. The peak corresponding to the second coordination shell increases as the Ga content increases in agreement to the diminution of the crystallographic orthorhombic distortion. However, the first peak corresponding to the Mn-O coordination does not show a monotonic evolution with the Mn dilution. If the tetragonal distortion decreased with the content of gallium in the sample, a continuous increase of the peak height should be observed. The quantitative analysis of the EXAFS spectra indicates that Mn-O environment is highly distorted in the whole series. Nevertheless, we note a continuous change along the series between two types of MnO_6 distortions that, in principle, can be ascribed to two different Jahn-Teller regimes (static or dynamic) [18]. The main results of the structural analysis are summarised in Fig. 3. This analysis gives interatomic (Mn-X (X = O, Mn or Ga, La) distances in agreement with the crystallographic data [13, 14]. For instance, Mn in $LaMnO_3$ is surrounded by four oxygens at 1.94 Å (hereafter denoted as Mn-O_{short}) and by two oxygens at 2.17 Å (Mn-O_{long}). It is worth realizing that the best fits at the Mn K-edge were obtained using four Mn-O_{short} and two Mn-O_{long} in samples with high content of Mn. Samples with low Mn-content instead, showed better fits using a unique Mn-O distance although with a high Debye-Waller factor. Therefore, the MnO_6 local geometry strongly changes along the series. It evolves from a tetragonal-distorted MnO_6 configuration in low Ga-doped samples to a regular MnO_6 octahedron at $x = 0.6$. This result agrees with previous crystallographic studies [13]

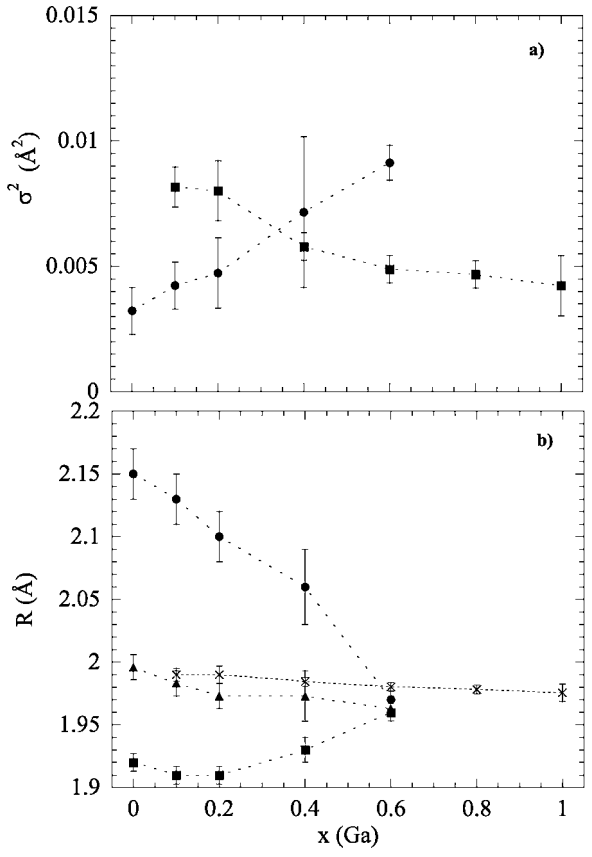

Fig. 3. (a) Average Debye-Waller factor versus x for Mn-O (circles) and Ga-O (squares) distances. (b) Interatomic Mn-O and Ga-O distances. Crosses, circles, squares and triangles refer to Ga-O, Mn-O_{long}, Mn-O_{short} and average Mn-O, respectively.

showing regular MeO_6 octahedra (Me = Mn, Ga) at the same composition. Nevertheless, we observe a significant increase of the Mn-O Debye-Waller factor coupled to the decrease of the tetragonal distortion. In fact, the average mean deviation for the Mn-O distances, obtained from the Debye-Waller factor values, is comparable to the tetragonal distortion observed in the other samples of the series.

Figure 2b shows the modulus of the Fourier Transform at the Ga K-edge taken between 2.4 and 12.5 Å^{-1}. It was obtained from the k-weighted EXAFS spectra for all samples. Two peaks corresponding to first and second coordination shells are also observed. In this case, the intensity of both peaks increases as the content of Ga does. The first peak (first coordination shell) is alike for all the samples. Only a slight decrease in the intensity can be observed with decreasing the content of Ga. It can be related to the structural stress induced by the neighbouring anisotropic Mn^{3+} ions. Anyway, the shape and intensity of this peak seems to indicate a high symmetrical oxygen environment around the Ga^{3+} ions for all samples.

The structural analysis for the Ga-edge is also displayed in Fig. 3. All samples show regular GaO_6 octahedra. The interatomic Ga-O distance remains almost constant for the whole series although we observe a continuous increase of the Ga-O Debye-Waller factor with decreasing the content of Ga. This is related to the mentioned intensity decrease of the first peak in Fig. 2b and we think it is a hallmark of the local structure stress induced by neighbouring MnO_6 with tetragonal distortion.

Finally, we also note that the average Mn-O interatomic distance (triangles in fig. 3) is very similar to the Ga-O distances, in agreement with the formation of a solid solution between Mn and Ga.

4. Discussion

The XAS study performed on this series allows us to provide a complete structural description of this system. The $LaMn_{1-x}Ga_xO_3$ compounds are formed by two kinds of octahedra: regular GaO_6 and distorted MnO_6, as expected. The non-magnetic Ga^{3+} ion ($3d^{10}$ configuration) acts as a building element of the crystal structure without participating in the magnetic interactions. On the other hand, the evolution of the distortion of the MnO_6 octahedron along the series should be matter of a detailed discussion. $LaMnO_3$ is formed by MnO_6 octahedra with a tetragonal distortion. At $T < T_{JT}$, the tetragonal-distorted octahedra are ordered in an antiferrodistortive pattern, *i.e.* Mn-O_{long} and Mn-O_{short} are alternated in the two directions of the *ab* plane (considering the frame of the Pbnm space group) whereas at $T > T_{JT}$, these tetragonal distortions are dynamically disordered [14]. The local tetragonal distortion on each MnO_6 octahedron is thought to be originated by the Jahn-Teller effect that removes the degeneration of the e_g states. Within this framework, one would expect that substitution of Mn by Ga give rise to a set of distorted MnO_6 octahedra randomly located in the bulk structure. However, we have shown that tetragonal distortion decreases continuously as the content of Mn does, MnO_6 being regular for $x = 0.6$. It is well known that Jahn-Teller theory differentiate two coupling regimes. These regimes give rise to different type of distortions: dynamic and static [18]. The dynamic regime is characterised by a linear coupling term higher than the anisotropic coupling one. Accordingly, the minimum of the Q3Q2 distortion modes lies in the so-called 'Mexican hat'. This means that MnO_6 freely fluctuates between the compressed and expanded tetragonal distortions along the three octahedral axes. On the other hand, the static regime can be viewed as the transformation from the 'Mexican hat' into a 'tricorn hat'; so only three tetragonal distortions (compressed or expanded) are accessible to the system. Taking into account that the MnO_6 octahedron is described by a regular octahedron with an unusual high Mn-O Debye Waller factor for $x \geq 0.6$, it can be described as a Jahn-Teller system in the dynamic regime. On the contrary, the tetragonal distortion of $LaMnO_3$ belongs to the static Jahn-teller regime where the distortions are oriented below T_{JT} [14]. Summarising, the dilution by gallium of the $LaMnO_3$ lattice produces a continuous change from the cooperative static Jahn-Teller regime of the MnO_6 octahedra into a non-correlated dynamic Jahn-Teller regime for $x \geq 0.6$ samples. Finally, we can also conclude that the increase of the ferromagnetic interactions with the gallium content is correlated with the regime change of the Jahn-Teller effect.

Abstract

We have measured Fe K-edge XMCD of Fe-metalloid (Si, Al, Sn) in the ferromagnetic and glass-like phases, where the latter phases are only observed for Fe-Al and -Sn systems in the high-concentration region. The observed characteristic features of the XMCD spectra for this state can be explained by use of full multiple scattering relativistic theory within Mattis' magnetic model.

1. Introduction

Spin-glasses show specific magnetic properties conditioned by frustration and randomness of exchange interaction. Sometimes they have small amount of magnetic atoms (about 0.1–10%) randomly distributed in metals, which have competitive exchange interaction.

Cannela and Mydosh measured susceptibility of gold alloy mixed with low concentration Fe atoms, which showed a sharp cusp near the critical temperature [1]. This result was explained by randomly frozen magnetic moments. Ylsukov *et al*. measured the Mössbauer effect for Fe-metalloid (Si, Al, Sn) alloys to study magnetic properties, which demonstrated in the high-concentration range some unusual magnetic behavior [2]. Detailed explanation of this interesting behavior has not been given yet. Mattis [3] considers a theoretical model of spin structure in which the magnetic moments are oriented in two opposite directions in such a way that each of the magnetic moments are randomly distributed in the lattice, whereas the magnetic moments are in the same directions in the same domains [4]. In the literature, this state is known as a Mattis' magnets or Mattis' spin glass.

The study of such random spin structures by XMCD approach is of great interest in virtue of its sensitivity to the value and direction of particular local magnetic structures. In this work, we have studied Fe-metalloid (Si, Al, Sn) alloys by Fe K-edge XMCD to clarify the local geometric, electronic and magnetic structures. In particular, we focus our attention on spin glass models.

2. Theory

The multiple scatterings play an important role in the analyses of XANES spectra; that is also the case for the XMCD analyses in the near edge region. As long as we neglect the relativistic effects at the nearby atoms (this approximation is proved to be reliable as shown in Ref [5]), we can easily renormalize the multiple scattering series,

$$T^{\infty} = T^{(0)} + T^{(1)} + \cdots \tag{1}$$

which is crucial in the near-edge XMCD analyses. The details are shown elsewhere [6].

Here we use a relativistic XMCD theory developed by us. We have observed good convergence in regard to the cluster size for ∼60 atoms.

3. Experiment

Nanocrystalline disordered powders of Fe-Si, -Al and -Sn alloys obtained by mechanical grinding in a planetary ball mill were taken for investigation. The average size of the powder particles was 2 μm for Fe-Si, 1–2 μm for Fe-Al and 4 μm for Fe-Sn alloys. XMCD spectra for Fe K-edge (7.130–7.180 keV) for the Fe-metaloid (Si, Al, Sn) samples were measured at BL28B OF Photon Factory in KEK (2.5 GeV) with circularly polarized X-rays that were generated by an ellipsoid multi-pole wigler and monochromatized using a Si(111) double-crystal monochromator [7, 8]. The absorption spectra were measured in transmission mode at 20 K. The XMCD signals were detected by ionization chambers filled by N_2 gas. Instead of switching helicity of the incident photons, the applied magnetic field, about 0.6 T which was still enough to saturate the magnetization of the sample, was reserved every 4 seconds to obtain MCD effect.

4. Results and Discussion

The magnetic structures of Fe-*M* (*M*=Si, Al, Sn) alloys depend on the metalloid concentration. When the metalloid concentration increases, we find a specific change of the magnetic moment on the Fe atom and of the geometric structure by using Mössbauer spectroscopy and XRD [4]. Figure 1 shows experimental Fe K-edge XMCD spectra for Fe-Al and Fe-Sn alloys, which only show the change of the intensity through the phase transition from ferromagnetic phase to spin glass phase. To explain these specific feature we calculate the Fe K-edge XMCD spectra for these systems.

First we calculate the Fe K-edge XMCD for crystalline ferromagnetic Fe_3Si, and compare it with the experimental one.

Table I. *The magnetic moment of Fe atoms at site Fe-1 and Fe-2 in Fe-M (M = Si, Al, Sn) alloys [9].*

Fe-M	Fe-1 (μ_B)	Fe-2 (μ_B)
Fe_3Si	2.30	1.35
Fe_3A1	2.18	1.50
Fe_3Sn	2.30	2.30

*Electronic address: Okamoto@graduate.chiba-u.jp

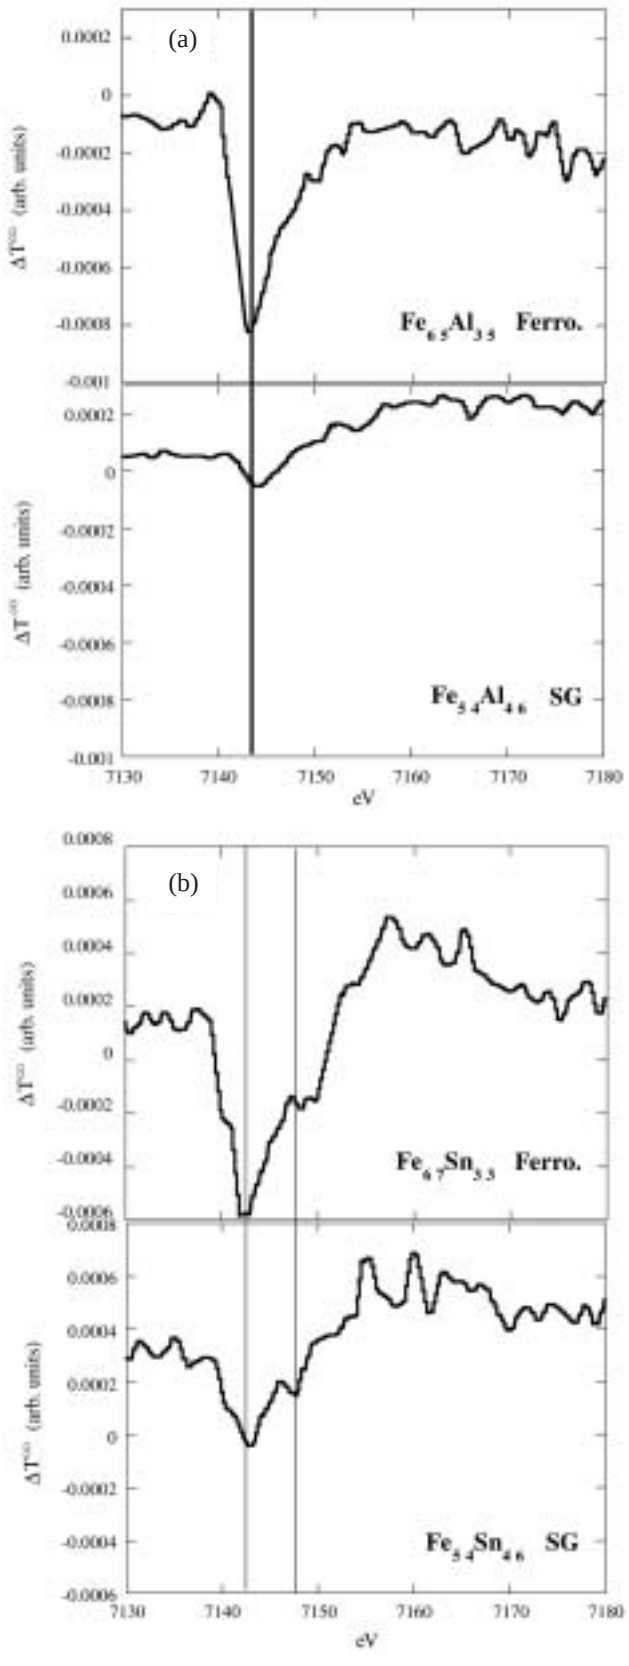

Fig. 1. Experimental Fe K-edge XMCD for ferromagnetic (Ferro.) $Fe_{65}Al_{35}$ and $Fe_{67}Sn_{33}$, spin glass (SG) $Fe_{54}Al_{46}$ and $Fe_{54}Sn_{46}$. In both alloys, XMCD shows no energy shift of the negative main peak, but changes the intensity in different magnetic phases.

We should note that there exist two different Fe sites, Fe-1 and Fe-2 with the ratio 1 : 2. For the present calculation we refer to the spin magnetic moments estimated by first-principle density-functional calculations based on ultrasoftpseudopotentials and all electron methods [9], which are listed in Table I. Figure 2 shows the calculated result compared with the experimental one; the energy 0 is set to be the onset of the Fe K-edge absorption. Satisfactory agreement is obtained. We have also obtained good results both for ferromagnetic Fe_3Al and Fe_3Sn.

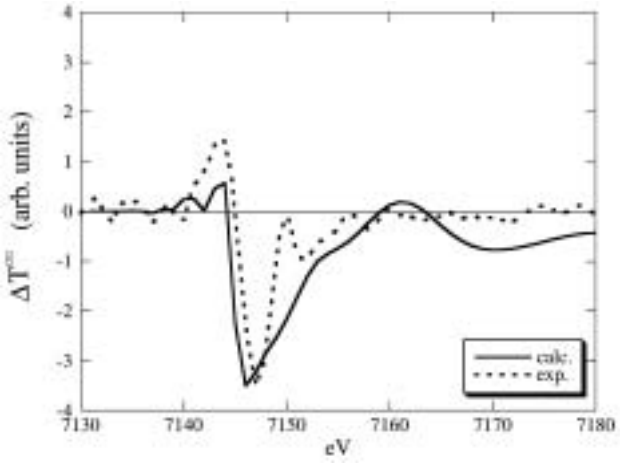

Fig. 2. Calculated (solid line) and experimental (dotted line) Fe K-edge XMCD in crystalline ferromagnetic Fe_3Si.

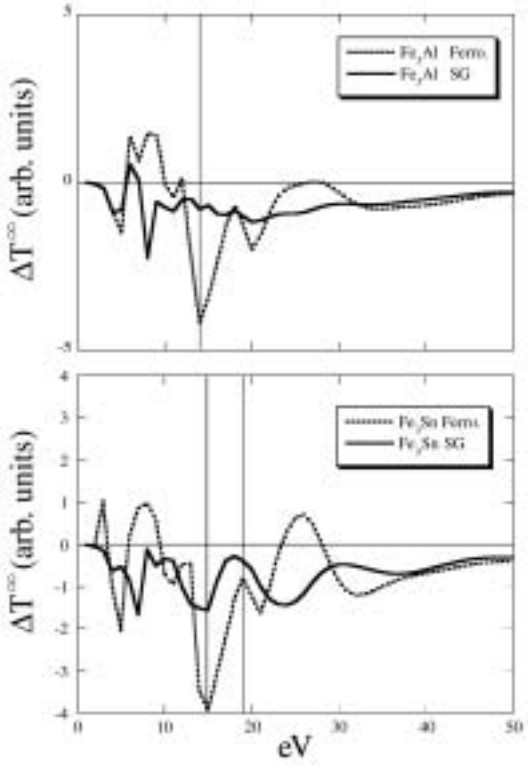

Fig. 3. Calculated XMCD spectra for Fe_3Al and Fe_3Sn glass-like models (solid lines) compared with the ones in ferromagnetic phase (dotted lines).

We next calculate the Fe K-edge XMCD spectra for some glass-like models where the spin orientation is randomly distributed in the whole space. To study these models we consider a simplified model where half of the Fe atoms in the first and second shells around an X-ray absorbing atom *A* have (−) spin whereas the others including the atom *A* have (+) spin for simplicity. Figure 3 shows the calculated XMCD spectra for the Fe_3Al and Fe_3Sn alloys according to this model compared with the ones in the ferromagnetic phase. We show the sum of the site-1 and -2 XMCD

with the weights of the different sites

$$\frac{1}{3}\Delta T^{\infty}(1) + \frac{2}{3}\Delta T^{\infty} \tag{2}$$

where $\Delta T^{\infty}(1)$ is the XMCD at the Fe-1 site whose fraction is $1/3$. In Fe_3Al the sharp prominent negative peak at about 14 eV observed for the ferromagnetic model is lost but observed at about 8 eV for the classical spin glass model, and the smaller negative peak at 20 eV for the former is lost for the latter. In Fe_3Sn the prominent sharp negative peak at 15 eV shows no peak shift for these models; the classical spin glass model gives rise to a broad shallow peak there. The small negative peak observed at 21 eV for the former is lost but observed at 23 eV for the latter. These calculated results for these glass-like models are not in accordance with the observed experimental results as shown in Fig. 1. We thus can rule out the possibility of glass-like model for these systems.

On the other hand the Mattis spin glass model simply predicts the XMCD

$$x^{+}\Delta T^{\infty}(+) + (1 - x^{+})\Delta T^{\infty}(-) = (2x^{+} - 1)\Delta T^{\infty}(+) \tag{3}$$

where x^{+} is the fraction of magnetic Fe atoms with (+) spin and $\Delta T^{\infty}(+)$ is the XMCD for those magnetic atoms and $\Delta T^{\infty}(+) = -\Delta T^{\infty}(-)$. We should note that each of $\Delta T^{\infty}(\pm)$ are calculated by use of the sum (2). We only expect the overall scale down of the XMCD observed for the ferromagnetic systems depending on x^{+} and no peak shift. The observed spectral changes as shown in Fig. 1 for $Fe_3X(X = \text{Al, Sn})$ are just what we expect from the above equation (3).

5. Concluding Remarks

In this work we have measured iron metalloid Fe K-edge XMCD in ferromagnetic and spin glass phases. The latter phase is only observed for Fe_3A1 and Fe_3Sn. The observed characteristic features in the observed XMCD spectra for the spin glass phase are well explained with aid of Mattis spin glass model. With increase of the metalloid concentration the small domain could be randomly broken into smaller pieces of magnetic domains, which gives rise to scale down of the XMCD. We have assumed the domain size is large enough to apply the simple additive rule as shown by eq. (3), however we should carefully study the interface effects of the domain when the domain size is of the order of $\approx$10 Å.

Abstract

$NdNiO_3$ presents a metal-insulator (*MI*) transition at 200 K with decreasing temperature. This system was characterized by neutron diffraction as orthorhombic with a very symmetric Ni site and almost no modification at the NiO_6 octahedra is observed across the transition. We carried out EXAFS measurements on $NdNiO_3$ from room temperature down to 10 K, crossing the *MI* transition and observed important local modifications at the Ni site. The phase derivative method shows that there are distorted Ni sites, with at least two different Ni-O distances, along all the temperature range measured. The modification across the *MI* transition concerns the increasing of the distorted phase. This hypothesis is sustained by the behavior of the Debye-Waller factor (σ^2) with temperature. With decreasing temperature, when the sample is around T_{MI} σ^2 rapidly increases due to the growing amount of distorted sites. These results give basis for a discussion in terms of a percolative transition.

Transition-metal oxides with perovskite structure exhibit a variety of interesting properties like high-T_C superconductivity and colossal magnetoresistance. These systems have in common a complex interplay between its magnetic, electronic and structural properties. In particular, RNiO$_3$ perovskites (R = rare earth), except for $LaNiO_3$, display metal-insulator phase transition as temperature decreases [1]. RNiO$_3$ systems have a distorted perovskite structure, where the NiO_6 octahedra tilt and rotate to fill the empty space left around the rare earth. Both the degree of distortion and the MI transition temperature, T_{MI}, increase as the R ion becomes smaller. Neutron diffraction results show that the crystallographic structure for systems with R = Pr, Nd and Sm has Pbnm symmetry where the unique Ni site has all Ni-O separations almost equal. Across the transition, minimum modifications at Ni-O distances and a slight change at Ni-O-Ni angles were observed. On the other hand results on Raman spectroscopy together with electron diffraction measurements have showed a structural modification for $NdNiO_3$ thin films across the MI transition that was associated to a Ni orbital ordering [2]. Moreover, also in $NdNiO_3$ films, a charge ordering was observed at the insulating phase [3]. Nevertheless, for systems with smaller R ions (Ho, Y, Er, Tm, Yb and Lu), Alonso *et al.* [4, 5] observed a monoclinic distortion which leads to the existence of two unequivalent Ni sites. When crossing the electronic transition the Pbnm symmetry is established [6] at the metallic phase.

This work presents results on EXAFS (Extended X-ray Absorption Fine Structure) at the Ni K edge (E = 8333 eV) for $NdNiO_3$ (T_{MI} = 200 K) showing modifications at the NiO_6 octahedra across the *MI* transition. The measurements were performed using a Si(111) channel-cut monochromator at the D04B-XAS beamline at LNLS, Campinas, Brazil. In order to perform the measurements, the powder sample is deposited over a cellulose membrane, such that a homogeneous sample optimized for transmission measurements is obtained. A He cryogenerator was used to decrease the sample temperature down to 10 K.

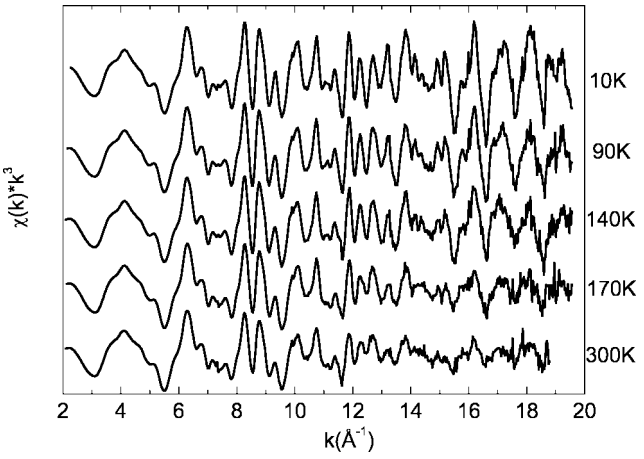

Fig. 1. EXAFS signal weighted in k^3 ($\chi(k) * k^3$) for $NdNiO_3$ (T_{MI} = 200 K). The spectra were translated in vertical for a better visualization.

The EXAFS signal was measured until 19.5 Å^{-1} for several temperatures varying from room temperature down to 10 K. In figure 1 the EXAFS signal is shown for some of the temperatures measured. There are no dramatic changes on the EXAFS signal as the *MI* transition is crossed. It is seen only a continuous increase of the oscillation amplitude with decreasing temperature.

The Fourier Transformed spectra for the measurements at 10 K and at room temperature are shown in figure 2. The dependence of the FT amplitude with temperature is evidenced by the peaks above 2 Å. As temperature is decreased the FT amplitude increases due to smaller thermal damping. However, looking at the first peak on the FT spectra, which comes from the Ni-O coordination shell, it is seen that the amplitude is almost the same, despite the great difference in temperature. Moreover, the Ni-O peak for the data at 10 K shows a splitting that probably comes from the existence of different Ni-O distances.

The multiple Ni-O distances were analyzed using the phase derivative method [7, 8]. This method is based on the fact that a filtered EXAFS signal that is formed by different interatomic distances presents a beating in the amplitude function and an inflexion point on the phase function. The position of this inflexion point (named k_b) gives a numeric estimate of the separation among the interatomic distances, in the case of being only two, given by $\Delta R = \pi/(2k_b)$. Figure 3 shows the phase functions for all temperatures measured. At the right side of figure 3 the correspondent first derivative of the phase functions are shown

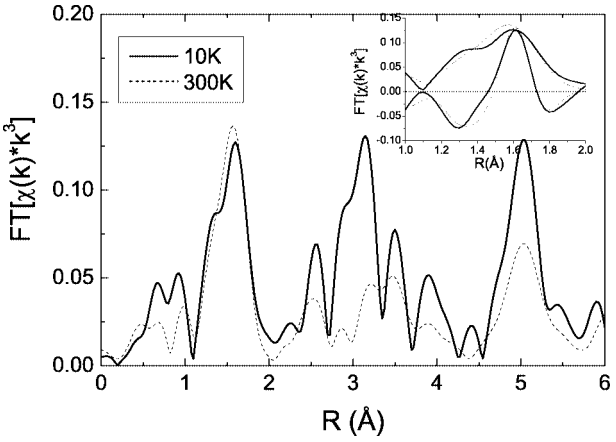

Fig. 2. Fourier Transform of the EXAFS signal for $NdNiO_3$ ($T_{MI} = 200$ K) at 10 K and room temperature.

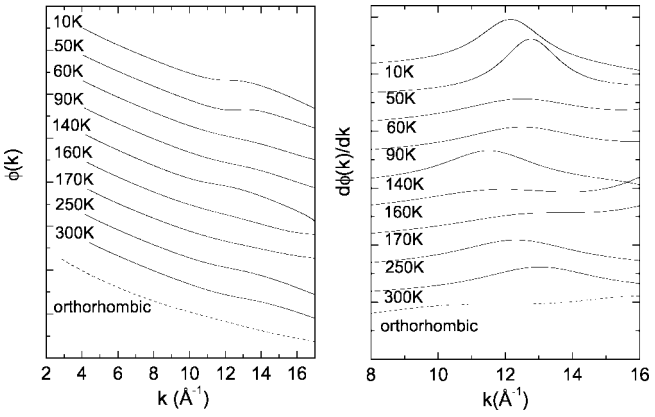

Fig. 3. Left, phase functions, and right, their corresponding first derivative. The curves were translated in vertical in order to have a better visualization.

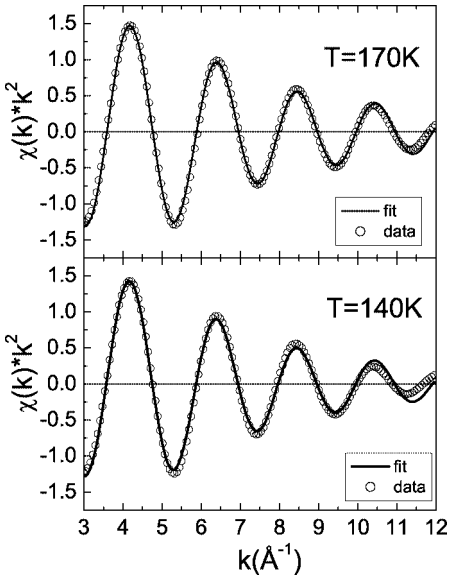

Fig. 4. Fit of the filtered EXAFS signal with one Ni-O distance.

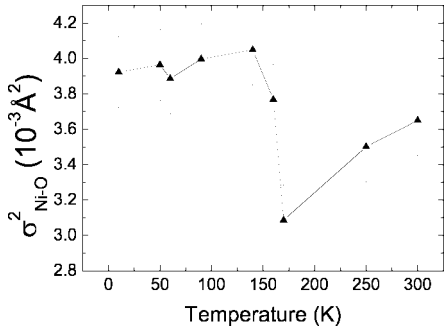

Fig. 5. Debye-Waller factor obtained from the fit of the $NdNiO_3$ data. See text for details.

to facilitate the visualization of the inflexion point. Taking the position of the inflexion point from these curves we obtain a separation of 0.13 Å between the different Ni-O distances. The most interesting result of the phase derivative method is that the inflexion point does not completely disappear at the metallic phase, indicating that some portion of distortion is still present and, then, that the structural transition is wider than the *MI* transition. The dotted line in figure 3 shows the phase function (and its first derivative) extracted from a simulated EXAFS signal using the crystallographic parameters found for $NdNiO_3$ [9]. Since the Ni-O distances found from diffraction are practically identical, the inflexion point is not seen for the simulated signal. Therefore, for none of the temperatures measured it is seen such a symmetric site for Ni from our EXAFS data.

The fitting of the filtered EXAFS signal with two different Ni-O distances using the complete range measured turned out to be very difficult due to the number of free parameters. Instead, we analyzed the data upto $k = 12\,\text{Å}^{-1}$. From figure 3 it is seen that the beating is localized between 12 and 13 Å^{-1}. Therefore, cutting the data at $12\,\text{Å}^{-1}$ we reduce the resolution and the different Ni-O distances are no longer distinguishable. So, a fitting with a unique Ni-O distance is possible. Figure 4 shows the fitted curve compared to the experimental signal for two spectra measured at different temperatures. The fitting was carried out using theoretical phase and amplitude functions obtained considering symmetric NiO_6 octahedra. The amplitude reduction factor (S_0^2) was maintained constant between different temperatures. From this figure it is seen that a unique Ni-O distance fits very well the data in this reduced k-range. Note that the data measured at 140 K show a stronger damping in the end of the spectrum compared to the data measured at higher temperature (170 K). The reason for this will be clarified in the following discussion.

Figure 5 shows the evolution of Debye-Waller factors obtained from the fitting as a function of temperature. σ^2_{Ni-O} shows a normal smooth decrease, with decreasing temperature, down to 170 K. Below this temperature, it suddenly increases. The increase in σ^2_{Ni-O} below 170 K is explained by an increase of the structural disorder contribution to the total Debye-Waller measured by EXAFS. Since the phase derivative method shows that distorted Ni sites exist in the metallic and insulating phases, such increase in σ^2_{Ni-O} can be attributed to a growth on the amount of distorted sites. In our fit it was considered only an average Ni-O distance when, in fact, there are more than one different interatomic distance. The width of this distance distribution is included in the Debye-Waller factor, that is also an average over all Ni sites. With the increase of the amount of distorted sites, the average disorder also increases, as figure 5 shows.

All the evidence presented here point to important modifications at Ni sites. The main modification across the *MI* transition comes from an increase of the amount of distorted Ni sites, which are present both in metallic and insulating phases. The fact that this distortion at the NiO_6 octahedra has not been seen by diffraction measurements [9] indicates that it takes place at a local scale and it does not have long range coherence. The

results shown by the phase derivative method together with the behavior of σ^2 with temperature give basis for a discussion over a percolative transition in $R\mathrm{NiO_3}$ systems.

Abstract

To understand the information one can obtain from MEXAFS, we develop a theory of MEXAFS within the spherical wave approximation. We show that the dominant signal is directly proportional to the magnetic moment per atom and smaller than regular EXAFS by an order of magnitude. We show that this explains the observed temperature dependence of MEXAFS. The higher order correlation functions can, in principle, be determined from double scattering paths, but they give contributions which are smaller by another two orders of magnitudes compared to that from the spin moment. Thus MEXAFS can serve as an alternative method for the element specific extraction of total spin magnetic moments. This can be achieved by modification of the regular EXAFS fitting routines and the output of the spin-dependent FEFF8 code.

Magnetic EXAFS is defined as the difference between the EXAFS signal for right and left circular polarized X-rays. This signal is typically very small, and one needs 3rd generation synchrotron sources to determine its temperature dependence. Thus accurate measurements of this effect became possible only recently [1–6]. The first theory and calculations of MEXAFS were developed assuming perfect ordering of spins (i.e., zero temperature) [7, 8]. Even the first experiment showed that MEXAFS amplitude is dominated by the total spin moment per atom [1, 2]. In this paper we generalize the theory of MEXAFS for nonperfect spin ordering, and determine the sensitivity of MEXAFS to the moments of the spin distribution.

For a ferromagnet at zero temperature the MEXAFS signal has been shown to be proportional to the difference in absorption between spin-up and spin-down electrons [7]. Using the spherical wave approximation [9] to facilitate understanding, the MEXAFS signal in Eq. (17)–(19) of [7] can be rewritten as a sum over individual path contributions:

$$\chi_M^{N-1}(k) = \mathrm{Im} C_{jl}\, \hat{\rho}_1 \cdot \hat{\rho}_N \prod_{n=1}^{N} \frac{\mathrm{e}^{\mathrm{i}\rho_n}}{\rho_n} \left[\mathrm{e}^{\mathrm{i}2\delta_\uparrow} \prod_{n=1}^{N-1} f_n^{\uparrow}(\theta_n) - \mathrm{e}^{\mathrm{i}2\delta_\downarrow} \prod_{n=1}^{N-1} f_n^{\downarrow}(\theta_n) \right], \quad (1)$$

where k is the wavevector of the photoelectron produced from an initial state with total momentum j, $\uparrow$ and $\downarrow$ indicate the direction of the photoelectron spin $s = \pm 1/2$. Here the scattering path consists of $N-1$ scatterers at positions $\boldsymbol{R}_\mathrm{i}$ and one absorbing atom at $\boldsymbol{R}_0 = \boldsymbol{R}_N$; $\boldsymbol{\rho}_n = k(\boldsymbol{R}_n - \boldsymbol{R}_{n-1}) = \hat{\rho}_n \rho_n$, and $\rho_n = |\boldsymbol{\rho}|$; θ_n is angle between $\boldsymbol{\rho}_n$ and $\boldsymbol{\rho}_{n+1}$; f_n^s is a scattering amplitude at n-th scatterer; and δ_s is the central atom phase shift. We will denote the corresponding phase factor as $f_N^s = \exp(\mathrm{i}\delta_s)$, as this will simplify our expressions.

Thus we take the standard picture of MEXAFS and separate the process into a) the production of spin-polarized photoelectrons, which is determined by atomic physics (i.e., the Fano effect), and b) the propagation of spin-polarized photoelectrons through the solid. Due to the strong spin-orbit interaction in the initial state, right (left) circularly polarized light produces more photoelectrons with spin-up (spin-down) along the X-ray k-vector. The excess is determined by Clebsh-Gordon coefficients and leads to a prefactor $C_{jl} = (-)^{j-l-1/2} l/(2j+1)$ in the Eq. (1), that depends on the initial state total j and orbital l momenta. For the initial s-states ($l = 0$) one has to include the small spin-orbit interaction in the final state. The approximate expression for this case is given by Eq. (9) [10]. Assuming that spin-orbit splitting is approximately constant, one can show that Eq. (1) for MEXAFS still holds with a different prefactor proportional to a derivative of signal with respect to energy $C_{1/2,0} = (\Delta_{so}/3)\delta/\delta E$. Notice that for each scattering path the derivative may be replaced with $2\mathrm{i}R/k$, since the fastest changing term with energy is $\mathrm{e}^{2\mathrm{i}kR}$ with $2R$ being the total path length.

During propagation the photoelectron scatters from sites which possess spin moments $\boldsymbol{s}_i$. In this work we will neglect the spin-flip processes and assume that scattering depends on the projection of $\boldsymbol{s}_i \cdot \boldsymbol{s}$. The scattering amplitudes are directly connected with the spin-dependent potentials at a given site, which are small perturbations on the average scattering potential. Thus the scattering amplitude is dominated by linear dependence on both spins. For example, the phase shifts and scattering amplitudes can be calculated via a generalized Born approximation. Since according to density functional theory [11] the spin-dependent potential is determined by the total spin-density, we can always write the spin dependent scattering amplitude as a linear combination:

$$f_n^s(s_n) = f_{n,0} + s\, s_n f_{n,1}, \quad (2)$$

where s_n is the projection of total spin on a scatterer on the X-rays k-vector. Higher order terms in $(\boldsymbol{s} \cdot \boldsymbol{s}_n)$ can be included in the above expansion, since this scattering amplitude should stay the same if we switch the sign for photoelectron spin and spin s_n. But such higher order terms will give an order of magnitude smaller contribution for each consecutive term, as demonstrated in Fig. 1.

The ratio $f_{n,1}/f_{n,0}$ for the central atom and for the backscattering amplitude for Gd metal (Fig. 1) exhibit significant energy dependence. However the typical ratio is about 0.1, which implies that magnetic scattering is an order of magnitude smaller. This is true even for the $4f^7$ configuration of Gd where one can expects the largest magnetic scattering, since all 4f electrons have spin-up in this case.

Since MEXAFS, apart from an atomic prefactor, is given by the difference between the absorption for spin-up and spin-down photoelectrons, one can generalize the MEXAFS calculation for arbitrary spin distributions using spin-dependent scattering

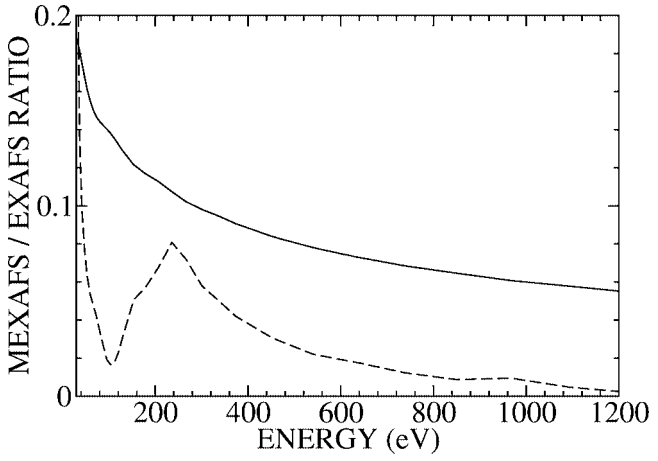

Fig. 1. The Gd metal ratio of $s_n f_{n,1}/f_{n,0}$ for the absorbing atom phase shift (solid) and the nearest neighbor backscattering amplitude (dashes) vs. energy above the L_3 edge. The ratio is plotted for the zero temperature with $s_n = 7/2$, which is appropriate for the ratio between MEXAFS and EXAFS (see Eq. (9)). Since the ratio is mostly below 0.1 the MEXAFS signal is proportional to the total spin on each site as discussed in text.

amplitudes as

$$\chi_M^{N-1}(\{s_n\}) = \mathrm{Im}\frac{C_{jl}\,\mathrm{e}^{2ikR}\hat{\rho}_1\cdot\hat{\rho}_N}{\prod_n \rho_n}\sum_s 2s\prod_n f_n^s(s_n), \tag{3}$$

where $2R$ is the total path length, and the spin of the photoelectron is $s = \pm 1/2$, and $\{s_n\}$ denotes the spin configuration: spin s_1 on atom 1, s_2 on atom 2 and s_N on atom N.

To obtain the observed signal we need to sum the results calculated for a given spin configuration $\{s_n\}$, weighted with the probability $P(s1, s2, \ldots, s_N)$ to find that spin configuration,

$$\chi_M^{N-1} = \int \mathrm{d}(s_1)...\mathrm{d}(s_N)\chi(\{s_n\})P(\{s_n\}). \tag{4}$$

Experimentally it is found that the main contribution to MEXAFS signal comes from single scattering paths and multiple scattering paths with three or fewer atoms [1, 3]. This means that the MEXAFS signal can be calculated if the 4-point spin-distribution function $P(s_1, s_2, s_3, s_4)$ is known. Fortunately, one does not need to know the distribution function precisely to analyze the MEXAFS data. This is because an expansion of the scattering amplitudes in powers of ss_i only picks up certain moments of the distribution function.

First, we demonstrate this for the single scattering contribution to MEXAFS. Within the spherical wave scattering limit,

$$\chi_M^1(s_1, s_2) = \mathrm{Im}\frac{C_{jl}\mathrm{e}^{2ikR}}{\rho_1\rho_2}(s_1 f_{1,1} f_{2,0} + s_2 f_{2,1} f_{1,0}), \tag{5}$$

so integrating over distribution functions, we obtain

$$\chi_M^1 = \mathrm{Im}\frac{C_{jl}\mathrm{e}^{2ikR}}{\rho_1^2}(\langle s_1\rangle f_{1,1} f_{2,0} + \langle s_2\rangle f_{2,1} f_{1,0}). \tag{6}$$

Thus the single scattering MEXAFS can be used to measure the average spin on each element, and is independent of spin-spin correlation function.

A similar procedure for the double scattering term, again within the spherical wave scattering limit, leads to

$$\chi_M^2(s_1, s_2, s_3) = \mathrm{Im}\frac{C_{jl}\mathrm{e}^{2ikR}\hat{\rho}_1\cdot\hat{\rho}_3}{\prod_n \rho_n}(s_1 f_{1,1} f_{2,0} f_{3,0} + s_2 f_{2,1} f_{1,0} f_{3,0} + s_3 f_{3,1} f_{1,0} f_{2,0} + s_1 s_2 s_3 f_{1,1} f_{2,1} f_{3,1}), \tag{7}$$

and we obtain

$$\chi_M^2 = \mathrm{Im}\frac{C_{jl}\mathrm{e}^{2ikR}}{\prod_n \rho_n}(\hat{\rho}_1\cdot\hat{\rho}_3)(\langle s_1\rangle f_{1,1} f_{2,0} f_{3,0} + \langle s_2\rangle f_{2,1} f_{1,0} f_{3,0} + \langle s_3\rangle f_{3,1} f_{1,0} f_{2,0} + \langle s_1 s_2 s_3\rangle f_{3,1} f_{1,1} f_{2,1}). \tag{8}$$

Thus in principle the double scattering term contains information about the 3-point correlation function $\langle s_1 s_2 s_3\rangle$. However this is expected to be two orders of magnitude smaller, since it contains two more powers of $f_{i,1}$ (see Fig. 1). Therefore this signal is practically undetectable. Notice that all even power correlation functions do not enter the result, due to the symmetry with respect to inversion of both spins on the photoelectron and on the atom. The summation over the photoelectron spin leaves only odd power moments of the spin distribution.

The above expression also explains why the neglect of the spin-flip processes is justified. For X-ray absorption calculations, the photoelectron must come back with the same spin as it left with. Thus for the single scattering term spin-flip cancels exactly, while for double scattering the spin-flip scattering must happen on both scatterers, which lead to an amplitude one order of magnitude smaller than the dominant term in spin conserving scattering. This will also be true for higher order scattering.

Similar manipulations can be done for the triple scattering term with the same conclusion. The dominant signal is proportional to the spin on each scattering site. The higher order correlation functions ($\langle s_1 s_2 s_3\rangle$, $\langle s_1^2 s_2\rangle$, etc.) can be hardly be measured from experiment, since they are suppressed by about 2 orders of magnitude.

From these equations one can also understand why the ratio of the multiple scattering to the single scattering contribution is larger for MEXAFS than for EXAFS. For systems with a single magnetic atom, one can assume that all ratios $f_{i,1}/f_{i,0}$ are nearly the same

$$\begin{aligned}\chi_M^1/\chi^1 &= 2\langle s\rangle f_{i,1}/f_{i,0},\\ \chi_M^2/\chi^2 &= 3\langle s\rangle f_{i,1}/f_{i,0},\\ \chi_M^3/\chi^3 &= 4\langle s\rangle f_{i,1}/f_{i,0}.\end{aligned} \tag{9}$$

This shows that relative magnitude of the multiple scattering peaks should be 1.5–2 times larger than the single scattering contributions. This is in agreement with previous works [4, 5].

Thus we find that for mono-atomic systems, only one magnetic parameter $\langle s\rangle$ can be obtained from MEXAFS experiment. The Debye-Waller factors arise from the averaging the $\exp(2ikR)$ factor with respect to atomic motion or disorder. Therefore they should be the same for EXAFS and MEXAFS. However a further reduction of the MEXAFS amplitude with temperature can be attributed to the reduction in the average spin per atom, i.e., which is proportional to the total temperature dependent magnetization. Wende et al. experimentally observe a close proportionality of the ratio between MEXAFS and EXAFS signals to the temperature dependence of the magnetization or $\langle s\rangle(T)$ [6]. In that work, authors suggest as an approximation, simply to differentiate the EXAFS signal with respect to energy and multiply it by a fitting parameter Δ_{ex}. This parameter is an estimate of the exchange splitting between spin-up and -down bands, which should be proportional to $\langle s\rangle$. Such an approximation is justified if the signal is dominated by the shortest single scattering path, which is usually the case in practice. The derivative with respect to energy automatically weights the larger distances stronger, since $\mathrm{d}/\mathrm{d}k\exp(2ikR) = 2iR\exp(2ikR)$. This seems to weight the single

scattering paths with large distances incorrectly. However, the signal is strongly dominated by the nearest neighbor single scattering path. As a results the direct proportionality of Δ_{ex} to $\langle s \rangle$ or magnetization has been observed for the temperature dependent measurement [12].

As we discussed above the MEXAFS signal is directly proportional to the total spin moments on each site. To extract $\langle s_i \rangle$ one can use calculations to estimate the the proportionality factors $f^M_{\mathrm{eff},i}$. Thus analogous to EXAFS, the MEXAFS can be parameterized as

$$\chi_M = S_0^2 \mathrm{Im} \sum_{paths} \frac{\sum_i f^M_{\mathrm{eff},i} \langle s_i \rangle}{kR^2} \mathrm{e}^{2\mathrm{i}kR + 2\mathrm{i}\delta_l} \mathrm{e}^{-2\sigma^2 k^2}. \quad (10)$$

Notice that we added S_0^2 and Debye-Waller factors to this equation but they should be the same as for EXAFS. Thus unlike the standard EXAFS equation, where FEFF8 [13] can be used to calculate one f_{eff} for each path, for MEXAFS one may need several $f^M_{\mathrm{eff},i}$, which are essentially derivatives of a particular path contribution with respect to spin on particular atom type. To obtain such derivatives one needs a few calculations of XMCD for some particular spin configurations (e.g. all $s_i = 0$ except one $s_{i0} = 1$). Notice that such calculation may include spherical wave corrections and spin-orbit interaction in final state. Thus the extraction of spin moment for systems with several magnetic atoms requires one to modify the FEFF8 output as well as the input to EXAFS fitting programs.

In conclusion, MEXAFS can be viewed as a method to extract the total spin moment for each element. There is, however, a significant distinction between these moments and the spin moments extracted from the sum rules. The MEXAFS spin is the total spin on each site, while the sum rules can be used to split this total spin in partial angular momentum contributions. For example, the Tb L_3 edge XMCD near the absorption edge can be used to obtain s_{5d}, while MEXAFS should be proportional to $\langle s_{4f} + s_{5d} \rangle$. The higher order correlation functions are practically undetectable by MEXAFS technique, since they are expected to give contributions two orders of magnitude smaller. As a consequence of that we suggest that MEXAFS analysis can be done similar to EXAFS analysis to extract information on site specific total spin moments.

Abstract

A feature at a binding energy of ∼2.5 eV which has not previously been discussed in the literature is observed in the photoemission spectra of the valence band of $La_{1-x}Sr_xMnO_3$ single crystals. To reveal the origin of this feature measurements of resonant photoemission on $La_{1-x}Sr_xMnO_3$ were performed as well as absorption spectra at the La N and Mn $L_{2,3}$ edges at liquid nitrogen and room temperatures. Only for Mn L edge we observed a clear resonance for a binding energy corresponding to the feature of interest. Comparison with the calculated density of states led to the conclusion that the feature corresponds to Mn t_{2g} states.

1. Introduction

Transition metal oxides with the composition $La_{1-x}Sr_xMnO_3$ have attracted tremendous interest during the last several years due to the discovery of colossal magnetic resistance (CMR) effect that occurs near room temperature [1] and therefore opens up possible technology applications. The parent compound $LaMnO_3$ is an A-type antiferromagnetic insulator with a Neel temperature $T_N \approx 140$ K. Doping $LaMnO_3$ with strontium transforms it into a magnetic metal at low temperatures.

For $x \geq 0.175$ near the magnetic transition temperature T_C the ferromagnetic transition is accompanied by a metal-insulator transition. For $0.1 < x < 0.175$ $La_{1-x}Sr_xMnO_3$ is an insulator for both $T > T_C$ and $T < T_C$. The CMR effect occurs when an external magnetic field gives rise to a temperature increase of this phase transition and a dramatic decrease of the resistance is observed [1].

For a proper description of such unusual properties the double-exchange mechanism with a strong Hund coupling [2] is needed as well as electron-phonon coupling (Jahn-Teller distortion) [3].

The local configuration of the Mn^{3+} ion in $LaMnO_3$ is $t^3{}_{2g}e^1{}_g$. With divalent metal substitution part of the ions turns into Mn^{4+}. But according to recent work [4, 5, 6] the doped holes have O 2p character, opposite to the usual double-exchange mechanism.

In this work we present resonant photoemission and X-ray absorption near edge structure (XAS) data of $La_{1-x}Sr_xMnO_3$ single crystals in the range of x from 0 (insulator) to 0.33 (metal) at both room temperature and close to the liquid nitrogen temperature near the Mn 2p and La 4d edges. These results were partly published in [7].

2. Experimental

Single crystals of $La_{1-x}Sr_xMnO_3$ (for $0 < x < 0.33$) were obtained by the floating zone method by light heating on the device URN 2-3 M made at the Moscow Power Institute. First, a ceramic bar was made from La_2O_3, $SrCO_3$ and Mn_3O_4 with purity no less than 99.99. The concentration of Mn_3O_4 was increased by 0.5 at% to compensate for evaporation of Mn. Original synthesis was performed during the annealing of a powder mixture at 1200 °C during 24 hrs. After pressing the bar was clinkered at 1350 °C during 24 hrs. Single crystals with $x < 0.075$ were grown in inert Ar atmosphere and single crystals with composition range $0.075 < x < 0.5$ were grown in air in the open crystallization chamber. Typical growing speed was 7–10 mm/hour and rotation speed was 60 rpm.

The crystal structure was determined by neutron and X-ray diffraction. It should be noted that the deviations of the slightly distorted orthorhombic and rhombohedral structures from cubic are negligible, so we will use cubic notations in the text of the present paper.

Photoemission spectra were obtained at the synchrotron radiation source MAX-I at the MAX-Lab laboratory, Lund University, Sweden. We used beamlines 22 and 41.

Beamline (BL) 22 is equipped with a modified SX-700 plane grating monochromator and a 200 mm mean radius hemispherical electron energy analyzer with a multi channel plate detector. The angle between the exciting radiation and the analyzer axis was 40°. The total resolution of the beamline was 0.1 eV in the valence band and 1 eV for resonance series around the Mn 2p absorption threshold.

BL 41 is equipped with a toroidal grating monochromator with three gratings and a goniometer mounted angle-resolved electron energy analyzer (VSW HA50). The acceptance angle of the analyzer is ±1° and the total energy resolution in these measurements was about 0.25 eV.

Samples were introduced into the experimental chamber via a load-lock system.

The energy calibration was made using a gold reference foil in electrical contact with the samples. The investigations were performed in the experimental chambers at 10^{-10} torr pressure and at two temperatures: room temperature (RT) and close to liquid nitrogen temperature (LT).

Single crystals were cleaved *in situ* by an anvil-knife cleaving system. The (001) axis was perpendicular to the sample surface. The resulting surfaces were rough but well defined since LEED images could be obtained. The method of *in situ* cleavage leads to samples with the surface quality much better than in the case of polycrystalline and thin film samples or by scraping samples in vacuum.

3. Results and discussion

Fig. 1 presents typical electron spectra for different strontium concentrations x in a binding energy E_b region up to 30 eV,

*e-mail: lev@isssph.kiae.ru

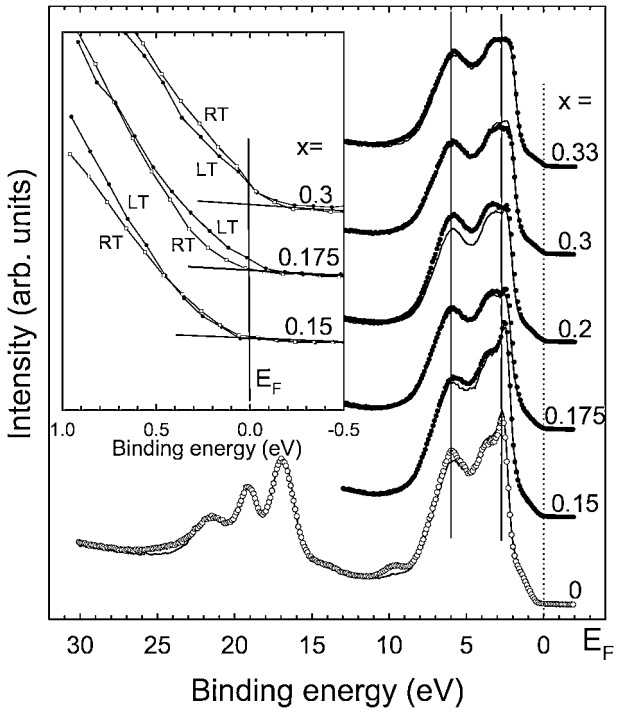

Fig. 1. Valence band photoemission spectra for samples with different strontium concentrations x measured at RT (solid lines) and LT (dots) for $h\nu = 130$ eV. All spectra were normalized to the La $5p_{3/2}$ peak taking into account a La concentration of $1 - x$ and shifted along the ordinate axis. For $x = 0$ the open circles show a spectrum obtained after several hours of measurements. The inset shows binding energy range close to E_F for $x = 0.15$, 0.175 and 0.3. Open circles shows curves for RT, black circles for LT. Spectra for different x shifted along ordinate axis.

measured at RT (solid lines) and LT (dots) for $h\nu = 130$ eV at BL 22 under the normal emission conditions. All spectra were normalized to the La $5p_{3/2}$ peak taking into account a La concentration of $1 - x$ and shifted along the ordinate axis. Zero value of the binding energy corresponds to the Fermi level E_F. A valence band is located at E_b 0 to 9 eV. In the figure for $x = 0$ one can see the following features: the La $5p_{3/2}$ and La $5p_{1/2}$ shallow core levels at $E_b \sim 16.8$ eV and ~19 eV respectively, and the O $2s$ peak at ~21.3 eV. The insulator $LaMnO_3$ samples were only measured at RT because of the charging effect. A comparison of the spectra of the clean sample surface (measured just after the cleavage, solid line) and of the contaminated surface (several hours after the cleavage, open circles) of the $LaMnO_3$ sample shows that, firstly, the spectrum of the contaminated surface has a feature at a binding energy of 9.5 eV, secondly, the emission from the states with binding energy of 5–8 eV increases compared to the maximum of the valence band spectrum and the background at high binding energies also increases. Thirdly, the intensity of the feature with a binding energy of ~2.5 eV decreases only slightly with contamination.

In fig. 1 can be seen a valence band shift towards lower binding energy with an increase of strontium concentration. The leading edge of the valence band (low E_b) moves monotonically in the whole range of x. The valence band is modified in such way that the high E_b edge remains almost constant (therefore an increase in x leads to the widening of the valence band spectrum). A shift of the binding energy for several features of photoemission spectra was also observed in [4] on ceramic samples. This shift qualitatively corresponds to a decrease in the Mn 3d count.

The integrated intensity of the valence band spectra decreases for $x \geq 0.175$. This is correlated with the transition of $La_{1-x}Sr_xMnO_3$ into a metal with increasing Sr concentration.

Analysis of the photoemission spectra near the Fermi edge (see inset in fig. 1) indicate that for $x = 0.15$ (and for all $x \leq 0.15$) the density of states at E_F is close to zero both for high and low temperatures, for $x = 0.3$ (actually for $x \geq 0.2$, which is metallic samples for all temperature range) the density of states at E_F differs from zero for high and low temperatures, but for $x = 0.175$ the density of states differs from zero at LT, and is close to zero at RT. This dependence of the density of states upon x agrees with our resistance and magnetic susceptibility data (not shown here).

It is worth mentioning that in spite of the fact that overall photoionization cross-sections for La and Sr valence band states are ~100 times less than for O 2p and Mn 3d states at a photon energy of 130 eV [8] the valence band changes significantly with Sr concentration. This fact is in contradiction to the x-dependence obtained in [9] on polycrystalline $Pr_{1-x}Sr_xMnO_3$, where the shape of the valence band did not change with Sr doping.

The changes in the valence band (fig. 1) are basically connected with a clear feature at ~2.5 eV binding energy. This feature diminishes when the strontium concentration is increased. Together with the entire valence band in the low binding energy region, this feature shifts toward lower E_b values as the Sr concentration increases: from $E_b = 2.7$ eV ($x = 0$) to $E_b = 2.3$ eV ($x = 0.33$). Below we refer to this feature as «~2.5 eV feature». This feature was also seen in earlier work on polycrystalline samples of $La_{1-x}Ca_xMnO_3$ [10], in $Pr_{1-x}Sr_xMnO_3$ systems [9] and on $Nd_{1-x}Sr_xMnO_3$ single crystals [11]. But for our samples this feature was much more pronounced, especially for low Sr concentrations, and we observed a Sr doping dependence (and also an angular dependence, [12]).

As we showed above, the part of the valence band, in which this feature is observed, does almost not change with surface contamination (the spectra for $x = 0$ on fig. 1). Therefore it is unlikely that the feature can be attributed to surface state emission. In order to determine a relationship between this feature and atomic electron orbitals of one of the sample elements, we investigated the valence band spectrum by resonance photoemission spectroscopy near the La 4d and Mn 2p absorption thresholds.

Fig. 2 presents a series of curves, measured at photon energies near the La 4d absorption threshold ($h\nu = 95$–134 eV) at LT for the sample with strontium concentration $x = 0.15$. Spectra were measured at BL41. The spectra are normalized to the photon flux by measuring the photocurrent from a gold mesh.

As can be seen from the figure, there are two processes that are happening near the La 4d absorption threshold. Firstly, the shape of the valence band changes with increasing $h\nu$ from 95 to 133.5 eV. At $h\nu = 130$ eV the ~2.5 eV feature becomes higher than the rest of the valence band, due to the decreasing emission from the 3–9 eV states. The second observation is that the intensity of the valence band is changing during the resonance photoemission process. Emission from the valence band states has a maximum for a photon energy of 117 eV, which corresponds to the maximum of the absorption curve (see inset to fig. 2). The emission increase is highest for ~3.5 eV and lower for ~2.5 eV.

Our results from measurements near the La 4d threshold lead us to the conclusion that the local density of states on the La atoms is created by states with binding energies across the entire valence band and the states at $E_b \cong 2.5$ eV are not uniquely contributing to the La 4d resonance emission. In addition, the contribution from

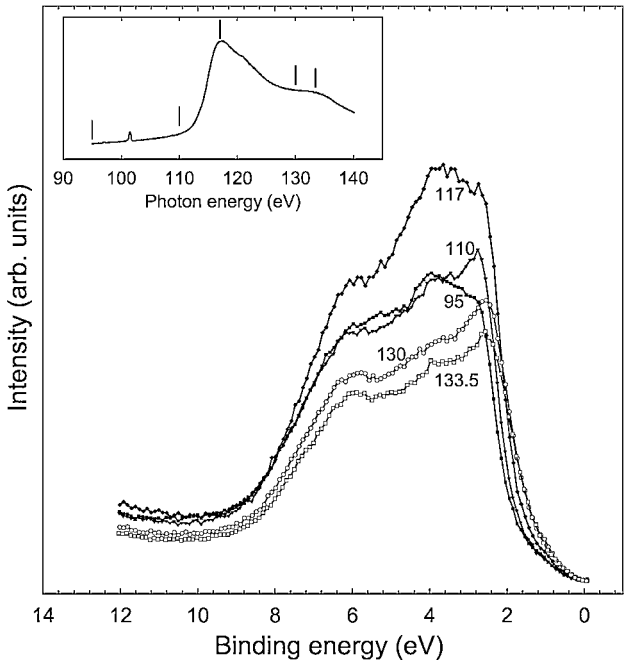

Fig. 2. Valence band photoemission spectra for the sample with $x = 0.15$, measured at a photon energy near the La 4d absorption threshold under normal emission conditions at LT. The spectra are normalized to the photon flux. The inset shows the absorption spectrum and the photon energies used in the photoemission measurements.

La states in the valence band for off-resonance photon energies, as mentioned above, is negligible due to a small photoionization cross-section. So one may suggest that the feature seen at ∼2.5 eV should not be contributed to La states.

Moving to fig. 3, we can see that the Mn 2p resonance displays the opposite properties: the ∼2.5 eV energy states become clearly distinguishable at a photon energy of 642 eV, i.e. at the maximum of the manganese absorption (the inset in figure 3), with a background of increasing emission from the entire valence band. Further increase of the photon energy leads to decreasing emission from the valence band. In the figure we can see the Auger-peak onset at $E_b = 6$ eV and its movement to the left with increasing photon energy. A sharp increase in the resonance of the emission near the Mn 2p absorption threshold allows us to draw the following conclusions: the manganese states exist in the entire valence band from 0 to 9 eV, and the ∼2.5 eV feature corresponds to a state that is strongly localized on the Mn atoms. In [4] authors attributed the state with binding energy ∼2.7 eV in $LaMnO_3$ to Mn 3d state with t_{2g} symmetry. The same conclusion was made in work [11] for $Nd_{1-x}Sr_xMnO_3$ single crystals.

We have recorded a full set of resonance spectra but in fig. 3 we show spectra only for typical $h\nu$. For all resonance spectra we plot constant initial state (CIS) spectra for the maximum of valence band, binding energy range around 2.3–2.6 eV (t_{2g} states, fig. 4, dotted lines) and for binding energy range 0–0.3 eV (e_g states, fig. 4, solid lines) for two temperatures: above (black circles) and below (open circles) the magnetic transition that occurs at 225 K according to our susceptibility data. The spectra are normalized to unity at $h\nu = 638$ eV, corresponding to the onset of the resonance. One can see that for temperatures below the magnetic transition the resonance is less pronounced for both binding energies, a fact that implies that the localization effect is less for the ferromagnetic phase than for the paramagnetic. More intensive resonance for t_{2g} states than for e_g states we also attribute to more localized character of t_{2g} states [4].

In [13] the authors suggested that the absence of the ∼2.5 eV feature in photoelectron spectra of ceramic samples is due to the poor quality of the surfaces. In our opinion, however, this feature in our experiment can be seen for both a clean surface and single crystal structure. However, we do not observe any dispersion of this state with changes in photon energy and emission angle [12]. For now we cannot definitely reject the band-related explanation

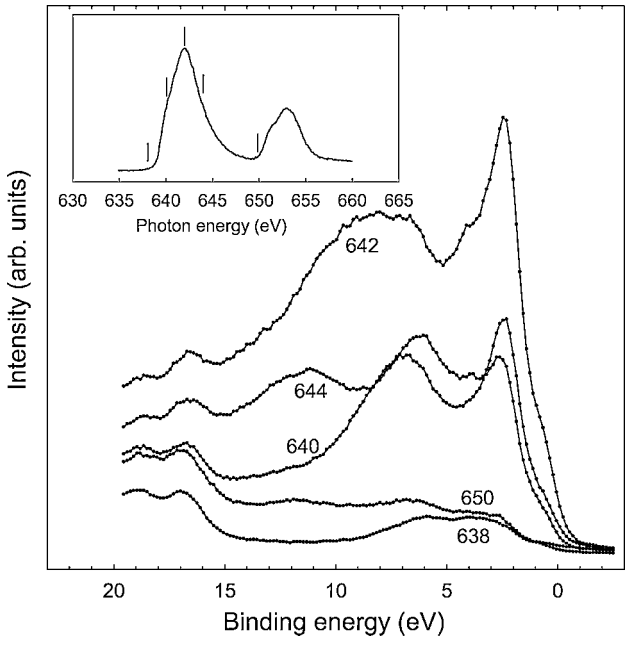

Fig. 3. Valence band photoemission spectra for the sample with $x = 0.15$, measured at a photon energy near the Mn 2p absorption threshold under normal emission conditions at LT. The spectra are normalized to the current in the storage ring. The inset shows the absorption spectrum and the photon energies used in the photoemission measurements.

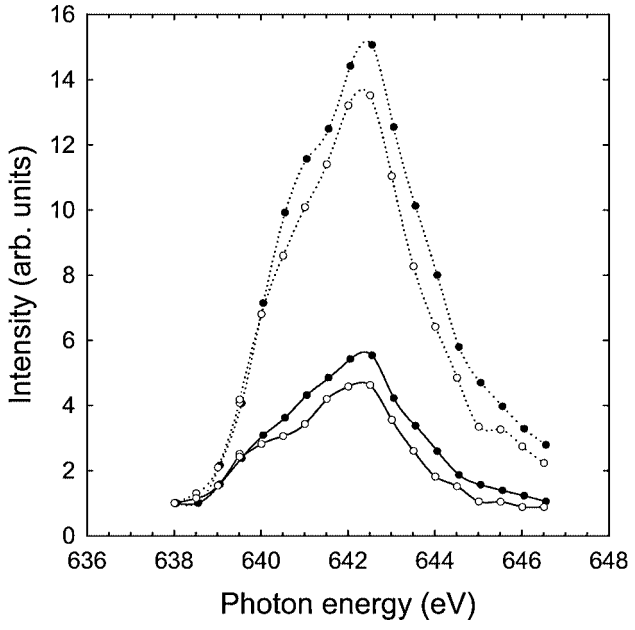

Fig. 4. CIS spectra for binding energy ∼2.3 eV (dotted lines) and ∼0 eV (solid lines) for two temperatures, above (black circles) and below (open circles) the magnetic transition and plotted for the set of photoelectron spectra measured at different $h\nu$ near the Mn 2p absorption edge. The spectra are normalized to unity at $h\nu = 638$ eV, corresponding to the onset of the resonance.

because theoretical calculations of the $LaMnO_3$ band structure [14] show that the dispersion of t_{2g} is also small. Elaborate measurements of the valence band photoemission spectra with high angular resolution and at different photon energies are required for a final conclusion.

4. Conclusion

Photoemission, XAS and resonant photoemission studies have been performed for $La_{1-x}Sr_xMnO_3$ single crystals with x ranging from 0 (dielectric) to 0.33 (metal) at two temperatures.

In agreement with previous results we observe an increase of the density of states at the Fermi level with increasing Sr doping level, providing direct evidence for a metal-insulator transition. A shift of the features in the photoemission spectra qualitatively corresponds to an increase of the hole concentration.

For single crystals we monitored the Sr-concentration dependence of the feature with a binding energy of $\sim$2.5 eV .The relative intensity of this feature decreases with divalent metal doping. Results of our resonant photoemission study together with cross-section dependence and theoretical calculations led us to assign this feature to Mn 3d t_{2g} states.

The relative intensity of the $\sim$2.5 eV feature changes only weakly with contamination of the sample surface, a fact supporting that this state is bulk related.

Abstract

The short- and long-range structures of $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.0$, 0.5 and 1.0) nanocomposites have been investigated by X-ray absorption fine structure (XAFS) and X-ray diffraction (XRD). The results indicate that the as-spun $Nd_9Fe_{85}B_6$ is mainly composed of amorphous $Nd_2Fe_{14}B$ and α-Fe phases. With the addition of the element Mn of about 0.5% (or 1.0%), the change of the disorder degree σ implies that the medium-range order around Fe atoms in the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ is strongly increased. In particular, the third peak ($R = 4.50$ Å) shows that the increase of medium-range order of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ is attributed to forming an α-Fe phase. We consider that during the melt-spun process, the element Mn diffuses into the $Nd_9Fe_{85-x}Mn_xB_6$ mixture and forms alloy phases of $Nd_2Fe_{14}B(Mn_y)$ and $Fe(Mn_y)$ nano-crystals. The $Fe(Mn_y)$ alloy with a bcc α-Fe structure keeps a medium-range order around Fe atoms.

1. Introduction

Recently, the potential nanocomposite $Nd_2Fe_{14}B/\alpha$-Fe two-phase permanent magnets that possess the feature of high coercivity from $Nd_2Fe_{14}B$ and high saturation magnetization from α-Fe, have attracted much attention because of their novel magnetic performance and lower cost [1–3]. In order to further improve the magnetic performance of the rare earth permanent magnets, a lot of studies have been devoted to the magnetic properties and the structures of Nd-Fe-B systems by changing the chemical compositions and adding some metallic or rare earth elements [4–8]. It has been found that the addition of element Mn into $Nd_2Fe_{14}B/\alpha$-Fe cast ingots can strongly modify their magnetic and electronic properties [9]. However, the relationship between the structure of the $Nd_2Fe_{14}B/\alpha$-Fe nanocomposites and the addition of element Mn is not clear enough . In order to understand the magnetic properties of nanocomposite $Nd_2Fe_{14}B/\alpha$-Fe doped by Mn, it is essential to perform structural characterization.

In the present work, X-ray absorption fine structure (XAFS) and X-ray diffraction (XRD) are used to study the structures of $Nd_9Fe_{85-x}Mn_xB_6$ modified by the added element Mn. We aim to find the structural changes induced by the addition of small amounts of Mn.

2. Experimental

Ribbons of $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.0$, 0.5 and 1.0) were prepared by using mixed metals and alloys of Fe (99.5 at%), Mn (99.8 at%), Nd (99.8 at%) and FeB alloy (B 24.99 at%). Ingot alloy with a homogeneous composition was obtained by arc melting 3 times, and then the molten alloy was spun with a molybdenum wheel at a linear speed of 20 m/s in argon atmosphere from a crucible. It is denoted as the as-spun sample.

The XRD patterns of $Nd_9Fe_{85-x}Mn_xB_6$ samples were measured on a Y-4ϕ rotating target diffractometer (Dandong X-ray photometer Co. LTD) using Cu K_α radiation ($\lambda = 1.5406$ Å, 40 kV and 100 mA). Fe K-edge XAFS spectra of $Nd_9Fe_{85-x}Mn_xB_6$ were collected at the U7C beamline of National Synchrotron Radiation Laboratory (NSRL) and the 4W1B beamline of Beijing Synchrotron Radiation Facility (BSRF). The storage ring of NSRL was operated at 0.8 GeV with a maximum current of 160 mA. The hard X-ray beam was from a three-pole superconducting Wiggler with a magnetic field intensity of 6 Tesla. Fixed-exit Si(111) flat double crystals were used as monochromator. The X-ray harmonics were minimized by detuning the two flat Si(111) crystal monochromator to about 70% of the maximum incident light intensity. Ionization chambers filled with Ar/N_2 mixed gases were used to collect XAFS spectra. The XAFS spectra were recorded in a transmission mode at room temperature. The XAFS data were analyzed by NSRLXAFS software packages [10].

3. Results and Discussions

XRD patterns of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.0$, 0.5 and 1.0) nanocomposites are shown in Fig. 1. It can be observed that there are obviously different characteristics in the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ with various concentrations of Mn. A weak and wide amorphous peak in the angle region (2θ) from 30° to 50°

*Correspondent, E-mail: slyin@vip.sina.com

where some weak diffraction peaks are appended appears in the Mn-free $Nd_9Fe_{85}B_6$ sample. For the as-spun $Nd_9Fe_{84.5}Mn_{0.5}B_6$ with Mn concentration of $x = 0.5$, the magnitude of its amorphous peak decreases to about two-thirds of that of the Mn-free sample. Furthermore, some diffraction peaks corresponding to the phases of crystalline $Nd_2Fe_{14}B$ and α-Fe can be observed. The peaks located at 44.67° and 64.80° come from the (110) and (200) reflections of the α-Fe phase, and the diffraction peaks at 32.88°, 37.24°, 39.14°, 42.28°, 42.82° and 44.01° correspond to the (311), (214), (313), (410), (411) and (314) reflections of the $Nd_2Fe_{14}B$ phase, respectively. With the amount of Mn going to $x = 1.0$, the intensities of all the diffraction peaks strongly increase to about twice those of the $Nd_9Fe_{84.5}Mn_{0.5}B_6$. This result indicates that the long-range order of nanocomposite $Nd_2Fe_{14}B$ and α-Fe grains in $Nd_9Fe_{85-x}Mn_xB_6$ increases sharply with the amount of element Mn. Hence, a small amount of Mn can promote the $Nd_9Fe_{85}B_6$ alloy to form crystalline $Nd_2Fe_{14}B$ and α-Fe phases in the melt-spun process.

Figure 2 shows radial structural functions (RSF) of Fe atoms of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ nanocomposites, which are obtained from Fourier transform (FT) of their XAFS oscillation functions $k^3\chi(k)$. It can be seen clearly that the increase of Mn concentration in the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ does not change the position (2.10 Å) of their first peaks, but the intensity increases slightly. However, a drastic change of their RSF curves occurs in the higher shells with Mn concentration. For the Mn-free sample, no strong RSF peaks appear in the higher shells, indicating the amorphousness of the as-spun $Nd_9Fe_{85}B_6$. As the Mn concentration x increases to 0.5, two strong peaks located at 3.60 and 4.50 Å are apparently present in the as-spun $Nd_9Fe_{85-x}Mn_xB_6$. The positions and heights of these two peaks remain almost the same as x increases further to 1.0. From the XAFS and XRD results, one can deduce that the short- and medium-range order structures of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.0$, 0.5 and 1.0) change remarkably with the Mn concentrations from 0.0 to 1.0.

The space group of $Nd_2Fe_{14}B$ is $P4_2/mnm$ [11], and there are six different Fe sites with inter-atomic distances of the first neighbors ranging from 2.46 to 2.78 Å. This complicated structure makes the XAFS signal of Fe atoms in $Nd_2Fe_{14}B$ much lower than that in α-Fe. In the fitting procedure, the number of independent

$Nd_2Fe_{14}B$	1	4	2.46–2.53	
	2	3	2.55–2.66	
	3	2	2.71–2.78	

data points N_d ($N_d = 2\Delta k \Delta R/\pi + 2$) is about 12 where the ranges Δk and ΔR are 11 $Å^{-1}$ and 1.5 Å, respectively. Since the first SRF peak is mainly due to Fe-Fe pairs, it is practically impossible to use more than three sub-shells in the XAFS fitting, due to the limitation of N_d. Hence, in order to properly model a reasonable structure for the data analysis of our samples, we need to seriously consider the structural feature of $Nd_2Fe_{14}B$ and α-Fe. Three sub-shells with average bond lengths $R_1 = 2.50$ (2.46–2.53), $R_2 = 2.59$ (2.55–2.66), $R_3 = 2.75$ (2.71–2.78) Å and with adjustable parameters of 10, are used for the XAFS simulation of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.0$, 0.5 and 1.0) nanocomposites. The fitting results are summarized in Table I.

Seen from Fig. 2, the theoretical XAFS spectrum of crystalline $Nd_2Fe_{14}B$ calculated by the FEFF7 software packages [12] is significantly different from the experiment XAFS spectrum of α-Fe. In particular, by comparing with α-Fe, the crystalline $Nd_2Fe_{14}B$ has a lower peak intensity for the first shell and no strong magnitude peaks for the higher shells. Hence, the stronger RSF peak at 4.50 Å for the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.5$ and 1.0) nanocomposites comes from the α-Fe phase. Deducing from the composition of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$, the ratio of $Nd_2Fe_{14}B$ phase to α-Fe phase is about 70% to 30% under ideal conditions. Therefore, we consider that the lower intensity in the RSF curves of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.5$ and 1.0) is mainly attributed to Fe atoms coexisting in the two phases of crystalline $Nd_2Fe_{14}B$ and α-Fe. Moreover, table I has shown that the coordination number N_1 (about 4.5) of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.5$ and 1.0) nanocomposites is slightly larger than the nominal value N_1 (4) of the $Nd_2Fe_{14}B_6$ alloy. This suggests further that a small amount of Fe phase with α-Fe structure-like exists in the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.5$ and 1.0) alloy. The reason is that there are 8 Fe-Fe pairs at 2.48 Å in the first shell of the bcc structural α-Fe. With the increase of Mn concentration, the disorder degrees of σ as shown in table I indicate that σ_1 (or σ_2 and σ_3) of the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ is 0.108 Å (or 0.120 and 0.120 Å), 0.105 Å (0.115 and 0.115 Å), 0.094 Å (0.104 and 0.104 Å) for $x = 0.0$, 0.5 and 1.0, respectively. These results mean that the addition of Mn can strongly increase the medium-range order around Fe atoms in the as-spun $Nd_9Fe_{85-x}Mn_xB_6$. In particular, the RSF peak intensity at 4.50 Å corresponding to the α-Fe phase largely increases for the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.5$ and

1.0) nanocomposites, indicating that the increase of medium-range order happens mainly in the Fe phase with a bcc α-Fe structure-like. We consider that during the melt-spun process, the element Mn has diffused into the $Nd_9Fe_{85-x}Mn_xB_6$ mixture and results in forming alloy phases of $Nd_2Fe_{14}B(Mn_y)$ and $Fe(Mn_y)$ nano-crystals where Mn significantly promotes the medium-range order around Fe atoms in the $Fe(Mn_y)$ phase with a bcc α-Fe structure. Hence, we propose that the as-spun $Nd_9Fe_{85-x}Mn_xB_6$ ($x = 0.5$ and 1.0) is composed of crystalline $Nd_2Fe_{14}B(Mn_y)$ and α-$Fe(Mn_y)$ nanocomposites with a nice medium-range order.

Abstract

The growth process of cerium oxide nanoparticles has been investigated by synchrotron Small-Angle X-ray scattering (SAXS) and X-ray absorption near edge spectroscopy (XANES) as a function of the annealing temperature in the range from 298 K to 973 K in atmosphere. The SAXS experimental intensity increases dramatically with increasing annealing temperature, corresponding the nucleation and growth of CeO_2 nanoparticles. SAXS also indicates that the growth of CeO_2 nanoparticles shows a fractal behaviour. When the annealing temperature increases CeO_2 nanoparticles changes from a volume to surface fractal index. The XANES of CeO_2 nanoparticles at the Ce L_3 edge reveals the increase of the relative intensity of the transition from Ce 2p to $4f^1$ 5d $e_g\underline{L}$, with increasing temperature up to 873 K. Because XANES does not show any significant change for temperature higher than 873 K, this result supports the fractal growth properties of CeO_2 nanoparticles addressed by SAXS.

1. Introduction

CeO_2 nanoparticles are of interest as catalysts in photocatalytic reactions, as a solid oxide fuel cell electrolyte material, and for gas sensors, optical coatings, high-T_c superconductors, and high storage capacitor devices. Therefore, not only is synthesizing CeO_2 nanoparticles important but also understanding its growth characteristics at the nanolevel is essential [1, 2, 3].

Small-angle scattering of X-rays (SAXS) is a technique of choice for probing structural features that occur on length scales between approximately 10 Angstroms and 1000 Angstroms [4]. It can offer opportunities to study nanoparticle systems, e.g. directly probing the self-similar structure behavior or fractal structures during the growth of nanoparticles.

X-ray absorption near edge structure (XANES) spectroscopy, a unique element-specific technique sensitive to the local structure, can provide insight into local environment as well as electronic structures of materials [5]. In particular, XANES at Ce L_3 thresholds can reveal oxidation states of cerium and covalence with oxide ligand [6].

In this paper, we prepare CeO_2 nanoparticles by sol-gel process. The SAXS and XANES are used to investigate the nanoparticle sizes, fraction behavior and binding property in CeO_2. Further the formation and growth mechanisms of CeO_2 nanoparticles are discussed.

2. Experiment

The cerium oxide for the present study was prepared by mixing 0.1 M $Ce(SO_4)_2{\cdot}4H_2O$ solution with ammonia solution. The precipitate obtained was filtered, washed with distilled water and dried at room temperature in an oven. To further study the effect of annealing temperature, the as-prepared sample was annealed at 423 K, 473 K, 573 K, 673 K, 773 K, 823 K, 873 K, 923 K, 973 K for 2 hours under air condition.

The SAXS data were collected on the 4B9A beamline at the SAXS station at Beijing Synchrotron Radiation Facility (BSRF) [7]. X-rays from a bending magnet are focused in both horizontal and vertical directions by a Pt coated toroidal mirror, monochromatized by a double Si(111) crystal monochromator with fixed exit. The energy range of the beamline is 3 keV to 12 keV with $3 \cdot 10^{-4}$ resolution when the storage ring is operated at 2.2 GeV. In our experiments, the data accumulation time was 50 seconds. The angular range was chosen to provide data from $h = 0.005\,\text{Å}^{-1}$ to $h = 0.15\,\text{Å}^{-1}$, where the magnitude of scattering vector $h = 4\pi \sin\vartheta/\lambda$, 2θ and λ being respectively the scattering angle and incident X-ray wavelength of 1.54 Å. The distance between the sample chamber and the detector is 1.495 m. The detector for SAXS data collection is an image plate (IP) system Fuji BAS-2500, with an active area of 400 mm by 200 mm and a minimum pixel size of 100 μm. Two ionization chambers were used to measure the sample transmission. Background scattering from the slit collimator and the residual air path between the vacuum chamber and the detector was measured and subtracted. Excess SAXS scattering from CeO_2 nanoparticles was also corrected for incident beam decay and sample transmission.

XANES spectra at the Ce L_3 edge were measured in transmission mode by using synchrotron radiation with a Si (111) double crystal mono-chromater at the EXAFS station (Beam line 4W1B) of the Beijing Synchrotron Radiation Facility. The storage ring was run at typical energy 2.2 GeV with an electron current of about 80 mA. To suppress unwanted harmonics, the angle between the monochromator crystal faces was adjusted to mistune the incident beam by 30%. The incident and output beam intensities were monitored and recorded using nitrogen gas and a 50% argon-doped nitrogen flowing ionization chamber. The spectra were scanned in the range of 5.5–6.2 keV, which cover the L_3 edge absorption of Cerium atoms. The energy resolution was about 1.5 eV for XANES.

3. Results

3.1. *SAXS*

Figure 1 shows SAXS plots of scattering intensity $I(h)$ versus scattering vector h for CeO_2 nanoparticles with different annealing temperatures. The scattering intensity increases feebly as the annealing temperature changes from 298 K to 823 K. As the temperature increases to 873 K, a drastic enhancement of the scattering intensity is observed, and in the following procedure little variation of the scattering intensity occurs at 923 K and 973 K in our work. These evolutions correspond to the nucleation and growth of CeO_2 nanoparticles, as reported from ref [8, 9].

*Corresponding author: E-mail: wuzy@ihep.ac.cn

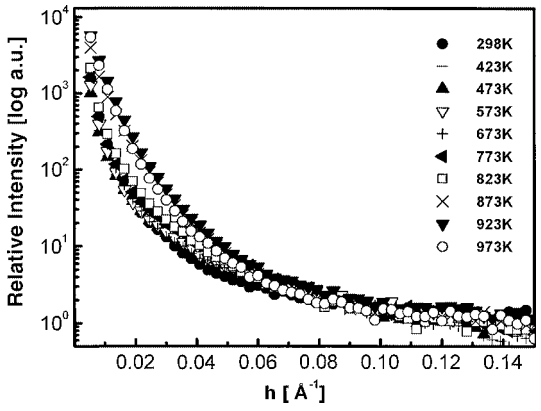

Fig. 1. SAXS plots of CeO_2 nanoparticles at different annealing temperatures.

To further characterize the microstructure of the nanoparticles, a fractal exponent is also extracted from the SAXS curves. Fig. 2 shows a log-log plot of I *vs* h as a function of annealing temperature. All spectra exhibit an almost linear behavior. As shown in Fig. 3, the value of the modulus of the slope (α) for 298 K–873 K is 2.0 $\sim$ 2.15. For further increasing temperature, α increases up to 3.45 $\sim$ 3.50. This reveals that the growth of CeO_2 nanoparticles follows a fractal rule, and the fractal dimension changes from mass fractals to surface fractals as the temperature increases in the range of 298 K and 973 K.

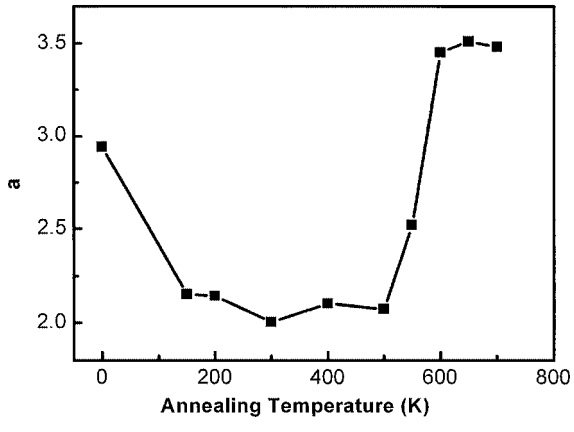

Fig. 3. Plot of α against annealing temperature for CeO_2 nanoparticles.

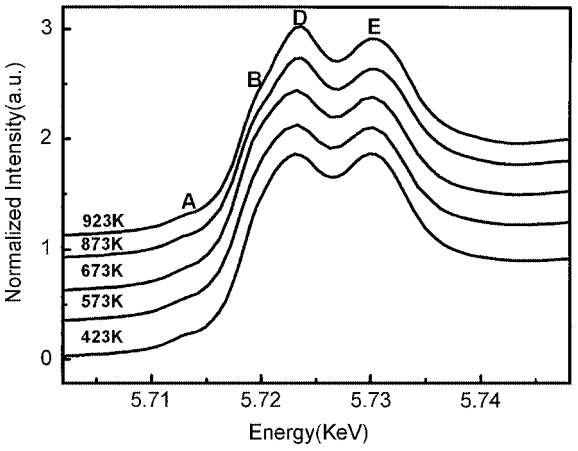

Fig. 4. XANES at Ce L_3-edge of CeO_2 nanoparticles at different annealing temperatures.

3.2. *XANES*

XANES is used to characterize the electric structure of CeO_2 nanoparticles during sintering. Figure 4 compares normalized Ce L_3-edge XANES spectra of select samples. The assignments of Ce L_3-edge spectra are based on references [10, 11]. The pre-edge structure, labeled A, is assigned to final states with delocalized d character at the bottom of the conduction band. Due to the cubic crystal-field splitting of Ce 5d states, features B and D are associated to the transitions of Ce 2p to the Ce $4f^1$ 5d $e_g\underline{L}$ and Ce $4f^1$ 5d $t_{2g}\underline{L}$ states, where $\underline{L}$ denotes an oxygen ligand 2p hole; $4f^1$ refers to an electron from an oxygen 2p orbital to a cerium 4f one (charge transfer-like). The energy separation between peaks B and D is about 3.6 eV, which is in agreement with previous work. The feature E is attributed to the contribution of a different final state configuration $4f^0$ 5d. Generally, the Ce spectrum has a distinct double-peaked structure (D, E) with the higher-lying peak corresponding to the Ce^{4+} valence state.

With increasing calcination temperature up to 873 K, the relative intensity of transition D increases, but further increasing temperature does not show a significant change in these parameters. The results suggest the decrease of oxygen vacancies in CeO_2 nanoparticles during sintering, as in ref [6, 12].

4. Discussion

In nanocrystalline ceramic particles like CeO_2, one would expect an increase in the concentration of oxygen vacancies with decreasing nanoparticle size below 20 nm [12]. From XRD and TEM, the size of CeO_2 nanoparticles in 423 K, 623 K, 873 K, 923 K are 2.3 nm, 4.6 nm, 17.2 nm, 65.3 nm, respectively. Hence, it appears that large concentration of oxygen vacancies may exist within the nanoparticles in lower temperature such as 423 K, 623 K. When the annealing temperature increase, the oxygen vacancies may drastically reduce. This in turn would cause an increase in the relative intensity of the transition Ce 2p to the Ce $4f^1$ 5d $e_g\underline{L}$ and Ce $4f^1$ 5d $t_{2g}\underline{L}$ states in XANES, as temperature increases.

An increase in oxygen vacancies is also known to accelerate mass-transport during sintering. By reducing the density of oxygen vacancies one could conceivably retard the grain growth [13, 14]. Therefore, the scattering intensity increases drastically as the annealing temperature changes from 823 K to 873 K, and little variation of the scattering intensity occurs at 923 K and 973 K.

Further analyzing from SAXS curves, aggregation of CeO_2 nanoparticles changes from a mass fractal structure to surface fractal structure. The mass fractal dimension is indicative of an irregular mass distribution or non-uniform density distribution in the material, whereas the surface fractal dimension indicates the presence of a rough surface in the material [15]. One of the main reasons is as follows: when the annealing temperature is in the range of 298–873 K, the size of CeO_2 nanoparticles is below 10 nm and there are lots of oxygen vacancies in the nanoparticles, which can accelerate the mass-transport during sintering. The aggregation of CeO_2 nanoparticles shows mass fractal structure. With increasing temperature, the sizes of the nanoparticles increase above 20 nm, and their oxygen vacancy density decreases dramatically, which can reduce the activation energy for mass compactness [14]. Therefore, the growth of CeO_2 nanoparticles is not controlled by mass fractal structure. CeO_2 nanoparticles become coarsen and coalesce, further their aggregation changes to surface fractal structure.

5. Conclusion

In summary, we prepare CeO_2 nanoparticles by sol-gel process. SAXS and XANES are used to investigate the formation and growth properties of CeO_2 nanoparticles. SAXS indicates that the growth of CeO_2 nanoparticles shows a fractal behavior. When the annealing temperature increases, CeO_2 nanoparticles change from volume to surface fractal index. The XANES of CeO_2 nanoparticles at the Ce L_3 edge reveal the increase of the relative intensity of the transition from Ce 2p to $4f^1\,5d\,e_g\underline{L}$, with increasing temperature up to 873 K, but further increasing temperature does not significant change the transition. These properties are assumed to be due to the formation of oxygen vacancies.

Abstract

A homogeneous CeO_2-ZrO_2 solid solution has an ordered cation arrangement and exhibits the highest oxygen storage/release capacity (OSC) among several types of CeO_2-ZrO_2 with the same composition (Ce/Zr = 1). The crystal structure of this CeO_2-ZrO_2 solid solution is usually termed the "κ-$CeZrO_4$ phase". Its OSC performance degrades upon high-temperature treatment under an oxidative atmosphere. Using Ce K- and Zr K-edges XAFS and powder XRD, this research investigated the structural change along with the thermal degradation of κ-$CeZrO_4$. The fresh sample was aged at 973 K, 1273 K and 1473 K under an oxidative atmosphere. Their OSC performances were characterized at 773 K by a thermo-gravimetric method. The OSC performance deteriorated in the order: the fresh sample $\approx$973 K > 1273 K > 1473 K-aged samples. We also found that, if the temperature went beyond 1273 K, the Ce/Zr ordered arrangement would collapse, and the local structure around Ce and Zr ions would also be changed remarkably. These results indicated that the OSC was strongly dependent on the atomic structure.

1. Introduction

Oxygen storage/release capacity (OSC) is one of the important functions required for automotive three-way catalysts (TWCs) and plays a critical role in efficiently detoxifying harmful compounds, such as hydrocarbons, CO and NOx in automotive exhaust gases [1]. In TWCs, ceria is widely used for its high OSC based on the reversible redox reaction ($CeO_2 \longleftrightarrow CeO_{2-x} + x/2\ O_2$; $x = 0$–0.5). The OSC performance and the durability of the pure CeO_2 were inadequate for practical application in the actual TWCs. More than ten years ago, we discovered that the addition of ZrO_2 to CeO_2 enhanced the OSC as well as improved its thermal stability [2]. Following this discovery, CeO_2-ZrO_2 has been widely utilized in the commercial catalysts. So far, a considerable number of studies have focused on the physical properties and structure of CeO_2-ZrO_2, and significant progress has been achieved to deepen our understanding of this material. Recently, we discovered that a homogeneous CeO_2-ZrO_2 solid solution had an ordered cation arrangement and exhibited the highest OSC among several types of CeO_2-ZrO_2 with the same composition (Ce/Zr = 1) [3]. The crystal structure of this CeO_2-ZrO_2 solid solution is usually termed the "κ-$CeZrO_4$ phase" [4]. Its OSC performance degrades upon high-temperature treatment under an oxidative atmosphere. In order to develop more efficient TWCs, it is really meaningful to investigate and clarify what caused this thermal degradation. We assumed that this thermal degradation resulted from a structural change. In this research, using XAFS and powder XRD, we tried to investigate what exactly happened to its structure along with the thermal degradation of κ-$CeZrO_4$ and correlated that with its OSC performance.

2. Experimental

CeO_2-ZrO_2 solid solution (Ce : Zr = 1 : 1 molar ratio), which has a κ-$CeZrO_4$ structure, was prepared by a coprecipitation process using $Ce(NO_3)_3$ and $ZrO(NO_3)_2$ aqueous solutions. The precipitate was reduced at 1473 K for 4 h with pure CO flowing and was then oxidized in air at 773 K for 3 h. This sample is referred to as "fresh". Portion of the fresh sample were aged in air for 3 h at 973 K, 1273 K and 1473 K. These obtained samples are referred to as "aged". All the samples were finally calcined in air at 773 K prior to XAFS and XRD measurements. Through the above treatment, oxygen was fully stored in the Ce oxides.

The OSC was measured by a thermo-gravimetric analysis [5]. The fresh and aged samples with 1 wt% platinum loading were cyclically reduced with 20% H_2 (N_2 balance) for 5 min, then oxidized with 50% O_2 (N_2 balance) for 5 min at 773 K. The weight loss and gain were quantified by a thermo-gravimetric analyzer (TGA-50, Shimadzu Corp.). The reductive/oxidative conditions were maintained until the weight became constant. The sample's weight change between the reductive and oxidative conditions corresponds to the total OSC at 773 K.

The powder XRD experiments were carried out using a RINT2000 (Rigaku Co., Ltd.) diffractometer with Cu-K_α radiation (1.5406 Å). The Ce K-edge (40.45 keV) and Zr K-edge (18.00 keV) XAFS spectra were measured at BL16B2 of SPring-8 (Hyogo, Japan). The measurements were carried out using a Si (311) double crystal monochromator in the transmission mode at room temperature. Data reduction of the XAFS was carried out as described elsewhere [6]. A quantitative curve-fitting analysis of the EXAFS spectra was performed for the inverse Fourier transforms on the cation-oxygen (cation = Ce, Zr) shells. Empirical parameters in the analysis were obtained from standard compounds, e.g., cubic CeO_2 for Ce-O bonding, 8 mol% Y-doped cubic ZrO_2 for Zr-O bonding.

3. Results and discussion

Table I lists the OSC performances of the samples. The Ce efficiency means the ratio of $Ce^{3+}/(Ce^{3+} + Ce^{4+})$ under the reductive condition. The Zr oxidation state in the CeO_2-ZrO_2 remains at Zr^{4+} under both the reductive and oxidative conditions at 773 K [7]. Thus, only the Ce atoms contribute to the OSC through the Ce^{3+}/Ce^{4+} redox couple. The fresh sample exhibited a high OSC, and its Ce efficiency was 90.0%. It is noteworthy that almost all of the Ce in the CeO_2-ZrO_2 contributes to the OSC. The OSC value of the 973 K-aged sample is almost equal to that of the fresh sample, while the OSC performance gradually decreases with increasing aging temperature.

Table I. *OSC properties of the fresh and the aged samples.*

Sample[a]	OSC [b] (μmol-O_2/g)	Ce efficiency[c] (%)
Fresh	750	90.0
973 K-aged	772	91.0
1273 K-aged	483	56.9
1473 K-aged	283	35.0

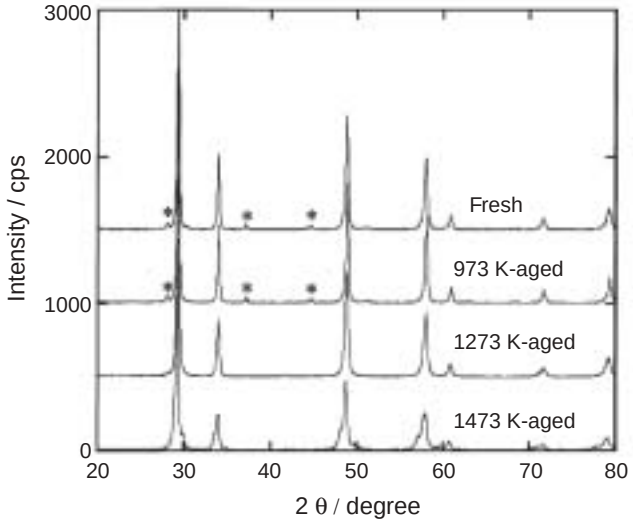

Fig. 1. X-Ray diffraction patterns of the fresh and aged samples. Small peaks marked with asterisks are characteristic of κ-$CeZrO_4$ due to the ordered arrangement of the cations, see ref. [4].

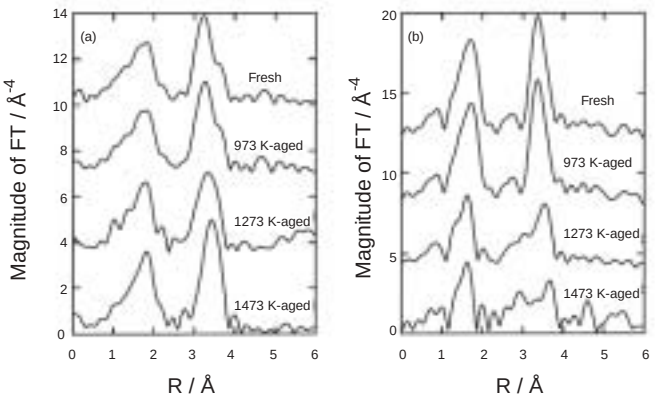

Fig. 2. k^3-weighted EXAFS spectra (left) and their Fourier-transforms (right) for (a) Ce K-edge and (b) Zr K-edge EXAFS of the fresh and aged samples.

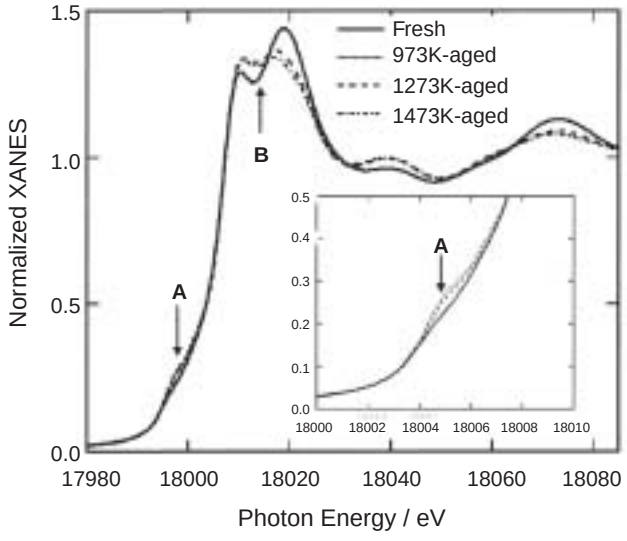

Fig. 3. Zr K-edge XANES spectra of the fresh and aged samples.

Fig. 1 shows the XRD patterns of the samples. For the fresh sample, we could observe small peaks, which marked here with an asterisk, except for the principal peaks which were attributed to the cubic fluorite $CeZrO_4$. These small peaks are ascribed to the ordered arrangement of the cations along the ⟨110⟩ direction [4]. This crystal structure of the cubic fluorite $CeZrO_4$, termed the "κ-$CeZrO_4$ phase" [4], has an ordered arrangement of the cations. Its structure was still maintained upon aging at 973 K. However, the ordering peaks disappear upon aging at 1273 K or higher, and only the principal peaks of cubic $CeZrO_4$ remain observable. In addition, the principal peaks for the 1473 K-aged sample become broad and begin to split partially. Therefore, we can assume that a phase separation occurred at 1473 K, and that the $CeZrO_4$ solid solution becomes partially divided into more stable CeO_2 and ZrO_2.

Fourier transforms (FTs) were carried out the Ce K- and Zr K-edges EXAFS spectra in about the 3.0–16 $Å^{-1}$ region. FTs of the Ce K-edge are presented in Fig. 2(a). The first peak at 1.8 Å and the second peak at 3.5 Å correspond to the Ce-O and Ce-cation (cation = Ce, Zr) bonds, respectively. The Ce-O and Ce-cation peaks of the 973 K-aged sample are located at the same positions as those of the fresh sample and have the same amplitude. On the other hand, the shapes of the FTs for the 973 K, 1273 K and 1473 K-aged samples are obviously different. Fig. 2(b) shows the FTs of the Zr K-edge EXAFS spectra. The first peak at 1.7 Å was assigned to Zr-O bonds and the second peak at 3.5 Å to Zr-cation bonds. The same observation for the Ce K-edge also applies to the Zr K-edge XAFS. The spectra of the fresh and 973 K-aged samples have the same features. The spectra of the aged samples are different from each other.

The XANES spectra at the Zr K-edge are shown in Fig. 3. A careful comparison of the spectra labeled A and B across the samples reveals several interesting facts. First, peak A, a weak shoulder on the steeply rising absorption edge, is more apparent for the 1273 K and 1473 K-aged samples than those of the fresh and 973 K-aged ones. This pre-edge absorption can be assigned to the $1s \rightarrow 4d$ which is sensitive to the Zr-O geometry. This transition is considerably strong in the case of pure tetragonal ZrO_2 [8]. In fact, the features of the XANES spectra of the 1273 K and 1473 K-aged samples are very similar to that of the pure tetragonal ZrO_2 [8]. Thus, it is clear that the 1273 K and 1473 K-aged samples have a tetragonal environment of the Zr-O coordination. As for peak B, it is in the form of a slight splitting in the 1273 K and 1473 K-aged samples, although it exhibits a clear splitting in the fresh and 973 K-aged samples. A clear splitting like this could also be observed for cubic ZrO_2 [8]. In addition, it is well-known that the peak A is weaker in cubic ZrO_2 than in tetragonal ZrO_2 [8]. Clearly, the fresh and 973 K-aged samples have a cubic environment of the Zr-O coordination.

Table II. *Curve-fitting analysis for Ce-oxygen shells*[a].

Table III. *Curve-fitting analysis for Zr-oxygen shells*[a].

Sample	Bond	*CN*	*R* (Å)	$\Delta\sigma^2$ [b] (Å^2)
Fresh	Zr-O	8.0(2)	2.27(0)	−0.0046(2)
973 K-aged	Zr-O	8.0(5)	2.26(0)	−0.0081(2)
1273 K-aged	Zr-O	4.0(5)	2.18(0)	−0.0072(5)
	Zr-O	4.0(5)	2.36(2)	0.0063(45)
1473 K-aged	Zr-O	— [c]	— [c]	— [c]

[a]The standard deviation at the last digit is given in parentheses.
[b]Relative Debye-Waller factor.
[c]Reasonable fit could not be obtained.

The quantitative curve-fitting results of Ce and Zr K-edges EXAFS are summarized in Tables II and III, respectively. Only the results for the cation-oxygen bonding around 1.0–2.0 Å in the FTs are presented here to focus on cation-oxygen geometry in the samples. First, all the Ce-O shells were fitted with a single Ce-O bond, and the CN for all samples was 8. This indicates that Ce-O coordination for all samples has a symmetric 8-fold coordination. Secondly, the Zr-O shells for the fresh and 973 K-aged samples were fitted with a single Zr-O bond. In contrast, the Zr-O shell for the 1273 K-aged sample was fitted with two sets of short and long Zr-O bond lengths. These short and long bond lengths and the CN (4 + 4) of Zr-O are close to the values for the typical tetragonal ZrO_2 [8]. But the distances of Zr-O for the 1273 K-aged sample is not equal to the values for the pure tetragonal ZrO_2, because a $CeZrO_4$ solid solution in the 1273 K-aged sample forms. These results indicate that Zr-O coordination in the fresh and 973 K-aged samples have a symmetric 8-fold coordination, while Zr-O coordination in the 1273 K-aged sample has two sets of nonequivalent tetrahedral geometry. This result is in agreement with the Zr K-edge XANES data. Although we could not obtain a reasonable fitting for the Zr-O shell of the 1473 K-aged sample caused by the partial phase separation, we can determine from the Zr K-edge XANES that this sample also has the above tetrahedral geometry.

We summarize our results and analysis as follows. The OSC performance deteriorated in the order: the fresh sample $\approx$973 K > 1273 K > 1473 K-aged samples. Furthermore, we found that, if the temperature went beyond 1273 K, the Ce/Zr ordered arrangement would collapse and the local structure around Ce and Zr ions was also changed remarkably. These results indicated that the OSC strongly depends on the atomic structure and provided us a key point on how to enhance or optimize the oxygen storage performance involved in three-way catalysts.

Acknowledgements

The X-ray absorption experiments were performed at the SPring-8 with the approval of the Japan Synchrotron Radiation Research Institute (JASRI) (Proposal No. C01A16B2-4020N).

Study of the Probe Molecule Adsorption on Co-Mo Sulfide Model Catalysts by Means of XAFS

Takeshi Kubota, Masatoshi Kawano and Yasuaki Okamoto*

Department of Material Science, Shimane University, Matsue 690-8504, Japan

Received June 26, 2003; accepted November 4, 2003

PACS number: 8245Jn

Abstract

The changes of the active sites of the Co-Mo sulfide model catalysts by the adsorption of NO or O_2 were investigated by means of Co K-edge XAFS and FT-IR techniques. It is clearly shown that the coordinatively unsaturated edge sites of MoS_2 are decorated by Co atoms by employing a CVD method using a vapor of $Co(CO)_3NO$. It is found from Co K-edge XANES spectra that Co atoms are scarcely oxidized by the adsorption of NO. On the other hand, with the O_2 adsorption in a closed system, Co atoms are gradually oxidized with adsorption time. It is also found that O_2 adsorption on a Co-Mo catalyst is significantly suppressed by pre-adsorption of NO.

1. Introduction

Alumina-supported Co(Ni)-Mo(W) sulfides have been extensively used as hydrodesulfurization (HDS) catalysts. These catalyst systems have attracted much attention, because it is well known that very strong synergy effects are observed between Co(Ni) and Mo(W) in these catalysts [1, 2]. Numerous studies have been conducted to clarify the cause of the synergy effects by means of a variety of spectroscopic techniques; EXAFS, Mössbauer emission spectroscopy (MES), XPS and so on [3–5]. Since the proposal by Topsøe *et al*. [3, 6], it is generally accepted that the so-called "Co(Ni)-Mo-S" phase is catalytically active for HDS reaction in these catalyst systems. In recent years, a structure for the Co-Mo-S phase is proposed in which Co atoms are atomically dispersed and located, most likely in front of the square sulfur faces of the MoS_6 trigonal prisms along the edges of the MoS_2 crystallites [7]. However, a detailed structure on the Co-Mo-S phase is still open to question [8–11].

NO and O_2 have been used as probe molecules for the characterization of active sites of the Co-Mo sulfide catalysts because these molecules adsorb on the unsaturated sites of metal atoms, which form active sites of the catalysts [1]. NO adsorption on metal sulfide catalysts has been studied by several workers [6, 11–13]. In particular, FT-IR spectra of adsorbed NO have been used for characterization of metal sulfide catalysts, since Co sites and Mo sites can be distinguished on the basis of the positions of absorption bands [6, 12, 13]. The adsorption capacity of probe molecules such as NO and O_2 are also used for the estimation of the number of the active sites of HDS catalysts. However, the influences of adsorption of these probe molecules are uncertain on the chemical state of the metal atoms (oxidation of the metal atoms, changes of the adsorption behavior caused by the preadsorbed molecules and so on). XAFS techniques have advantages that it can analyze the local structure of X-ray absorbing atoms under in situ conditions and are suitable for the investigation of probe molecule adsorption. Hence, XAFS techniques were applied to the characterization of Ni-Mo catalysts using NO adsorption [14]. Although Nielsen *et al*. have reported that oxidation of Ni occurs on Ni-Mo sulfide catalysts by NO adsorption [14], the XAFS investigation on the effects of NO and O_2 adsorption has not been carried out for Co-Mo catalysts, which are mainly used for HDS reaction. However, it is difficult to selectively extract the information on the Co-Mo-S structure for catalysts prepared by a conventional method, since besides the Co-Mo-S phase, several Co species are simultaneously formed in these catalysts such as Co_9S_8 and Co^{2+} ions bound to the support [1–5].

In our previous studies, we have reported that MoS_2 edge sites are selectively decorated with Co atoms to form the Co-Mo-S phase by employing a CVD method using a $Co(CO)_3NO$ vapor [15, 17]. This model catalyst system can be regarded as an ideal catalyst for spectroscopic studies. In this paper, we will clarify the influence of the adsorption of probe molecules, NO and O_2 on the chemical states of the Co atoms forming the Co-Mo-S phase by means of Co K-edge XANES and FT-IR.

2. Experimental

2.1. *Catalyst preparation*

An alumina-supported Mo oxide catalyst (MoO_3/Al_2O_3) was prepared by a conventional impregnation method using $(NH_4)_6Mo_7O_{24}4H_2O$ as a precursor. Al_2O_3 was supplied by the Catalysis Society of Japan as Reference Catalysts (JRC-ALO-6; $180\,m^2\,g^{-1}$, 250–500 mesh). The catalyst was dried at 373 K overnight and calcined at 773 K for 5 h. MoO_3/Al_2O_3 was sulfided at 673 K in a flow of $H_2/H_2S = 90/10$ for 1.5 h (MoS_2/Al_2O_3). A model catalyst [15, 16], CVD-$Co/MoS_2/Al_2O_3$, was prepared by a CVD method using $Co(CO)_3(NO)$. MoS_2/Al_2O_3 (0.1 g) was evacuated ($<10^{-3}$ Pa) at 673 K for 1 h and then exposed to a $Co(CO)_3(NO)$ vapor at room temperature for 5 min, followed by evacuation for 10 min at room temperature to remove $Co(CO)_3(NO)$ molecules physisorbed on the surface of MoS_2/Al_2O_3. Detailed preparation procedures have been reported previously [15, 16]. A catalyst prepared by a conventional impregnation method using $Co(CH_3COO)_2$ is denoted Co-MoS_2/Al_2O_3. The Mo and Co contents were 8.7 and 2.7 wt.% for the CVD catalyst and 8.7 and 2.0 wt% for the impregnation catalyst, respectively.

2.2. *XAFS measurement*

The Co K-edge XAFS spectra for Co-Mo catalysts were measured in a fluorescence mode at BL-7C of the Photon Factory in the Institute of Material Structure Science, High Energy Accelerator Research Organization (KEK-IMSS-PF) in Japan under in situ conditions. The synchrotron radiation was monochromatized by a Si(111) double-crystal monochromator. The storage ring was operated in 2.5 or 3.0 GeV. The photon flux was 1×10^{11} photons/s. The estimated energy resolution at 9 keV was

*e-mail: yokamoto@riko.shimane-u.ac.jp

about 2 eV and the monochromator was scanned in a 0.5 eV step for the Co K-edge region. The higher harmonics were eliminated by detuning the incident X-ray to 60%. The fluorescence detection was carried out by using a Lytle type detector with flowing Ar. The incidence X-ray was monitored by an ion chamber with flowing N_2. The spectra were obtained by collecting signals I_f/I_0, where I_0 indicates the intensity of incidence X-ray and I_f the intensity of fluorescence X-ray. Normalized XANES spectra were obtained by subtracting the pre-edge background from the raw data assuming a straight line. Normalization was carried out by the edge height.

The catalyst was evacuated at room temperature after sulfidation and then transferred to an XAFS cell with Kapton windows without exposure to air. After the XAFS measurement of the sample in a vacuum, 6.7 kPa of NO or O_2 was introduced to the cell and the XAFS spectra of the catalyst exposed to the probe molecule were recorded again. After keeping for 2–3 h, the NO or O_2 gas was evacuated for 5 min to replace NO (O_2) by O_2 (NO). Subsequently, 6.7 kPa of O_2 or NO was introduced to the cell. After the replacement, XAFS spectra were measured again.

2.3. *FT-IR and NO adsorption capacity measurement*

The FT-IR spectra of NO adsorption on the catalysts were measured by FT/IR620 (JASCO) using an in situ cell. A self-supporting disk of the catalyst was presulfided at 673 K and transferred to the cell in a glove-box filled with N_2. The disk was resulfided at 673 K in the cell and evacuated, followed by introduction of 6.7 kPa of NO. The amounts of NO and O_2 adsorption capacity on the catalysts were measured using a pulse method between 200 K and 323 K [11].

3. Results and discussion

Figure 1 shows the FT-IR spectra of NO adsorbed on the metal sulfide catalysts. With MoS_2/Al_2O_3, a doublet peak appeared at 1776 and 1685 cm^{-1}, assigned to NO adsorbed on coordinatively unsaturated sites (cus) of Mo sulfides [6, 12, 18]. After the addition of Co atoms by the CVD method, a new doublet peak appeared at 1851 and 1805 cm^{-1}. These peaks are assigned to NO adsorbed on cus Co sulfides as a dinitrosyl form [6, 12]. The intensity of the peak at 1677 cm^{-1} was extremely weak, indicating that cus sites at MoS_2 edges are almost completely covered with Co atoms after the addition of Co by the CVD method. On the other hand, with Co-MoS_2/Al_2O_3, three peaks were observed at 1685, 1794 and 1846 cm^{-1}. These peaks are interpreted as overlapping of two doublet peaks due to adsorbed NO on cus Co and Mo sulfides [6, 12]. It is concluded from the FT-IR spectra that cus sites at MoS_2 edges of the catalyst prepared by the CVD method are covered with Co atoms more effectively than those of the catalyst prepared by a conventional impregnation method. It is revealed that the edge sites of MoS_2 are essentially fully covered with Co atoms by the CVD method.

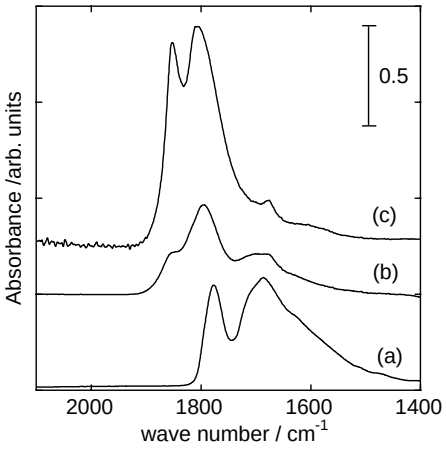

Fig. 1. FT-IR spectra of NO adsorbed on the metal sulfide catalysts. (a) MoS_2/Al_2O_3, (b) Co-MoS_2/Al_2O_3 prepared by a conventional impregnation method (Co 2.0 wt%), (c) CVD-Co/MoS_2/Al_2O_3 prepared by the CVD method.

Figure 2(A) shows the Co K-edge XANES spectra of the metal sulfide catalysts, $CoAl_2O_4$ and Co_9S_8. With the spectra for the catalysts prepared by the impregnation method, a small peak was observed at 7726 eV, characteristic of Co^{2+} in $CoAl_2O_4$, indicating that a part of Co atoms bind with Al_2O_3 surface to form Co^{2+} as in $CoAl_2O_4$, in agreement with other workers [1–3]. This is highlighted by the difference spectrum, in Fig. 2(B) (Fig. 2(A) (b)–(c), close to the XANES of Co^{2+} in $CoAl_2O_4$). However, with the catalyst prepared by the CVD method, XANES

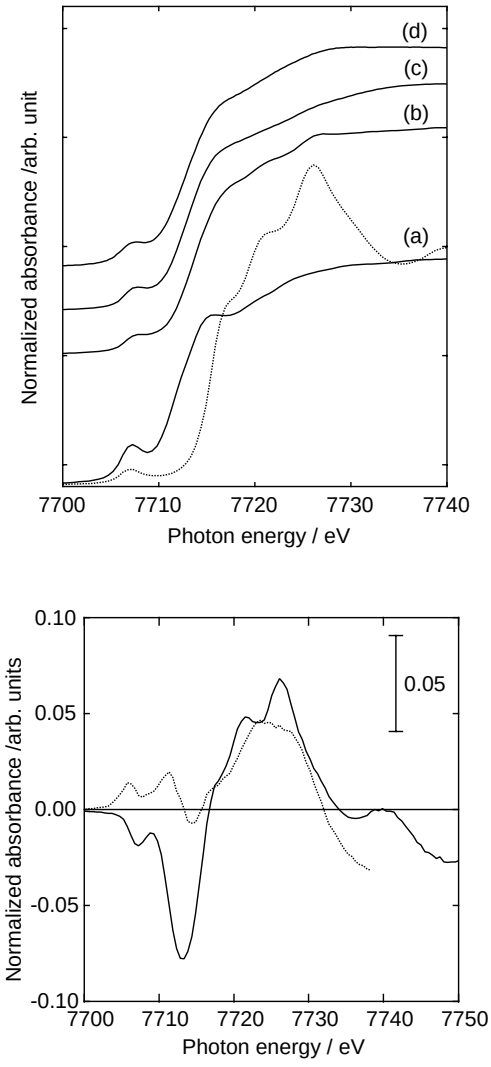

Fig. 2. (A) Co K-edge XANES spectra of Co-Mo sulfide catalysts and reference compound. (a) Co_9S_8 (solid line) and $CoAl_2O_4$ (dotted line), (b) Co-MoS_2/Al_2O_3 prepared by an impregnation method (2.0 wt% Co), (c) CVD-Co/MoS_2/Al_2O_3 prepared by the CVD method, (d) CVD-Co/Al_2O_3 prepared by the CVD method. (B) Co K-edge XANES difference spectra of Co-Mo sulfide catalysts obtained by subtracting the spectrum of CVD-Co/MoS_2/Al_2O_3 prepared by the CVD method. Solid line; (b)–(c) and dotted line (d)–(c).

spectrum in Fig. 2(A) showed no peak at 7726 eV except a weak s-d transition peak. Furthermore, no formation of bulk Co_9S_8 in CVD-Co/MoS_2/Al_2O_3 is confirmed by the absence of a shoulder peak characteristic of bulk Co_9S_8 (7715 eV), when the spectra for CVD-Co/MoS_2/Al_2O_3 and Co_9S_8 in Fig. 2(A) are compared. The XANES spectrum of CVD-Co/Al_2O_3 is also shown in Fig. 2(A). The difference XANES spectrum in Fig. 2(B) between CVD-Co/Al_2O_3 and CVD-Co/MoS_2/Al_2O_3 shows a broad feature around 7725 eV, suggesting interactions between Co atoms in CVD-Co/Al_2O_3 and oxygen atoms on the support or the presence of highly dispersed Co_9S_8 clusters (see Fig. 2(B)). These results clearly demonstrate a selective formation of Co species characteristic of the CoMoS phase in the model catalyst. A linear correlation between Co content in CVD-Co/MoS_2/Al_2O_3 and NO adsorption capacity of MoS_2/Al_2O_3 also supports a selective formation of the Co-Mo-S phase [15].

Figure 3(a) and (b) present the Co K-edge XANES spectra of CVD-Co/MoS_2/Al_2O_3 before and after adsorption of probe molecules, NO and O_2, respectively. With the NO adsorption, a small but reproducible shift of the absorption edge was observed (0.5 eV). The same shift (0.5 eV) was also observed for the catalyst after NO adsorption by the pulse method. These results indicate the changes of electronic state of the Co atoms by the NO adsorption. It is considered from a comparison of XANES that dissociation of NO and concomitant oxidation of the Co sites do not take place even after 3 h, since no changes were observed characteristic of oxidation of Co atoms (appearance of the white line at 7726 eV or a large shift of the absorption edge). However, Nielsen *et al*. reported that about 30% of Ni atoms were oxidized by NO adsorption for Ni-Mo catalysts at room temperature [14]. The difference is interpreted in terms of the difference between Co and Ni in the tendency toward dissociation of NO molecules. On the other hand, as shown in Fig. 3(b), O_2 adsorption caused a larger shift of the absorption edge (ca. 1.0 eV), accompanying an evolution of a peak at 7727 eV, characteristic of the oxidized Co atoms (Co^{2+} in $CoAl_2O_4$, Fig. 2(A)). The intensity of this peak increased with time, indicating a gradual oxidation of Co atoms by O_2 adsorption at room tempetature. These results clearly indicate that NO is superior to O_2 as a probe molecule for the characterization of Co-Mo HDS catalysts.

Figure 3(c) and (d) show the Co K-edge XANES spectra of CVD-Co/MoS_2/Al_2O_3 after NO or O_2 adsorption following the pre-adsorption of O_2 or NO, respectively. The Co K-edge XANES spectrum was scarcely changed by O_2 adsorption following the NO adsorption after 5 min. Only a small peak at 7725 eV was observed after 2 h. This indicates that O_2 adsorption on cus Co sites is strongly inhibited by the pre-adsorption of NO. It is considered that NO and O_2 molecules adsorb on the same Co sites, and that cus Co sites, which cause the dissociation of O_2 , are blocked by the adsorbed NO molecules. On the other hand, the NO adsorption following the O_2 adsorption caused a decrease in the intensity of the peak induced by the O_2 adsorption. It is considered that the pre-adsorbed oxygen reacts with NO, and the adsorbed O_2 molecules are gradually replaced by NO. These XANES spectra clearly show the difference of the adsorption property of NO and O_2.

To clarify the effects of pre-adsorbed molecules, the amounts of NO and O_2 adsorption were measured at various temperatures, as shown in Fig. 4. It is confirmed from Fig. 4 that O_2 adsorption is significantly suppressed by the pre-adsorption of NO. Furthermore, it is also found that the O_2 adsorption capacity is monotonously increased with adsorption temperature, while NO adsorption capacity is almost constant over a wide range of adsorption temperature. These results suggest that O_2 is inappropriate as a probe molecule, since it is considered from XANES results that Co atoms are oxidized by the O_2 adsorption under static conditions (Fig. 3) and the adsorption amount of O_2 depends strongly on the adsorption temperature (Fig. 4).

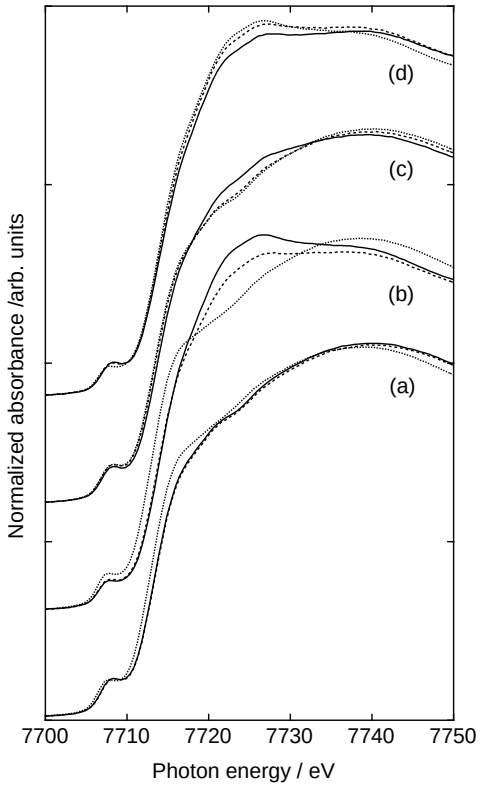

Fig. 3. Co K-edge XANES spectra of CVD-Co/MoS_2/Al_2O_3. (a) before adsorption (dotted line), after 10 min (dashed line), and after 3 h (solid line) for NO adsorption. (b) before adsorption (dotted line), after 6 min (dashed line), and after 2 h (solid line) for O_2 adsorption. (c) O_2 adsorption following the NO adsorption and (d) NO adsorption following the O_2 adsorption. Pre-adsorbed (dotted line), after 5 min (dashed line), and after 2 h (solid line) for the second adsorption. Adsorption of probe molecules was carried out under static conditions at room temperature.

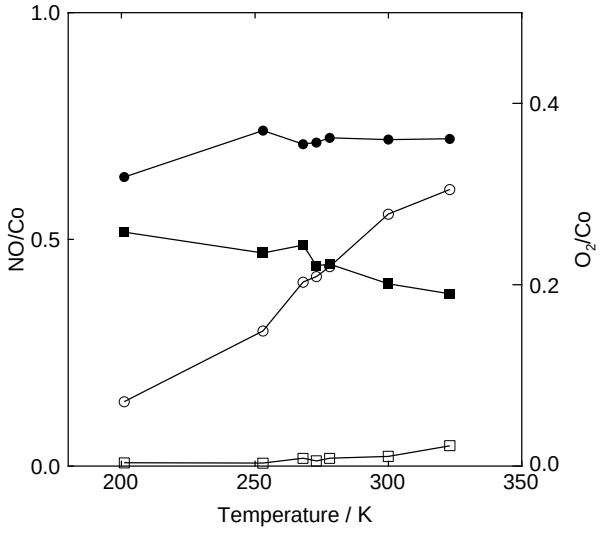

Fig. 4. Amounts of adsorbed NO and O_2 per Co atom as a function of adsorption temperature. Closed circle: NO/Co, open circle: O_2/Co, closed square: NO/Co after the O_2 adsorption, and open square: O_2/Co after the NO adsorption.

4. Conclusions

1) The Co K-edge XANES spectra show that Co species characteristic of the CoMoS phase are selectively formed in a Co-Mo sulfide model catalyst by a CVD method using $Co(CO)_3NO$.

2) NO or O_2 adsorption on Co atoms changes the Co K-edge XANES spectrum. NO is more appropriate probe molecule for the Co-Mo-S phase because the Co atoms in the Co-Mo-S phase are oxidized by O_2 adsorption at room temperature as shown by Co K-edge XANES.

3) Significant suppression of O_2 adsorption by the pre-adsorption of NO is observed by XAFS in agreement with the adsorption capacity measurement.

Abstract

We present the first *in situ* characterization of the conditioning process of a Vulcan supported precatalyst based on PtRu nanoparticles with either aluminumorganic or tetraalcylammonimum protection shells, obtained by X-ray absorption spectroscopic measurements on the Pt L_{III}-edge. To perform these measurements, a suitable reaction cell was developed. In combination with results from transmission electron microscopy, these data provide the basis for a detailed understanding of the abovementioned process. In detail, we find that whereas the increase in particle size during this process and thus agglomeration of particles is rather small, there is a reduction of disorder in both types of particles, especially in the ones with an aluminumorganic protection shell. Furthermore, we observe different behavior of the Pt component in the two different types of particles during the oxidative step of the conditioning process, as only in aluminumorganically stabilized particles Pt atoms are subject to oxidation, whereas in the other sample they remain strictly zerovalent. Tentatively, these findings can be related to the internal structure of the as synthesized particles as obtained from preliminary evaluation of Pt L_{III} EXAFS-spectra.

1. Introduction

Presently, PtRu nanoparticles supported by Vulcan [Cabit corp] are discussed intensely as an promising electrode material for the PEMFC [2–9], mainly due to the small particle sizes (<3 nm) which promise a large active surface contribution. Naturally, it is essential to analyze whether this property of the nanoparticles is maintained during the conditioning process and whether this process might change the intrinsic catalytic properties of the material, which would lead to changes in the electronic structure of such catalysts. The aim of this study is to provide a detailed characterization of the changes in electronic properties and particle size which electrocatalysts made of nanoparticles undergo during the formation process. Whereas the changes in particle size of this material during conditioning were investigated *ex situ* using transmission electron microscopy (TEM), the electronic structure was investigated in situ using the X-ray Absorption Near Edge Structure (XANES). Such an *in situ* study is essential for two reasons: First of all, the direct extrapolation of results obtained from *ex situ* techniques performed after a change of the ambient conditions, especially those obtained under UHV such as XPS, seems at least questionable and needs verification. For example, in the previous XPS studies [3–5] no information could be obtained about the oxidation-state of the metals before the first conditioning step because of several experimental restrictions, mainly overlapping signals which prevented direct access to certain stages of the process. Secondly, even if one assumes that results obtained from *ex situ* investigations can be extrapolated, such studies can elucidate changes induced in the sample during the process of conditioning, but they provide no information on the mechanism which caused these changes and thus no starting point for a possible refinement of the formation process.

XANES spectroscopy is especially suited for *in situ* investigations during an ongoing reaction because it offers direct access to the electronic bulk structure of a given sample while it is being exposed to a given atmosphere. It is, however, well known that particle size effects can exert a considerable influence on the electronic structure of a sample. The addition of systematic TEM measurements on the identical set of samples and EXAFS (extended X-ray absorption fine structure) analysis of the morphology of the starting material which is discussed in detail elsewhere [1] enables us to separate chemical and particle size effects on a given sample, thus allowing for a detailed understanding of the conditioning process.

2. Experimental

2.1. *Synthesis and supporting procedure*

Two types of colloids have been investigated in this study: The first class of colloids were obtained by coreduction of $PtCl_2$ and $RuCl_3$ with $N(oct)_4[B(et)_3H]$ [2, 10, 11]. The resulting PtRu nanoparticles have an average diameter of about 1.6 nm and a metal content of 6.9 wt.% Pt and 3.6 wt.% Ru which corresponds well to the results obtained in previous studies [2, 10]. The particles are stabilized by the *in-situ* generated surfactant. The colloids were supported on high surface area carbon (20 wt.% metal content) by combining a THF dispersion of the PtRu-colloid with a suspension of Vulcan in THF. After 24 h the solvent was evaporated from the remaining solution. The supported pre-catalyst was washed and dried at room temperature in vacuum (10^{-3} mbar).

The second type of colloids consists of particles, which were synthesized by the reaction of Pt-acetylacetonates and $Al(alkyl)_3$, and are only about 1.1 nm small. The elemental analysis shows 13.2 wt.% Pt, 6.8 wt.% Ru and 12.4 wt.% Al. The particles are surrounded by a stabilizing matrix of aluminiumorganic compounds, which still contains Al-methyl groups. Therefore, the matrix can be modified with protic agens, whereby the particles for themselves are not significant growing [3, 4]. To support the aluminumorganic PtRu colloid on the high area support Vulcan XC 72 (20 wt.% metal content), a dispersion of the colloid in toluene was dropped at 40 °C to a vigorously stirred suspension of Vulcan in the same solvent. The resulting suspension was stirred for 24 h again at 40 °C. The solvent was evaporated and the remaining powder was dried in vacuum for 24 h (10^{-3} mbar, 60 °C).

*modrow@physik.uni-bonn.de

2.2. *Conditioning*

The precatalyst cannot be used in electrocatalysis directly, because the protecting shell is still present and blocks the particle surface for the electrochemical reaction. It is removed quantitatively by application of a "conditioning process" which consists of three succeeding steps:

1. Heating the sample in an inert gas (Ar) atmosphere to the necessary conditioning temperature (300 °C for the $N(octyl)_4$-stabilized colloids and the modified aluminiumorganic colloids; 250 °C for the non-modified aluminiumorganic colloids).
2. Annealing of the sample with an O_2/Ar-mixture for 30 minutes, which yields a complete removal of the stabilizer molecules from the particle surface.
3. Annealing of the sample with H_2 for 30 minutes, which leads a complete reduction of the active metals in the sample.

2.3. *In-situ-XANES-measurements*

Pt LIII-XANES measurements have been recorded in transmission mode at beamline BN3 at the Electron Stretcher and Accelerator ELSA [12] at the University of Bonn running in storage ring mode at an electron energy of 2.7 GeV with an average current of 25 mA. A modified Lemonnier-type [13] double crystal X-ray monochromator, equipped with a pair of plane Ge(422)-crystals ($2d = 2.304$ Å) was used. Ionization chambers were filled with 300 mbar Argon as detection system. Energy-calibration was made relative to the first inflection point in the spectrum of the Pt-foil, which was set to 11564 eV. The photon energy was scanned from 11500 to 11650 eV with an integration time of 800 ms per point. For a quantitative comparison, a linear background was fitted to the pre-edge region (11500–11550 eV) of the spectra and subtracted from the raw data. To normalize the spectra, the inflection point of the broad shape resonance at 11637 eV was assigned a value of 1.

2.4. *The in situ cell*

A special designed heating cell for air-sensitive samples, which is presented in figure 1, was used to perform the conditioning. The heating cell consists of two parts. One part is a slightly modified inert gas sample holder described elsewhere [4]. Part of a cylindric mini press (SPECADIE P/N 3550 from Graseby Specac) was mounted at the end of the sample holder. Pellets of the sample could be made inside an Argon-filled glove-box by tightening two screws of the mini press at the sample holder. With a special outlet at the sample holder, a thermocouple was led through the holder, whose end was placed directly on the sample. After sample preparation the sample holder was sealed and transferred to the beamline. The ionization chambers and the sample chamber were filled with Argon before the sample holder was opened.

The second part of the heating cell consists of a 2 mm spiral heating cable (Thermocoax) mounted onto a second holder which was placed perpendicular to the sample holder and the beam onto the experiment. The spiral heating cable could be sled directly to the sample leaving a cylindric hole for the synchrotron beam to pass through. Before the conditioning procedure an *ex-situ* XANES-spectrum of the sample was recorded. After each conditioning step in situ spectra were taken. No measurements could be performed at the Ru L-edges of the PtRu- samples because pellets cannot be used at low energies as the absorption becomes too strong. Also, the temperature used in the conditioning process prevents the use of tape as carrier material for the powder. Measurements at the Ru K-edge were not possible due to the limited spectral range of the Bonn synchrotron radiation source.

3. Results and Discussion

3.1. *In-situ-XANES-measurements*

3.1.1. *PtRu-N(octyl)$_4$Cl-stab.-catalyst.* Figure 2 presents the XANES spectra ot the PtRu-$N(octyl)_4$-catalyst at the Pt L_{III} edge during the course of the conditioning. Changes in the Pt L_{III} XANES-spectra of the catalyst are small, but significant. A comparison between the spectrum of the catalyst and the

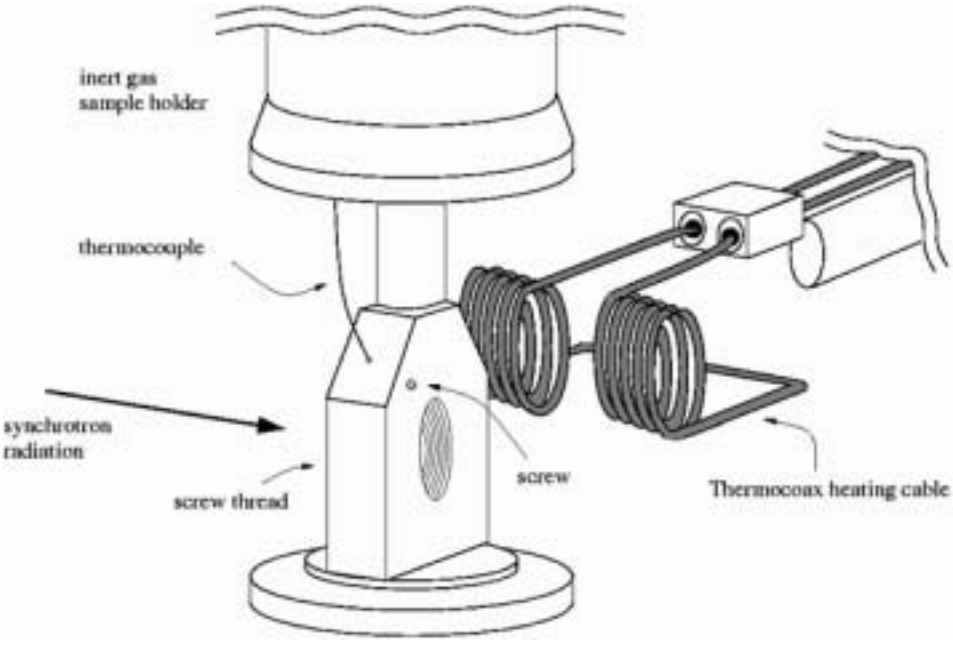

Fig. 1. Sample cell for the heating of airsensitive samples.

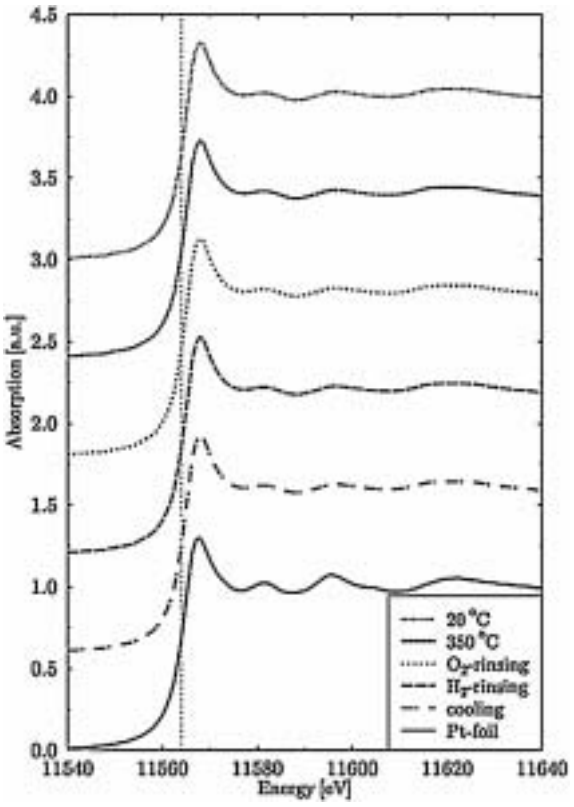

Fig. 2. Pt L_{III}-XANES: Conditioning of the PtRu-N(octyle)$_4$-catalyst.

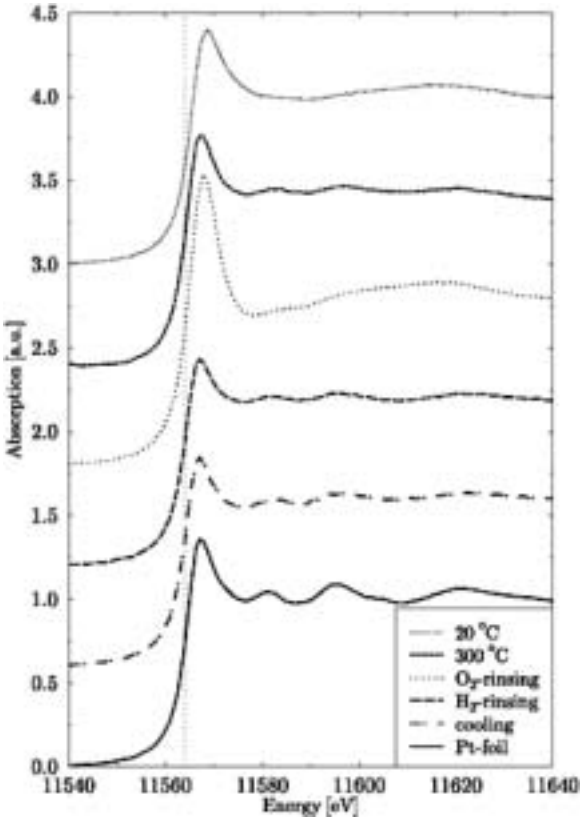

Fig. 3. Pt L_{III}-XANES: Conditioning of the aluminumorganic PtRu-catalyst.

one obtained from a Pt reference foil shows the coincidence of the energy positions of the first inflection point and the shape resonances. This indicates a zerovalent character of the Pt component in the catalyst and shows that Pt is mostly surrounded by Pt atoms, indicating segregation of Pt and Ru in the particles. The spectrum of the catalyst is in perfect agreement with the spectrum of the unsupported colloid presented in [10]. This shows that supporting the colloids on Vulcan has no influence on the metal core of the colloid as long as the protection shell is present. The only change during the conditioning procedure is the slightly more distinct presence of the three shape resonances during the heating of the sample in Ar atmosphere, which might partly reflect a slight particle growth from $d_{vol} = 2.7$ to 3.3 nm observed by TEM, but is more likely to be a result of crystallisation/ordering of the particles during the heating process of the first step. During the subsequent conditioning steps, oxidation and reduction, no further changes in the shape resonances are observed. Also, no shift in the absorption edge and no increase in white-line intensity could be observed during the oxidative step. This shows clearly that the oxidation state of the completely reduced Pt does not change during the floating of the catalyst with O_2. This result is in agreement with former XPS-measurement [10]. The chemically more noble Pt remains resistent to oxidation. In literature, one finds the observation that an O_2 rich atmosphere usually leads to a segregation of Ru atoms to the particle surface. XPS results [10] indicate that Ru is oxidized after the oxidative step. A Ru oxide-layer at the surface of the particles could act as a protective coating for underlying particles and therefore preventing the Pt atoms from oxidation. In the last conditioning step, the reduction of the catalyst, again no changes are observed at the Pt L_{III} edge. The possible reduction of Ru [10] has no influence on the Pt. From the spectra it cannot be concluded if a segregation of the Ru component on the surface is taking place during the conditioning procedure.

3.1.2. *PtRu-Alorg.-catalyst.* Figure 3 presents the XANES spectra of the PtRu aluminumorganic-catalyst at the Pt L_{III} edge during the course of the conditioning. Again, XANES spectra of the pure colloid and the supported catalyst are identical, as in the case discussed above indicating again that the supporting procedure has no influence on the metal core of the nanoparticles. Although the edge position of the catalyst spectrum is slightly shifted to higher energies (0.4 eV) compared to the edge position of the Pt foil spectrum, this shift lies within the measurement error, as 1 motorstep is equal to 0.7 eV. The small intensity of the observed whiteline suggests that again Pt is present in a zerovalent state at the beginning of the reaction. However, during the first conditioning step, the heating of the sample under Ar atmosphere, weak shape resonances arise. Again, this might be attributed partly to the particle growth observed in TEM from 1.1 to 1.3 nm, whose relevance is supported by a U-test [15], but is more likely to be related to the increasing order in the particles, as this difference in size corresponds at most to the addition of one shell to the particle.

While rinsing the sample with oxygen in the next conditioning step, a clear increase in the white-line intensity can be observed, which indicates the partial oxidation of the Pt atoms. During rinsing with H_2 the intensity of the white-line is decreased again which now corresponds to the reduction of the Pt. This is in strong contrast to the above results of the PtRu-N(octyl)$_4$-catalyst where no changes in white-line intensity could be observed, but in good agreement with XPS measurements [4], where an oxidation and reduction of Pt in the second and third conditioning step was also found. The reduced intensity of the whiteline in the spectrum compared to the spectrum before the conditioning procedure indicates the removal of the organic ligands. This was previously shown only indirectly by XPS, as no C(1s) signal could be detected after the conditioning. The initally formed shape resonances are still observed after the conditioning process.

Naturally, the observed differences, especially with respect to the behavior of the Pt atoms during the oxidative step, need further discussion. Based on the preliminary analysis of our Pt-L-III EXAFS spectra, which is discussed in detail elsewhere [1], we find clear evidence for a ragged, incompact, surface rich structure of the aluminumorganically stabilized particles in contrast to a more compact structure in which stricter segregation is observed for the tetraalkylammonium-stabilized particles. Allowing for some degree of speculation, this might also account for the observed stability against oxidative processes during the conditioning process: Whereas in a ragged particle the formation of a protecting shell of (oxidized) Ruthenium is not easily possible, in a compact atomic arrangement the formation of such a core shell structure is much easier to accomplish. An alternative attempt of an explanation might be a different degree of protection of the varying organic ligands. However, the latter approach seems questionable due to the observed successful removal of the protection shell in the course of the conditioning process.

4. Conclusions

Using a specially designed reaction cell, we have been able to apply Pt LIII-XANES successfully to investigate *in-situ* the conditioning process of two different types of catalysts based on PtRu nanoparticles. No significant changes between the XANES spectra of the nanoparticles and the catalysts made thereof by supporting them on Vulcan were observed. By correlation of the results of these measurements with particle size information obtained by TEM, we obtained evidence for ordering within the particles during the first step of the conditioning process, whereas the trend to induce agglomeration of particles is comparatively small. XANES spectra also allowed the observation of the oxidation state. The experiment showed that the $N(octyl)_4$-stabilized colloid catalysts are far more stable against oxygen exposure then the aluminumorganic catalysts. This can either be explained by the bigger size of the $N(octyl)_4$-stabilized catalysts, but more likely by differences in the initial internal structure of the PtRu nanoparticles shown by the analysis of *ex situ* EXAFS data. Comparison of *ex-situ* XPS- and *in situ* XANES-measurements yields a consistent picture of the conditioning process.

Abstract

The local structures of supported $CuO/\gamma\text{-}Al_2O_3$ monolayer dispersive catalysts with different CuO loadings have been investigated by XAFS. For the $CuO/\gamma\text{-}Al_2O_3$ catalyst with CuO loading of 0.4 mmol/100 m^2, the XAFS results indicate that only one peak corresponding to the Cu-O first shell appears in the radial structural function of Cu atoms, and that the bond length $R_{Cu\text{-}O}$ and coordination number N are 1.95 Å and 3.8, respectively. We consider that the CuO active species on the surface of $\gamma\text{-}Al_2O_3$ are in the form of isolated atomic clusters $(CuO_4)_m{}^{n+}$ with distorted structure for the $CuO/\gamma\text{-}Al_2O_3$ (0.4 mmol/100 m^2) catalyst. It has been found that small amount of CuO nano-grains is formed on the surface of $\gamma\text{-}Al_2O_3$ for $CuO/\gamma\text{-}Al_2O_3$ (0.8 mmol/100 m^2) catalyst while the CuO loading is just equal to the threshold 0.8 mmol/100 m^2. For the catalyst with CuO loading of 1.2 mmol/100 m^2, the local structure of Cu atoms in $CuO/\gamma\text{-}Al_2O_3$ is similar to that of CuO powder. On the basis of the XAFS results, a schematic monolayer dispersion model has been proposed for $CuO/\gamma\text{-}Al_2O_3$ catalysts.

1. Introduction

The elimination of atmosphere pollutants and automobile exhaustions, such as the reduction of NO and CO concentrations, have attracted considerable attention in the last two decades [1–4]. Although the noble metals catalysts of $Pt/\gamma\text{-}Al_2O_3$ and $Pd/\gamma\text{-}Al_2O_3$ show a nice catalytic property in reduction of NO in the presence of CO or oxidation of CO [3, 4], they are not widely used due to their expenses. Hence, one needs to find a cheaper catalyst. A number of studies by Kummer [5], Kapteijn *et al*. [6], and Chen *et al*. [7] have indicated that the supported $CuO/\gamma\text{-}Al_2O_3$ monolayer-dispersed catalysts possess higher catalytic activity at room temperature for the reduction of NO in the presence of CO or oxidation of CO. Especially, $CuO/\gamma\text{-}Al_2O_3$ catalyst has a lower price than those of the noble metal catalysts [8, 9]. It means that $CuO/\gamma\text{-}Al_2O_3$ is a promising candidate for applications in controlling environmental pollutions.

Xie *et al*. [10], Chen *et al*. [7, 11] and Friedman *et al*. [12] have reported that under proper calcination conditions, the copper oxide species can be spontaneously dispersed as a monolayer on the surface of $\gamma\text{-}Al_2O_3$ support. The threshold for CuO monolayer dispersion on the surface of $\gamma\text{-}Al_2O_3$ is about $0.8 \sim 1.6$ mmol/100 m^2 [7, 11]. The monolayer dispersion has been confirmed by X-ray diffraction (XRD). No peaks corresponding to the crystalline CuO phase appear in the XRD pattern of $CuO/\gamma\text{-}Al_2O_3$ when the CuO loading is lower than its monolayer dispersive threshold. However, peaks of crystalline CuO phase can be observed in $CuO/\gamma\text{-}Al_2O_3$ while the CuO loading is higher than its monolayer dispersive threshold. Unfortunately, even if a lot of studies have been done on $CuO/\gamma\text{-}Al_2O_3$ monolayer dispersive catalysts, the occupations of Cu^{2+} ions on the surface of $\gamma\text{-}Al_2O_3$ support are not clear enough yet [7, 11–13].

In this present approach, the local structures of supported $CuO/\gamma\text{-}Al_2O_3$ monolayer dispersive catalysts prepared via impregnations have been investigated by XAFS. Three different CuO loadings of 0.4, 0.8 (equal to the monolayer dispersion threshold of 0.8 mmol/100 m^2) and 1.2 mmol/100 m^2 are used to study the local structures of $CuO/\gamma\text{-}Al_2O_3$ catalysts. On the basis of the XAFS results, a simple monolayer dispersion model has been proposed to interpret the structures of $CuO/\gamma\text{-}Al_2O_3$ catalysts.

2. Experimental

$\gamma\text{-}Al_2O_3$, obtained from Fusun Petrochemical Institute in China, had been calcined at 973 K for 5 hours before using for preparing supported catalysts; the BET surface area was 195 $m^2 \cdot g^{-1}$. The supported $CuO/\gamma\text{-}Al_2O_3$ catalyst was prepared by incipient wetness impregnation of $\gamma\text{-}Al_2O_3$ support with an aqueous solution containing the requisite amount of copper nitrate hexahydrate. The catalyst was dried at 373 K for 24 hours, and subsequently calcined at 923 K in air for 3.5 hours. The $CuO/\gamma\text{-}Al_2O_3$ catalysts with different CuO loadings were as follows, $CuO/\gamma\text{-}Al_2O_3$ (0.4 mmol/100 m^2), $CuO/\gamma\text{-}Al_2O_3$ (0.8 mmol/100 m^2) and $CuO/\gamma\text{-}Al_2O_3$ (1.2 mmol/100 m^2).

The Cu K-edge absorption spectra of $CuO/\gamma\text{-}Al_2O_3$ catalysts were measured at the XAFS station of 4W1B beamline of Beijing Synchrotron Radiation Facility. The electron beam energy was 2.2 GeV and the maximum stored current was about 80 mA. Fixed-exit Si (111) flat double crystals were used as monochromator. The X-ray harmonics were minimized by detuning the two flat Si (111) crystals to about 70% of the maximum incident light intensity. Data were collected in transmission mode using ion chambers with mixed Ar/N_2 fill gas at room temperature. XAFS data were analyzed by using USTCXAFS3.0 [14] and UWXAFS3.0 codes [15].

3. Results and Discussion

The Cu K-edge EXAFS functions $k^3\chi(k)$ and their Fourier transformations (FT) for CuO powder and $CuO/\gamma\text{-}Al_2O_3$ catalysts with different CuO loadings are shown in Figure 1 and Figure 2, respectively. The FT is performed using the k region from 2.5 to 12 $Å^{-1}$ and a Hanning window. It can be observed that several stronger oscillations as shown in Figure 1 appear in the high-k region extended to 12 $Å^{-1}$ for the CuO powder. The oscillation feature of $CuO/\gamma\text{-}Al_2O_3$ catalyst with CuO loading

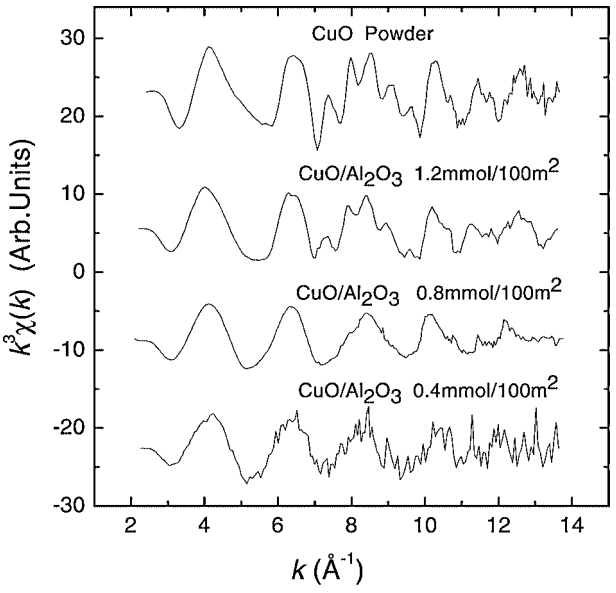

Fig. 1. $k^3\chi(k)$ functions of CuO powder and CuO/γ-Al_2O_3 with different CuO loadings.

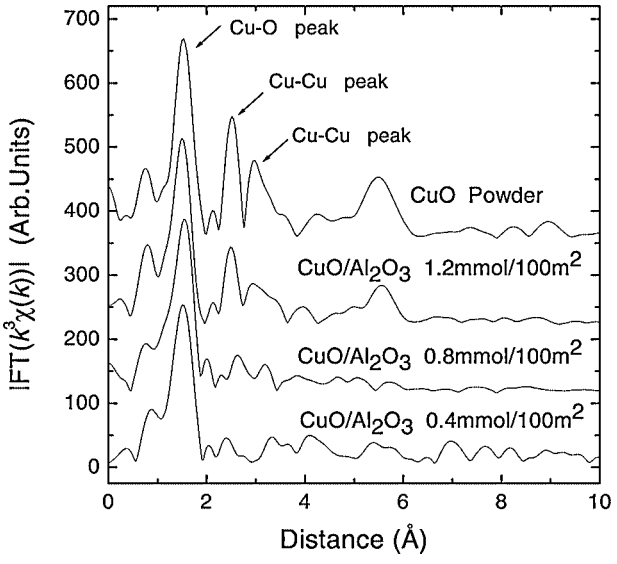

Fig. 2. RSF curves of CuO powder and CuO/γ-Al_2O_3 with different CuO loadings.

of 1.2 mmol/100 m^2 is similar to that of CuO powder, unless its magnitude in the high-k region is slightly deceased. With the CuO loadings decreasing to 0.8 or 0.4 mmol/100 m^2, the magnitude of the oscillation peaks for the CuO/γ-Al_2O_3 catalyst is further deceased by compared with that of CuO/γ-Al_2O_3 (1.2 mmol/100 m^2). Figure 2 demonstrates that there are three stronger peaks located at about 1.5, 2.5 and 3.4 Å in the FT curve of the CuO powder. The first and second peaks correspond to the first shell of four Cu-O pairs with bond length of 1.96 Å, the second shell of two Cu-O pairs with bond length of 2.78 Å and ten Cu-Cu pairs with an average bond length of 3.03 Å, respectively. With the CuO loading changing from 1.2 to 0.4 mmol/100 m^2, only the peak of the first shell exists and the peaks of the higher shells disappear for the monolayer dispersive CuO/γ-Al_2O_3 catalyst.

For obtaining the structural parameters of CuO/γ-Al_2O_3 catalysts, least-squares curve fit was performed for the data analysis by using the USTCXAFS3.0 code [14]. The theoretical amplitude functions and phase shifts were calculated by FEFF7.0

Table I. *The structural parameters of CuO powder and CuO/γ-Al_2O_3 with different CuO loadings.*

Sample	Bend type	R/Å	σ^2/Å^2	N	ΔE/eV
CuO/γ-Al_2O_3	Cu-O	1.95	0.0052	3.8	−1.9
(0.4 mmol/100 m^2)	Cu-O	2.78	0.0161	0.1	−1.9
	Cu-Cu	2.97	0.0220	0.2	−1.9
CuO/γ-Al_2O_3	Cu-O	1.95	0.0050	3.9	−1.6
(0.8 mmol/100 m^2)	Cu-O	2.78	0.0153	0.2	−1.6
	Cu-Cu	2.97	0.0214	3.4	−1.6
CuO/γ-Al_2O_3	Cu-O	1.95	0.0049	4.0	−1.9
(1.2 mmol/100 m^2)	Cu-O	2.78	0.0139	2.0	−1.9
	Cu-Cu	2.97	0.0221	8.1	−1.9

	Cu-Cu	2.97	0.0220	9.6	2.1

[15]. The curve fits, based on single-scattering theory, were performed in R-range between 1.0 and 2.9 Å for the two first nearest Cu-O sub-shells ($R_1 = 1.96$, $R_2 = 2.78$ Å) and one Cu-Cu second shell ($R_3 = 3.03$ Å). The fitting results are summarized in Table I.

Seen from Table I, the structural parameters of the Cu-O first sub-shell are almost the same for all the CuO/γ-Al_2O_3 catalysts with CuO loadings of 0.4, 0.8 and 1.2 mmol/100 m^2. Their bond lengths R and the coordination numbers N are 1.95 Å and 3.8, 1.95 Å and 3.9, 1.95 Å and 4.0, respectively. However, the N of the Cu-O second sub-shell ($R = 2.78$ Å) is about 2.0 for CuO/γ-Al_2O_3 (1.2 mmol/100 m^2) while those of CuO/γ-Al_2O_3 (0.8 or 0.4 mmol/100 m^2) are close to zero, and the N of the Cu-Cu second shell ($R = 2.97$ Å) are 8.1, 3.4 and 0.2 for CuO loadings of 1.2, 0.8 and 0.4 mmol/100 m^2, respectively. These structural parameters have clearly shown that only the XAFS signal corresponding to the Cu-O first shell appears in the CuO/γ-Al_2O_3 (0.4 mmol/100 m^2) catalyst that is lower than the monolayer dispersion threshold of 0.8 mmol/100 m^2. When the CuO loading is increased to the monolayer dispersion threshold or exceeds it, the peaks of their higher shells appear in the FT curves as shown in Figure 2. It is noteworthy that the bond lengths ($R = 1.95$ Å) and coordination numbers ($N = 3.8$) of the Cu-O first shell of CuO/γ-Al_2O_3 (0.4 mmol/100 m^2) catalyst is almost the same as those ($R = 1.95$ Å and $N = 4.0$) of CuO powder, CuO/γ-Al_2O_3 (0.8 mmol/100 m^2) and CuO/γ-Al_2O_3 (1.2 mmol/100 m^2) catalysts. This feature implies that the first nearest neighbors of Cu^{2+} in CuO/γ-Al_2O_3 catalysts are similar to that of crystalline CuO powder, which is independent of the CuO loadings. Xie *et al.* [10], Chen *et al.* [7, 11] and Friedman *et al.* [12] have considered that CuO species are highly dispersed (or monolayer dispersive) on the surface of γ-Al_2O_3 under the monolayer dispersive threshold of CuO, since their XRD patterns indicate that no diffraction peaks corresponding to crystalline CuO were observed for CuO loadings of 0.8 mmol/100 m^2. In fact, there are two possible reasons for the disappearance of CuO diffraction peaks. One is that CuO species are monolayer dispersive on the surface of γ-Al_2O_3, which is just as the results reported by Xie *et al.* [10] and Chen *et al.* [7, 11]. The other is that CuO species are much smaller clusters with high dispersion on the surface of γ-Al_2O_3. XRD technique is difficult for detecting the diffraction signals while the grain sizes of the particles are small enough [16]. Our XAFS results indicate that Cu^{2+} ions are in the form of atomic clusters $(CuO_4)_m^{n+}$

with distorted structure on the surface of γ-Al_2O_3, even for the CuO/γ-Al_2O_3 catalyst in which CuO loading is lower than the threshold of 0.8 mmol/100 m^2. Meanwhile, the disappearance of higher Cu-O and Cu-Cu coordination shells for CuO/γ-Al_2O_3 (0.4 mmol/100 m^2) catalyst indicates that there are no Cu^{2+} ions existing in incorporated form on the surface vacant sites of the γ-Al_2O_3 support, or in other words, there are no Cu-Cu or Cu-Al second coordination shells in CuO/γ-Al_2O_3 (0.4 mmol/100 m^2). Otherwise, the peak associated with the Cu-Cu or Cu-Al second shell should appear in the monolayer-dispersed CuO/γ-Al_2O_3 catalysts [12]. This result suggests that CuO species on the surface of γ-Al_2O_3 do not exist in the form of Cu_2O [17] or spinal $CuAl_2O_4$ [18]. In addition, the present results seem to indicate that it is impossible to have Cu^{2+} coordinated by 5 oxygen atoms in the first nearest neighbor as claimed in Refs. [11] and [12]. In order to well interpret the XAFS results, we consider that the CuO active species on the surface of γ-Al_2O_3 are in the form of isolated atomic clusters $(CuO_4)_m{}^{n+}$ with distorted structure. This result means that the $(CuO_4)_m{}^{n+}$ cluster as a basic structural element occupies the surface vacant site of the γ-Al_2O_3 support for the monolayer-dispersed supported CuO/γ-Al_2O_3 catalyst after calcined at a lower temperature of 723 K.

The weak peaks of the higher coordination shells for the CuO/γ-Al_2O_3 catalyst with CuO loading of 0.8 mmol/100 m^2 show that most of the Cu^{2+} ions are in the form of isolated atomic clusters $(CuO_4)_m{}^{n+}$, but there is also a small amount of CuO nano-grains forming on the surface of γ-Al_2O_3 support. For the CuO/γ-Al_2O_3 catalyst with CuO loading of 1.2 mmol/100 m^2, Cu^{2+} ions on the surface of the γ-Al_2O_3 support are mainly in the form of poly-crystalline CuO. Our results are consistent with those reported by Shi *et al*. [19]. They have studied the local structures around Mo for monolayer-dispersed MoO_3/γ-Al_2O_3 catalysts with XAFS, and show that below the monolayer dispersive threshold of MoO_3 loadings, the dispersion phase of MoO_3 active species on the surface of γ-Al_2O_3 support consists of [MoO_4] polyhedrons that are not connected to each other.

In summary, we propose a schematic mechanism to interpret the local structural change for monolayer dispersive CuO/γ-Al_2O_3 catalyst during the preparation by impregnation. After the mixture of γ-Al_2O_3 support and copper nitrate aqueous solution is dried, Cu^{2+} ions exist in the form of $Cu(NO_3)_2$ absorbed randomly onto the surface of γ-Al_2O_3 support. Then, the $Cu(NO_3)_2$ compound with the crystal water are probably decomposed at the calcinating temperature of 723 K in air for 3.5 hours, the CuO species are in the form of atomic clusters $(CuO_4)_m{}^{n+}$ (or $(Cu(OH)_4)_m{}^{n+}$) with distorted structure as a basic cluster element occupying the surface vacant sites of the γ-Al_2O_3 support.

Abstract

Heat induced amorphisation of cobalt and zinc ion-exchanged zeolites A and Y has been used as a synthetic method to prepare the spinel phases $CoAl_2O_4$ and $ZnAl_2O_4$. We report here some of our early results from an *in situ* investigation into the formation of these phases and we discuss the possibilities of estimating spinel particle size from the magnitude of the second peaks in the EXAFS Fourier transform.

1. Introduction

Transition metal oxide spinels have been used in many industrial applications including semiconductors, magnetic storage media and in sensor technology [1]. However, their thermal stability, high oxygen anion mobility and the ease with which other ions can be accommodated into the spinel framework mean that they are often considered to be potentially good candidates for use in heterogeneous catalysis. Although it is possible to prepare spinels possessing large surface areas by means of co-precipitation procedures (this method is preferred to the mixing of the solid oxides), these methods normally involve calcination temperatures in excess of 1000 °C and are often plagued with problems such as the crystallisation of additional unwanted phases and phase transformation to an inactive form. As such new approaches have been developed for the preparation of such materials, including the crystallisation of spinels from collapsed ion-exchanged zeolite precursors and hydrothermal procedures [2, 3]. Normally zeolites collapse to first form an amorphous material before transforming to dense phase systems, at elevated temperatures [2, 4]. The abundance of silicon and oxygen in the zeolite framework means that quartz and cristobalite are some of the common phases that crystallise at elevated temperatures. However, zeolites containing high concentrations of aluminium require an equal amount of charge balancing monovalent ions such as sodium and yield other phases such as nepheline ($NaAlSiO_4$) [2]. These extra-framework sodium ions can be readily replaced with other metal ions, for example Co^{2+} or Zn^{2+}. It was soon discovered that other materials such as the spinel phases $CoAl_2O_4$ and $ZnAl_2O_4$ can be obtained by collapsing these Co^{2+} and Zn^{2+} exchanged zeolites [2, 5]. More recently [1, 6] this work has been developed further resulting in a viable, reproducible and cheap method for the preparation of the transition metal aluminates $CoAl_2O_4$, $NiAl_2O_4$ and $ZnAl_2O_4$ with surface areas often in excess $100\,m^2/g$.

Although the recent investigation showed the formation of small particles by XRD, the results did not show whether a highly disordered spinel phase was produced in the amorphous phase. Thus, we focussed our attention on a detailed investigation by combined XRD/QuEXAFS (since this method combines both the techniques that are sensitive to long-range and short-range ordering). For this purpose we investigated the formation of $CoAl_2O_4$ and $ZnAl_2O_4$ spinels from various heat-treated cobalt and zinc ion exchanged zeolites. We performed both *in situ* and *ex situ* experiments to investigate the structures that are formed prior, during and after transformation of the amorphous phase to the final dense crystalline product. X-ray absorption spectroscopy, in particular, allowed us to clearly distinguish the formation of either Co_3O_4 or $CoAl_2O_4$ phase in the heat-treated cobalt exchanged zeolites.

2. Experimental

Zeolites A (Si : Al = 1) and Y (Si : Al = 2.52) were used since they had previously been employed successfully to prepare spinel phases [1, 4–6]. In a typical experiment 5 g of zeolite was added to 250 ml of distilled water containing 0.1 M of either cobalt acetate/nitrate or zinc nitrate. Ion exchange was carried out at 70 °C for 30 minutes before the solid materials (pink in colour for cobalt exchanged samples but white for zinc) were filtered, washed and dried overnight at 100 °C. Combined *in situ* XRD/QuEXAFS experiments of the oven-dried samples were carried out on station 9.3 at the SRS Daresbury Laboratory. In a typical experiment 20 mg of the zeolite samples were pressed into a disc of 13 mm diameter and placed into an *in situ* cell permitting combined measurement [6–8]. Samples were heated at 5 °C/minute to 950 °C with XAS and XRD data collected sequentially. XAS data was collected for 380 s and XRD for 180 s resulting in a total cycle time of 10 minutes. XRD data were collected on an INEL detector at a wavelength of 1.661 Å. XAS data were processed using the Daresbury Laboratory suite of programmes namely EXCALIB, EXBROOK and EXCURV98. Based on the *in situ* study we focused our *ex situ* measurements on samples heated at 850 °C and 950 °C. For this purpose, pellets were pressed from 0.3 g portions of the ion-exchanged zeolites and these were placed in a ceramic crucible before firing began at a heating rate of 5 °C/minute. Samples were withdrawn and the reaction quenched at 850 °C and 950 °C respectively before they were subjected to *ex situ* XRD and XAS measurements. XRD patterns were recorded using a Siemens D500 diffractometer with Cu-Kα_1 radiation. Cobalt and zinc K-edge XAS measurements on 20 mg portions (of 20 mm diameter) of the as-prepared and calcined samples were carried out on the Swiss-Norwegian beamline at the ESRF.

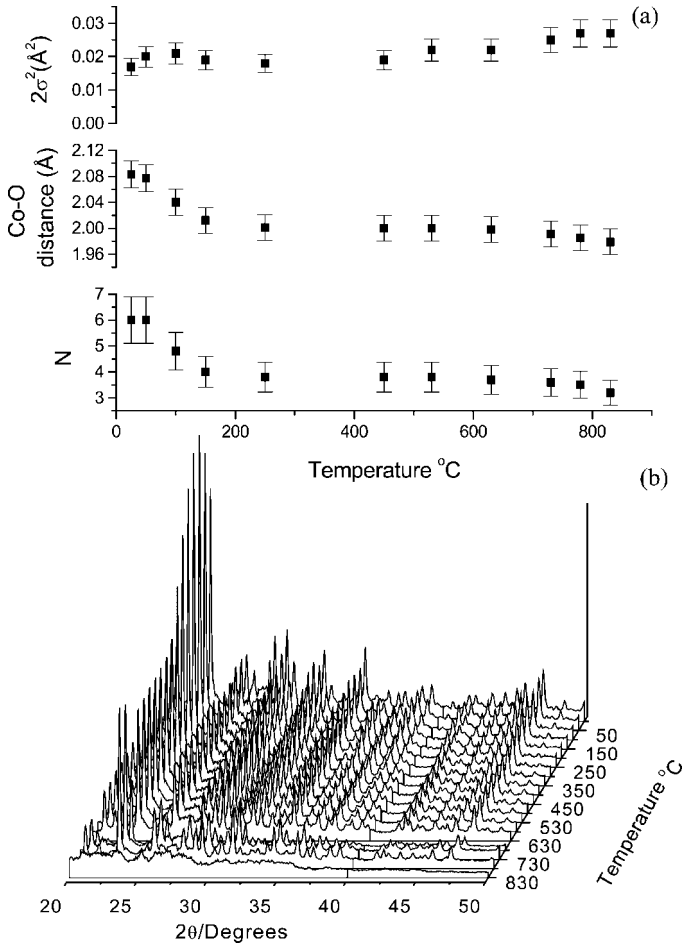

Fig. 1. Plot of the data obtained from a single scattering first shell analysis of the QuEXAFS data (a) and a stacked plot of the XRD data (b) collected sequentially with the QuEXAFS during calcination of cobalt exchanged zeolite Y. The estimated error in the determination of bond distance (as shown by the error limits in marked in 1(a)) is approximately 1% whereas for the occupancy and disorder this is in the order of 15%.

Table I. *Structural parameters determined from Co/Zn K-edge EXAFS of ion exchanged zeolites A.*

Zeolite	Salt	M-O distance[1] (Å)	N^1	$2\sigma^2$ (Å^2)[1]	*R*-factor (%)
A	Cobalt acetate	2.08	5.9	0.016	20.2
A	Cobalt nitrate	2.08	5.7	0.016	19.8
A	Zinc nitrate	1.97	4.4	0.017	25.7
Y	Cobalt nitrate	2.09	6.0	0.016	17.7

[1]The estimated error for the M-O distance is *ca* 0.02 Å and for the occupancy and disorder is *ca* 10 percent.

The results of the detailed analysis of the cobalt and zinc K-edge EXAFS data of the as-prepared (oven-dried) samples, recorded ex-situ, employing single scattering analysis procedures are given in table I. It is clear from this analysis that the cobalt ions are coordinated to six oxygen atoms with an average metal oxygen distance of 2.08 Å, whereas the zinc ions are connected to four oxygen atoms at a distance of 1.98 Å with both results similar to previously reported measurements for ion-exchanged cobalt and zinc ions in zeolites [2, 9].

As noted above in the *in situ* XRD/QuEXAFS measurements, after calcination of the samples, both the XRD and XAS data, recorded *ex situ*, underwent a number of changes. A typical best fit to the EXAFS data and the associated Fourier transforms are shown in figure 2 for the cobalt and zinc nitrate ion-exchanged zeolite A samples calcined at 950 °C. It is clear from a simple first shell analysis that the Co-O and Zn-O distances have shortened after the heat treatment to *ca* 1.95 Å, which is consistent with the formation of tetrahedral Co^{2+} and Zn^{2+} containing spinel structures [10, 11]. The XRD patterns, which are not shown here, also contain reflections pertaining to the spinel phases. Higher coordination shells have also been fitted in an attempt to obtain information on particle size. For this purpose XAS data were collected first on the bulk $CoAl_2O_4$ and $ZnAl_2O_4$

3. Results and discussion

In order to follow the formation of spinel phases from the amorphised zeolites a combined XRD/QuEXAFS study was carried out during calcination of cobalt-exchanged zeolite Y to 950 °C. In figure 1 we show the a stacked plot of the XRD data collected sequentially with the QuEXAFS data and the variation of structural parameters obtained from the analysis of the Co K-edge data of cobalt ion-exchanged zeolite A sample; the EXAFS data of the first shell was analysed for this purpose employing single scattering procedures. The XRD data clearly showed that the crystalline zeolite structure is lost above 830 °C and no appreciable structural modification is seen at temperatures below 800 °C. However, the EXAFS results clearly showed several gradual changes during the heat treatment process. In particular the average Co-O distance and the coordination number decreased during the initial stages of the heat treatment, which may be attributed to the loss of adsorbed water. The changes observed by both techniques suggest that the formation of the cobalt spinel phase occurs via a reduction in coordination number and bond length of the local cobalt environment in the initial stages (at temperatures *ca* 250 °C most probably as a result of zeolite dehydration) before the cobalt spinel forms from the amorphised zeolite at temperatures *ca* 850 °C.

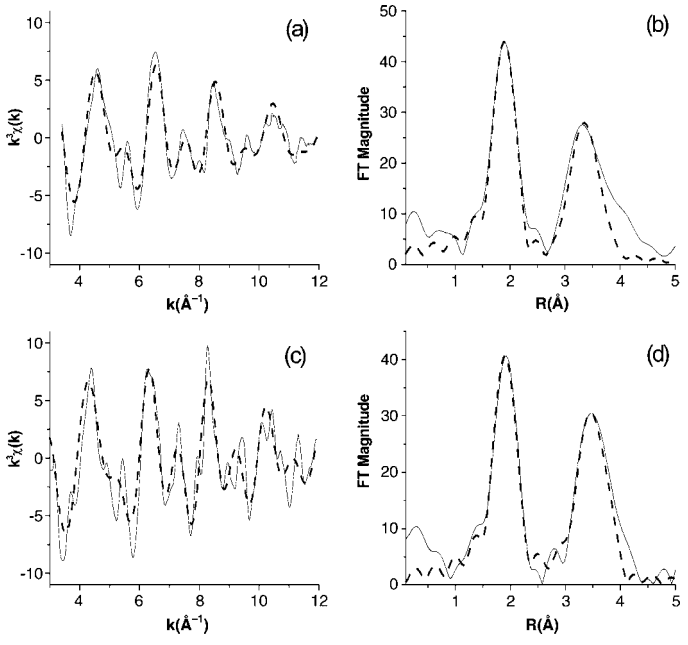

Fig. 2. Best fit between experimental Co (a) and Zn (c) K-edge EXAFS data (solid line) and the calculated best fit (dashed line) and associated Fourier transforms (b and d) for cobalt/zinc nitrate exchanged zeolite A samples calcined at 950 °C.

Table II. *Structural parameters determined from Co/Zn K-edge EXAFS of ion exchanged zeolites A after heat treatment at 850 and 950°C respectively.*

[1]The estimated error for the M-O distance is *ca* 0.02 Å and for the occupancy and disorder is ca 10 percent.
[2] The error associated with M-Al and M-M distances representing higher shells have slightly higher error of *ca* 0.04 and the respective coordination number and Debye-Waller factors have 15 percent.

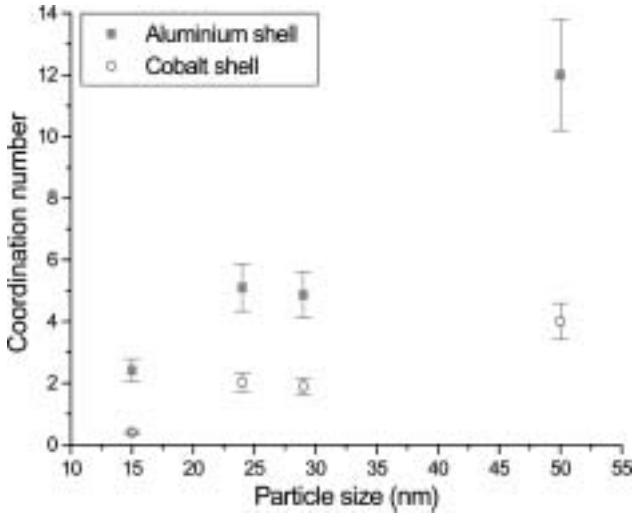

Fig. 3. Comparison of second and third shell coordination numbers and the particle size estimated from the FWHM of the 311 reflection in the XRD pattern using the Scherrer equation.

structures and the data refined with the coordination numbers for the higher aluminium and cobalt/zinc shells fixed to 12 and 4 respectively to avoid correlation effects. It is clear from a comparison of second and third shell coordination numbers of the bulk with the samples prepared from zeolite that the latter ones has much smaller particles compared to the bulk; the particle size estimated from the FWHM of the 311 reflection in the XRD pattern using the Scherrer equation support the findings of the EXAFS results (Table II and figure 3). Similar to many other nano-sized oxide systems, a coordination number of 4 for the first shell indicated that irrespective of the particle size the particles terminate with oxygen. Further work is necessary to determine accurately the coordination number of the higher-shell data, by perhaps carrying out measurements at very low temperatures to remove the dynamic disorder contribution and estimate only the static disorder resulting from the small particle nature of the systems prepared from zeolites.

4. Summary

Cobalt and zinc ion exchanged zeolites A and Y have successfully been used to prepare the spinel phases $CoAl_2O_4$ and $ZnAl_2O_4$. Evidence suggests that the spinels form directly from the amorphised zeolites and therefore it does not appear that the spinel formation promotes zeolite collapse. A comparison of the coordination numbers obtained from a second shell analysis of the calcined materials revealed small spinel oxide particles are formed by employing this procedure. These results suggested that the preparative process could be controlled to yield nano-sized cobalt and zinc aluminate particles for applications in particular in the area of catalysis.

Acknowledgments

Abstract

X-ray absorption/emission spectroscopies were combined in order to elucidate how hybrid xerogels complexed with $CuCl_2$ could bind reversibly O_2. *Difference* EXAFS analyses at the Cu K-edge revealed the existence of binuclear structures with long Cu . . . Cu distances, *i.e.* $R_{Cu-Cu} \approx 3.98$ Å and 3.87 Å for the oxygenated and *oxygen-free* xerogels. In oxygenated xerogels, dioxygen would bridge two Cu atoms in a μ–$\eta^1 : \eta^1$ peroxo-like conformation. The Cu-O signal found at short distance ($R_{Cu-O1} = 1.85 \pm 0.01$ Å) is fully consistent with 40% of O_2 molecules being chemisorbed per Cu site. In oxygen-free xerogels, Cl K-edge EXAFS revealed the presence of Cu^I sites with short Cl-Cu bond lengths ($R_{Cl-Cu} = 2.11 \pm 0.03$ Å) and of pentacoordinated Cu^{II} sites with longer Cl-Cu bond lengths ($R_{Cl-Cu} = 2.45 \pm 0.03$ Å). Another signal at $R_{Cl \ldots Cu} \approx 2.73$ Å may suggest that Cl could bridge [Cu^I, Cu^{II}] sites. Deconvoluted XANES spectra of the active xerogels exhibit a strong pre-edge resonance that was assigned to the Cu^I sites. The chemical shifts of the Cu K$\beta_{1,3}$ lines also confirmed the coexistence of Cu^I, Cu^{II} sites.

1. Introduction

Advanced industrial applications require AIR LIQUIDE to remove trace amounts of dioxygen in inert gases. Recently, organic-inorganic hybrid polymers or xerogels incorporating metal chelating ligands such as the 1,4,8,11-tetrazacyclotetradecane (Cy = cyclam) macrocycle have attracted much attention for trapping dioxygen since it was found that hybrid xerogels complexed with $CuCl_2$ along route (B) could bind *reversibly* O_2 whereas xerogels prepared by a similar Sol-Gel process but along route (A) were inactive [1, 2] (Fig. 1). It was our aim to elucidate how xerogels of type (B) could bind dioxygen [3]. Materials and methods are briefly reviewed in section 2. As illustrated with section 3, much information was extracted from difference EXAFS analyses carried out at both the Cu and Cl K-edges. In section 4, it is shown that numerically deconvoluted XANES spectra exhibit a strong, characteristic pre-edge resonance signal in *all* active xerogels. XANES simulations performed beyond the *muffin-tin* approximation led us to assign this signal to Cu^I sites. The chemical shifts of the Cu K$\beta_{1,3}$ lines confirmed the coexistence of Cu^I and Cu^{II} sites.

2. Materials and Methods

All samples, including model compounds were synthesized and characterized at the LIMSAG in Dijon. Active, oxygen-free xerogels were handled under controlled atmosphere in a glove box and stored as powdered pellets in a vacuum-tight cell carefully designed for this project. Hereafter, **XB1** denotes *oxygen-free* xerogels of type (B) complexed with $CuCl_2$ and **XB2** the corresponding oxygenated xerogels; **XB3** denotes *oxygen-free*

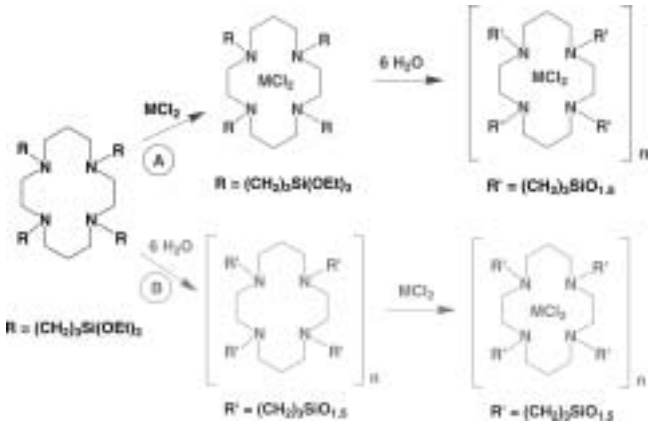

Fig. 1. Alternative routes to yield metalled xerogels.

xerogels of type (B) complexed with $CuBr_2$ and **XB4** the corresponding oxygenated xerogels. In contrast, **XA1** will denote an inactive xerogel of type (A). Relevant model compounds which were investigated include [3]: **1** = [TPP Cu^{II}]; **2** = [Cy Cu^{II}] $2ClO_4^-$; **3** = [TMCy Cu^{II}] $2BF_4^-$; **4** = [TMCy $Cu^{II}Cl$] BF_4^-; **5** = [$N(Me)_2N(CH_2\text{-}Pyr)_2$ Cy Cu^{II}] $2BF_4^-$; **6** = [$N(Pr)_4$ Cy $Cu^{II}Cl$] Cl^-.

High quality EXAFS and XANES spectra were recorded at the windowless ESRF beamline ID12 which is equipped with helical undulator sources [4, 5]. All data were taken at low temperature ($T = 80$ K) in the fluorescence detection mode using an array of 8 PNN^+ photodiodes. At the Cu K-edge, the μ-step gap scan technique made it possible to detect useful EXAFS signal over 2000 eV ($k_{max} \leq 23$ Å^{-1}). At the Cl K-edge, the spectra had to be truncated ($k_{max} \leq 14.4$ Å^{-1}) due to a contamination with a weak potassium K-edge signal. The Cu K$\beta_{1,3}$ lines emission spectra were collected using a spherically bent Si (440) crystal analyzer operated at 46.17° Bragg angle. The high signal/noise ratio allowed us to increase artificially the energy resolution by numerical deconvolution.

Hereafter we will display *optical* FT EXAFS spectra corrected for the amplitude and phase shifts of a selected (dominant) shell j [6, 7, 8].

$$\bar{\chi}_j(R) = \int_0^\infty \mathrm{d}k \cdot W(k) \cdot \chi_j^{(cor)}(k) \cdot \exp[-2\mathrm{i}kR] \tag{1}$$

where $W(k)$ is the Kaiser-Bessel window and:

$$\chi_j^{(cor)} = \chi(k) \cdot \frac{kR_j^2 \cdot \exp[2\sigma_j^2 k^2 - \mathrm{i}\psi_j(k, R_j)]}{F_j(k, R_j) \cdot D_j(\Gamma; k; R_j) \cdot S_0^2(k)} \tag{2}$$

in which F_j, ψ_j are the scattering amplitude and phase-shift of shell j, whereas $D_j \cdot S_0^2$ describes the multielectron response of the system. All corrections were generated by running the FEFF8.9 code [9]. Fits and simulations (in $k + R$ spaces) were performed with code x0 [6, 7, 8]. The numerical deconvolution of the XANES spectra (4096 data pts) was carried out using a Voigt lineshape accounting for both the core hole lifetime and instrumental broadening. For simplicity, we used $\Delta E_G(fwhm) = \Delta E_L(fwhm) \approx 1.4\,\text{eV}$ at the Cu K-edge [3]. XANES simulations were carried out with the advanced code FDMNES [10].

3. EXAFS Analyses

The Cu K-edge FT EXAFS spectra $\Im m\,\bar{\chi}_N(R)$ of xerogels **XB1** and **XB2** are compared in Fig. 2A. Given that the signatures assigned to the Cu…N and Cu…C_α shells of the cyclam macrocycle were nicely superimposed, we carried out the analysis of the difference $\Delta\chi$ [**XB2-XB1**]. The most striking feature in the FT difference spectrum (Fig. 2B) is a well resolved peak assigned to a short Cu-O bond: $R_{Cu-O(1)} = 1.855 \pm 0.005$ Å. Fitting this Fourier-filtered signal led to an average number of bound oxygen atoms $N_{O(1)} = 0.76 \pm 0.06$ *per* Cu site in remarkable agreement with the BET isotherms measured at 77 K. Note that the fitted distance $R_{Cu-O(1)}$ is very close to the bond length (1.852 Å) found in binuclear [Cu^I-O_2] model compounds of oxy-hemocyanin [11], *e.g.* in end-on μ–$\eta^1 : \eta^1$ *trans*-peroxo complexes [12]. In the FT difference spectrum (Fig. 2B), there is also at *ca.* 4 Å, a characteristic signal which is most likely resulting from a small variation of the distance $R_{Cu\,\ldots\,Cu}$ when dioxygen is bound to Cu. From tentative simulations, we obtained: $R_{Cu\,\ldots\,Cu} = 3.99 \pm 0.03$ Å for the oxygenated xerogel **XB2** and $R_{Cu\,\ldots\,Cu} = 3.89 \pm 0.03$ Å for the oxygen-free xerogel **XB1**. Most encouraging, the number density $N_{Cu(2)} \approx 0.76$ went out identical to $N_{O(1)}$ As far as our assignment is correct, we may rule out any *side-on* peroxo configuration for which $R_{Cu\,\ldots\,Cu} \leq 3.56$ Å [11]. At this stage, the assignment of the long distance $R_{Cu-O(2)} \approx 2.96$ Å to the most intense peak found between 2–4 Å is much more tentative. Nevertheless, if we admit that the distance $d_{O(1)\,\ldots\,O(2)}$ is of the order of 1.44 Å (as suggested by the vibrational RAMAN spectrum), we would expect the angle [Cu-O_1-O_2] to be 128° whereas Quantum Chemistry calculations would predict 130° [13]. This would have the important implication that the sequence [$Cu_{(1)}$-$O_{(1)}$-$O_{(2)}$-$Cu_{(2)}$] could not be coplanar, the $Cu_{(1)}$-$O_{(1)}$ and $Cu_{(2)}$-$O_{(2)}$ bonds being rotated by *ca.* 93° with respect to each other.

The Cl K-edge FT EXAFS spectra $\Im m\,\bar{\chi}_{Cu}(R)$ of xerogels **XB1** and **XB2** are compared in Fig. 3A and the corresponding FT difference spectrum is displayed in Fig. 3B. In Fig. 3A, we may identify a triplet of well resolved Cl…Cu distances: the shortest one ($R_{Cu-Cl} = 2.11 \pm 0.03$ Å) is characteristic of a Cu^I-Cl bond; the next one ($R_{Cu-Cl} = 2.45 \pm 0.03$ Å) was typically

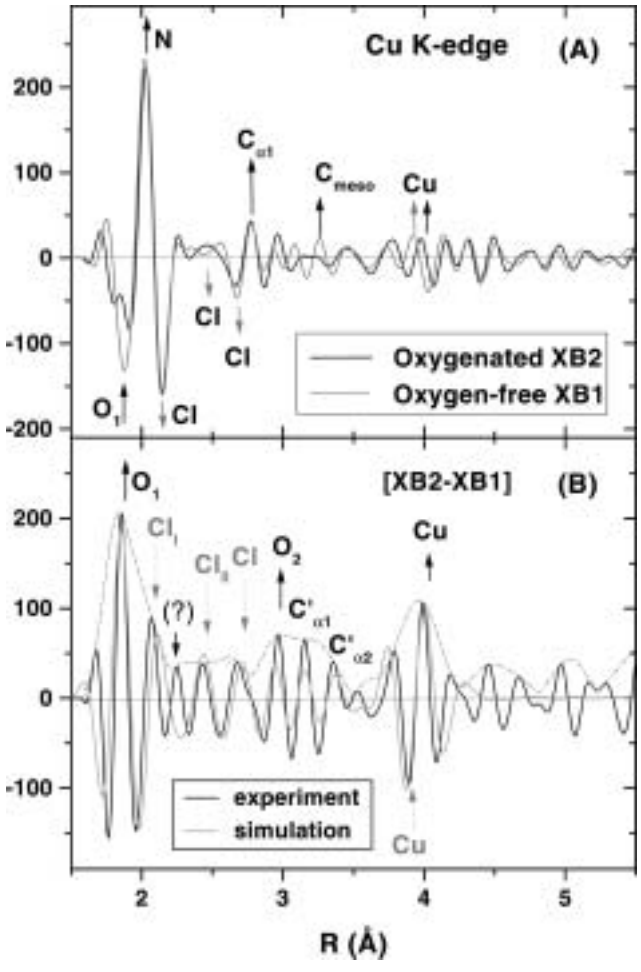

Fig. 2. Cu K-edge FT spectra of active xerogels. Fig. 4. Numerically deconvoluted Cu K-edge XANES spectra.

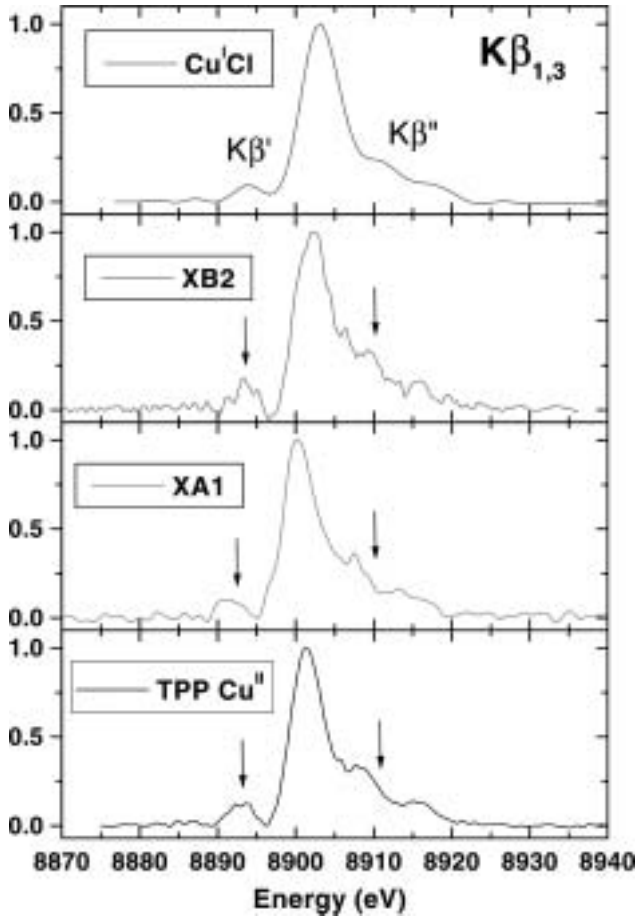

Fig. 5. Chemical shifts of the Cu $K\beta_{1,3}$ fluorescence lines.

found in pentacoordinated model compounds (*e.g.* species **6**) for a Cu^{II}-Cl; there is an additional signal at long distance ($R_{Cu\ldots Cl} = 2.71 \pm 0.03$ Å) which may be characteristic of Cl atoms bridging [Cu^{I}, Cu^{II}] sites [14]. The FT difference spectrum of Fig. 3B clearly indicates that the signal assigned to the pentacoordinated $Cu^{(II)}$ site nearly totally vanishes in the oxygenated xerogel **XB2**.

We have regrouped in Fig. 4A the deconvoluted Cu K-edge XANES spectra of various active/inactive xerogels. For the sake of comparison, we have also reproduced in Fig. 4B the deconvoluted XANES spectra of several model compounds of known structure. Most striking is the systematic presence of a strong resonance peaking at 8985.33 eV – labelled (C) – in all active xerogels. Note that its intensity decreases by only 15% in the oxygenated xerogels. Whereas we were rather successful in simulating the XANES spectra of all model compounds of known structure using the MSW option of the code FDMNES, we systematically failed in reproducing the resonance (C) using binuclear clusters of stereogeometry consistent with the EXAFS study. A very promising result [3] was nevertheless obtained using the *Finite Difference* option of FDMNES which makes it possible to carry out XANES simulations beyond the common *muffin-tin* approximation: once we could get rid of the uncertainty associated with the *muffin-tin zero*, it became obvious that resonance (C) should be unambiguously associated with Cu^{I} sites. Another valuable advantage of the code FDMNES is to allow us to control the charge transfer from the ligand toward the metal: this proved to be important in the case of neutral cyclam ligands.

A perennial dificulty with XANES is that the information regarding the electronic structure (valence, charge transfer etc . . .) is often obscured by structural effects. It has long been argued that the chemical shifts of the Kβ fluorescence lines could as well yield valuable information regarding the population of the valence orbitals. We have reproduced in Fig. 5, the X-ray emission spectra of xerogels **XA1** and **XB2** in the energy range of the $K\beta_{1,3}$ fluorescence lines. The emission spectra of $Cu^{I}Cl$ and **1** = [TPP] Cu^{II}] were added for the sake of comparison. Note the presence of the well known Kβ′ and Kβ″ satellites. Selecting the copper porphyrin **1** as reference, the inactive xerogel **XA1** exhibits a *negative* chemical shift (−0.84 eV), whereas the active xerogel **XB2** has a *positive* chemical shift (+0.81 eV) which increases up to 1.2 eV in the case of $Cu^{I}Cl$. This confirms that the electron density is higher around Cu in the active xerogel than in the inactive one. This result is implicitly consistent with the coexistence of Cu^{I}, Cu^{II} sites in the active xerogels.

In conclusion, it appears that the active sites in the oxygenated xerogel **XB2** should not be viewed as *true* peroxo complexes involving $[O_2]^{2-}$ anions with a formal Cu^{II} valency: it would be more appropriate to refer here to a Cu^{I}-(O_2)-Cu^{I} adduct compound. This would be fully consistent with the reversible character of the dioxygen trapping.

Abstract

The structure of RbBr aqueous solution confined in the interstitial nanospaces of single-wall carbon nanohorn (SWNH) assemblies was elucidated by using extended X-ray absorption fine structure (EXAFS) technique. The decrease of hydration number around a Rb ion is clearly observed. The EXAFS analysis indicates that the highly distorted and dehydrated structure around ions of aqueous solution confined in the nanospace (nanosolution: NSN) to form quasi one-dimensional structure in the interstitial nanospaces of SWNH assemblies. This unique hydration structures formed in nanospaces of SWNH is quite different from that not only of the bulk aqueous solution, but also confined in the slit-shaped nanospaces of activated carbon fiber (ACF).

1. Introduction

Nano-confined molecules surrounded by solid-pore walls have gathered much attention from the aspects of their unique structures and properties. This is because the nano-confinement has an intensive possibility to get an essential understanding of matters and it can be helpful to develop new technologies related to gas storage, gas separation, purification, and electronic devices [1, 2]. We have been challenged to elucidate the molecular nano-confinement using solid nanospaces from the above viewpoint, reporting that the molecules adsorbed in hydrophobic nanospaces tend to form highly ordered structures which depend sensitively on the nanospace geometry and the properties of adsorbate molecules [3]. Water and alcohol molecules, for instance, adsorbed in the slit-shaped carbon nanospaces form a highly ordered structure even at 303 K as revealed by *in situ* X-ray diffraction (XRD) technique [4–7]. Also CCl_4 [8], NO [9], and Xe [10] form a highly condense structure in the carbon nanospaces even at 303 K. This effect is named pseudo-compression effect.

Properties of ionic solutions have been studied to develop fundamental understanding of their natures. Classical hydration models, such as Frank-Wen model [11], are indeed helpful to understand the properties of electrolytic solution. However, it is quite difficult to elucidate more exactly the ionic solution structure. Furthermore, we wonder if such a model can be applied to nano-scale phenomena and structures. The ionic aqueous solution in the bulk phase has an isotropic structure. The chemical and physical natures of the isotropic bulk structure are understood from the hydration structure. A better understanding of the solution is requested on the points of the role of hydrogen bonding to form long-range hydration structure and the presence of local anisotropic structures. As nanospaces can induce an effective anisotropic molecular field for restricted molecules and ions, a new insight on solution chemistry can be expected. We have challenged this subject using well-characterized hydrophobic nanospaces with extended X-ray absorption fine structure (EXAFS) [12–14], because EXAFS has been applied to elucidate local structures around a target ion with an intensive theoretical background [15, 16].

Activated carbon fiber (ACF) having different pore widths is available and it has contributed to develop the studies on nano-confinement. Although abundant single-wall carbon nanotubes (SWNT) [17, 18] cannot be produced without metallic catalysts, high purity single-wall carbon nanohorn (SWNH) [19] which has a structure close to SWNT is available for studies on nano-confinement. Hence, comparative studies on the nano-confinement using SWNH and ACF are preferable. Here, the adsorption isotherm of nitrogen at 77 K on SWNH is of type II, although isotherms of two kinds of ACFs are of type I. The average slit pore widths of two kinds of ACFs are 0.7 nm and 1.1 nm, respectively, from the analysis of subtracting pore effect (SPE) method for high-resolution α_s-plot [20, 21]. Grand canonical Monte Carlo (GCMC) simulation on molecular adsorption in the interstitial nanospaces of SWNH indicates the presence of quasi one-dimensional pores between four SWNH particles [22]. Then we examined the hydration structure of RbBr aqueous solution confined in the interstitial nanospaces of SWNH assemblies with EXAFS and related analysis.

2. Experimental

Electrolytic aqueous solution of RbBr ($1\,mol/cm^3$) was introduced into the interstitial pores of SWNH and dried by evacuation to 0.1 mPa and 423 K for 2 hours. After the deposition of RbBr, water vapor was adsorbed to provide the corresponding solution only in the nanospaces of SWNH; we denote the NSN made by RbBr aqueous solution on SWNH as NH-NSN. In

* Corresponding author: kaneko@pchem2.s.chiba-u.ac.jp

addition, NSNs in the slit-shaped nanospaces of ACFs are also shown for comparison in this article which are denoted by ACF(x)-NSN. Here, x is the average pore width of ACFs obtained by N_2 adsorption isotherms at 77 K.

These samples were installed in an EXAFS glass cell with windows of Mylar film (350 μm: Toray Ind. Inc.). The EXAFS measurements were performed on both Rb and Br K-edges for the NSNs at the National Laboratory for High Energy Accelerator Research Organization (KEK) in Tsukuba after pre-examination with a laboratory XAFS measurement system (EXAC820: Technos Co. Ltd.) which was equipped with Mo rotating-anode X-ray source. The EXAFS spectra of the corresponding solutions were measured for comparison. The structure determination was carried out by the curve fitting of the reverse Fourier transformed function of the 1st shell in each radial structure function (RSF) with theoretical parameters calculated by FEFF code [23].

3. Results and Discussion

Fig. 1 shows the RSFs around a Rb ion for NSNs and bulk aqueous solution. The peak positions of 1st hydration shells for NSNs are shorter than that of bulk aqueous solution, indicating the pseudo-compression effect in the nanospaces. Also, the 1st hydration shell of NH-NSN includes another peak at longer distance. This peak comes from the carbon atoms of SWNH or the other hydration shell in the nanospaces. However we cannot predict the structure indicated by the additional shoulder-like peak. In this study, we included the additional shoulder-like peak of NH-NSN in the curve fitting.

Fig. 2 shows the RSFs around a Br ion for NSNs and bulk aqueous solution. The RSF of NH-NSN clearly contains two kinds of shells indicating the 1st hydration shell and another shell of carbon atoms of SWNH or the other hydration shell in the nanospaces. The determination of hydration structure around a Br ion is quite difficult because of the weak hydration of water molecules to a Br ion [24] and the double excitation effect of photoelectrons [25, 26]. The analysis of hydration shell around a Br ion needs theoretical calculation. Hence we must focus on the nano-confinement effect for the NSN with the hydration structures around a Rb ion.

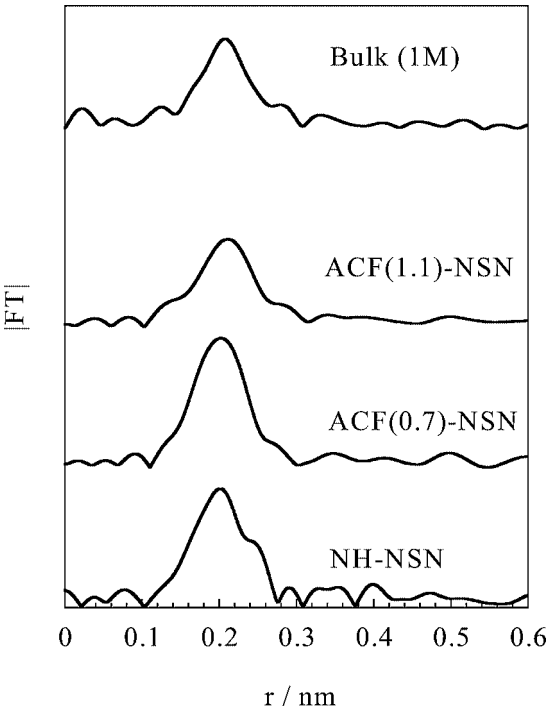

Fig. 1. Radial structure functions around a Rb ion.

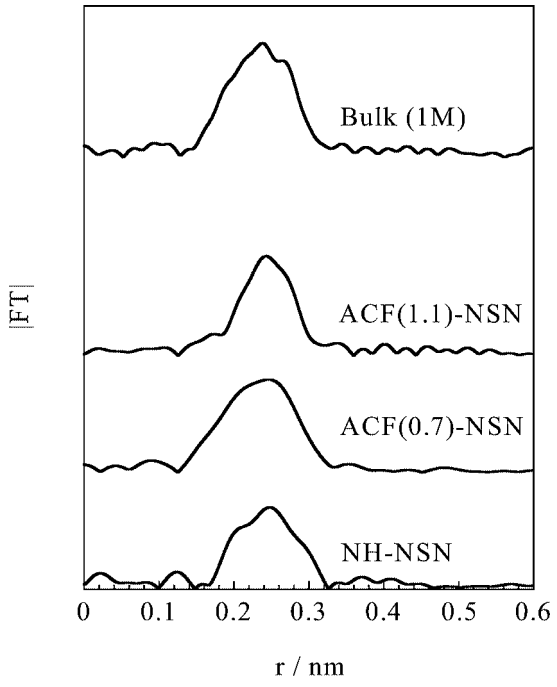

Fig. 2. Radial structure functions around a Br ion.

The structural parameters obtained by a least-squares fit of Fourier-filtered EXAFS spectra around a Rb ion are summarized in Table I. The fitting on a Rb ion for each sample was carried out by using an EXAFS formula including a 3rd order cumulant term C_3. This table shows that the structure around a Rb ion of NH-NSN is different from that of both ACF-NSN and bulk aqueous solution. The coordination number around a Rb ion for NH-NSN, which is only 2.6, is the least. On the other hand, the Rb-H_2O distance for NH-NSN is slightly longer than those of ACF-NSN. This result indicates that the hydration structure around a Rb ion in the quasi-one dimensional nanospace of SWNH is completely different from that in the slit spaces of ACFs. Furthermore, the DW factor for NH-NSN is much less than those for ACF-NSN and the 3rd order cumulant term is larger than for any other aqueous solutions, suggesting that the Rb-hydrated complexes form highly compressed structure with low dimension in the interstitial nanospaces of SWNH assemblies. Hence, this characteristic hydration anomaly of NH-NSN stems from the confinement in the quasi one-dimensional nanospaces. EXAFS study on NSN using nanospaces of different geometries is going to show the presence of different hydration structures.

However we must be cautious for giving an explicit conclusion on the above hydration structure, because the reliability of curve fitting for NH-NSN is relatively higher than any other samples. The fact that the 1st hydration shell of NH-NSN contains two kinds of structural shells should also be examined in future study with the theoretical model obtained by molecular simulation technique.

Table I. *Structural parameters obtained by a least-squares fit of Fourier-filtered EXAFS spectra around a Rb ion.*

Sample	r_{Rb-O}/nm	N_{Rb-O}	${\sigma^2}_{Rb-O}$/nm^2	$C_3/10^6$ nm^3	R/%
NH-NSN	0.290(±0.002)	2.6(±0.2)	1.07(±0.09)	4.2(±0.8)	14.9
ACF(0.7)-NSN	0.286(±0.001)	5.3(±0.1)	2.45(±0.03)	3.3(±0.2)	6.4
ACF(1.1)-NSN	0.283(±0.002)	3.8(±0.1)	2.35(±0.05)	2.0(±0.4)	7.4
RbBr solution (1M)	0.291(±0.002)	6.0*	2.58(±0.01)	3.6(±0.5)	8.2

Distance between two atoms r, coordination number N, DW factor σ, 3rd order cumulant term C_3, and reliability of fitting procedure R for each sample. Here, the R factor can be defined as:

$$R(\%) = \frac{\sqrt{\sum \left\{\chi^{data}(k) - \chi^{fit}(k)\right\}^2}}{\sqrt{\sum \left\{\chi^{data}(k)\right\}^2}} \times 100.$$

Here, $\chi^{data}(k)$ and $\chi^{fit}(k)$ are the EXAFS functions of the experimental data and the fitting function, respectively. The first and second elements in the subscripts denote the central and scattering atoms, respectively. The asterisk (*) shows the fixed parameter.

Abstract

The local structure of Fe in Fe-ZSM-5 prepared by solid-state exchange was investigated with EXAFS. Fe K-edge spectra taken at liquid nitrogen temperature of He- and CO-pretreated sample show two main peaks, one at 1.6 Å and the other at 2.5 Å. To interpret the origin of these peaks, RSFs were simulated for a number of mono- and di-iron structures obtained from quantum chemical calculations. The peak at 1.6 Å is clearly identified with scattering from O atoms coordinated to a Fe atom. The peak at 2.5 Å has been used to argue for the presence of di-iron oxo species. However, the origin of this peak and its interpretation remains an open question. The imaginary part of the Fourier-transformed data for the peak at 2.5 Å has the same characteristics as that generated theoretically for Fe-Al scattering. This evidence strongly suggests that iron in Fe-ZSM-5 is present as isolated cations in an aluminum framework. Further evidence for such a structure is the absence of any change in the magnitude of the peak at 2.5 Å with sample treatment.

1. Introduction

It has been demonstrated that N_2O-pretreated Fe-ZSM-5 react with methane to methoxide species, which subsequently hydrolyze to form methanol. A number of studies have been carried out aimed at understanding the effects of catalysts preparation and pretreatment on the structure of Fe in Fe-ZSM-5 and relating this information to catalyst activity. Formally, the electronic state of iron is either +2 or +3, depending strongly on the pretreatment. The most difficult issue to address is the nuclearity of Fe once exchanged into the zeolite. Joyner *et al.* have concluded that Fe in Fe-ZSM-5 occurs in different forms, ranging from isolated metal ions to large oxide clusters and small oxygen-containing nanoclusters such as Fe_4O_4 and Fe_4O_3 [1]. Marturano *et al.* [2] and Battiston *et al.* [3] have reported evidence for binuclear iron-oxo complexes and diferric(hydroxy)oxo-bridged complexes based on EXAFS spectra of fully exchanged Fe-ZSM-5 ($Fe/Al \cong 1$). These di-iron structures resemble the core unit in methane monooxygenase (MMO) and are characterized by a Fe-Fe distance of approximately 3 Å. However, when the loading of Fe in Fe-ZSM-5 is such that $Fe/Al < 1$, isolated Fe species have been found as principal species [4].

The aim of the present work was to establish the effects of Fe/Al ratio and pretreatment conditions on the speciation of iron in Fe-ZSM-5. Fe-ZSM-5 with Fe/Al ratios of 0.33 to 0.80 was prepared by solid-state exchange and was characterized by EXAFS. The interpretation of EXAFS data was aided by simulations of radial structure function (RSF)s for iron-containing species proposed to exist in Fe-ZSM-5.

2. Experimental Method

Fe-ZSM-5 was prepared by solid-state exchange using $FeCl_3$ (Adrich, 99.99%). Without exposure to air, the calcined H-ZSM-5 ($Si/Al = 25$) was mixed with an appropriate amount of anhydrous $FeCl_3$ with resulting Fe/Al ratios of 0.33, 0.66, and 0.80, respectively. After the mixture was heated from 298 to 583 K, the sample was washed with deionized water.

The as-prepared material was contained in a specially designed cell and pretreated on three different conditions with He, O_2, and CO. XAFS measurements were conducted on beamlines 4-2 and 4-3 of Stanford Synchrotron Radiation Laboratory (SSRL). The radiation was monochromatized using a Si(111) double-crystal and the incident beam was detuned by 15% in order to minimize higher harmonics. Fe K-edge spectra were taken in transmission mode at liquid nitrogen temperature. The collected data were analyzed with the UWXAFS 3.0 package [5] and the FEFF 8 code [6]. The procedure for EXAFS data analysis is described elsewhere [7]. The reference materials used as standards for fitting the experimentally derived RSFs were generated with the FEFF 8 code and the Fourier-filtered data were fitted in momentum space.

3. Theoretical Method

The structures of both isolated and di-iron species were determined from quantum chemical calculations. For isolated sites, the Fe atom and a portion of the zeolite framework were represented by a 23-26-atom cluster. To represent a di-iron species, the two Fe atoms and the associated portion of the zeolite framework were represented by a 40-46-atom cluster. Quantum chemical calculations of the geometries were performed using non-local, gradient-corrected density-functional theory (DFT). The Jaguar 4.0 suite of programs (Schrödinger, Inc.) and Gaussian 98 were used for this purpose. With the exception of the terminal Si atoms, all of the atoms in the cluster were allowed to relax during the course of calculations. The atomic coordinates for each mono- and di-iron species, determined from the quantum chemical calculations, were then used to generate the theoretical EXAFS function $\chi(k)$.

4. Results and Discussion

Among the theoretically calculated isolated iron species, the structure of $Z^-[Fe(O)_2]^+$, where Z^- represents the zeolite framework, and its simulated RSF are presented in Fig. 1. The RSF exhibits a peak between 1 and 2 Å, a peak between 2 and 3 Å, and a pair of overlapping peaks centered near 3 Å.

*E-mail: shchoi@postech.ac.kr

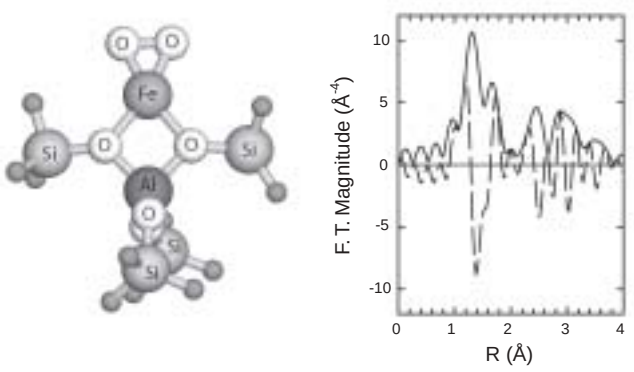

Fig. 1. Fourier transforms of theoretical data for isolated iron species of $Z^-[Fe(O)_2]^+$ in Fe-ZSM-5. The imaginary parts of Fourier transformed data are also plotted as dashed lines.

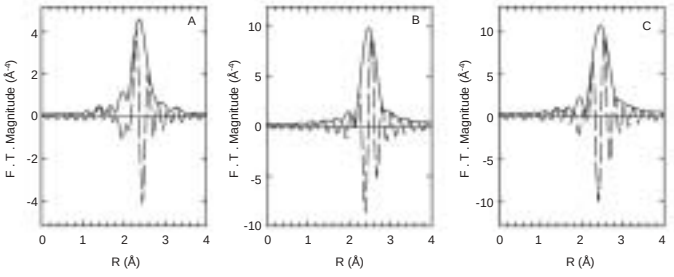

Fig. 2. k^3-weighted Fourier transformation about the Fe K-edges of theoretical data for (A) Fe-Al pair, (B) Fe-Fe pair, and (C) combined contribution of Fe-Al and Fe-Fe pairs. The theoretical EXAFS $\chi(k)$was generated with FEFF 8 for the structure of $Z^-[HOFe(OH)_2FeOH]^{2+}Z^{-1}$.

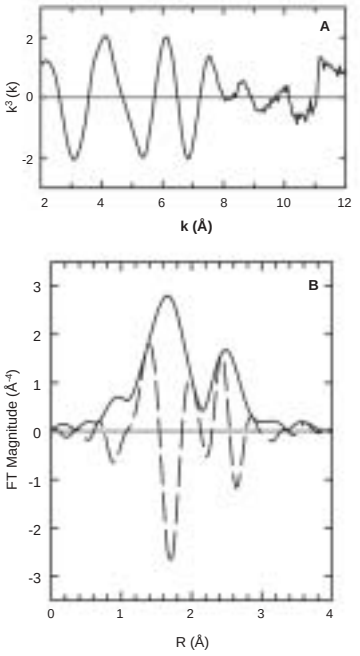

Fig. 3. k^3-weighted EXAFS function (A) and its Fourier transformation (B) about the Fe K-edge of Fe-ZSM-5 (Fe/Al = 0.33) pretreated with He.

Calculations using the FEFF 8 code show that the first of these features is attributable exclusively to scattering from O atoms bound to Fe. Similar calculations for the second peak in RSF indicate that the dominant contribution is due to scattering from the Al atom in the charge site. The theoretically derived RSF of $Z^-[Fe(OH)_2]^+$ shows close similarities to $Z^-[Fe(O)_2]^+$. The theoretical EXAFS spectra of di-iron species are more complicated than that for an isolated Fe species because of the greater number and variety of the scattering paths associated with the former species. For all di-iron structures, the peak appearing in the range of 1–2 Å can be assigned exclusively to Fe-O scattering. The peak appearing in the region of 2–3 Å is now comprised of two dominant parts – one due to Fe-Al scattering and the other due to Fe-Fe scattering. Figure 2 shows the contributions of Fe-Al and Fe-Fe scattering to the RSF peak at 2–3 Å for $Z^-[HOFe(OH)_2FeOH]^{2+}Z^-$. The results presented in Figure 2 suggest that it would be difficult to determine whether a peak appearing in the RSF for a sample of Fe-ZSM-5 is due to Fe-Fe or Fe-Al backscattering alone or is due to a combination of the two types of backscattering, if attention is given only to the magnitude function. This would be particularly true if the Fe-Fe and Fe-Al distances are nearly the same. Identification of which contribution dominates can be made, though, by comparison of the imaginary part of the RSF for the peak in the region of 2–3 Å with that characteristic of Fe-Al, Fe-Fe, or Fe-Al and Fe-Fe backscattering.

A plot of $k^3\chi(k)$and the RSF of for Fe-ZSM-5 (Fe/Al = 0.33) pretreated with He are shown in Fig. 3. Two distinct peaks are observed in the RSF when the sample pretreated in He or CO- one at about 1.6 Å and the other at about 2.5 Å. The RSF of the O_2-pretreated sample shows the same two peaks together with a new peak at about 1.1 Å. As noted earlier peaks in the region of 1–2 Å can be attributed to scattering from oxygen atoms coordinated to an iron absorber. The appearance of a new peak for Fe-O back scattering following O_2 pretreatment suggests that some of the Fe atoms have undergone a change in their environment. The peak at 2–3 Å is still observed in the RSF for O_2-pretreated sample. As discussed above this peak could be due to either Fe-Fe or Fe-Al scattering. Samples pretreated with He, O_2, and CO and non-pretreated show close similarities in the RSFs. Interestingly, the peak at 2.5 Å does not change with sample pretreatment. Even a fresh sample with no pretreatment has a magnitude comparable to that of pretreated samples. It is also evident that pretreatment in He, O_2, and then in CO has little effect on the intensities of the peaks at 1.6 Å and 2.5 Å. Comparison of RSFs of Fe-ZSM-5 with different Fe/Al ratios demonstrates that the RSF following He and CO pretreatment are virtually the same, the only significant difference being that the ratio of the peak at 1.6 Å to that 2.5 increases slightly with increasing Fe/Al ratio. After O_2 pretreatment, the peaks at 1.1 Å and 2.5 Å are independent of Fe/Al ratios, whereas the peak at 1.6 Å increases with increasing Fe/Al ratios.

The Fourier filtered EXAFS data were fitted using a model consisting of a single Fe absorber coordinated to one or two shells of O atoms and a shell of Al atoms. The decision to consider Fe-Al and not Fe-Fe, or a combination of Fe-Al and Fe-Fe backscattering was based on the shape of the imaginary portion of the RSF for the peak at 2.5 Å. Examination of Figs. 1 and 2 shows that the shape of the imaginary portion of this peak is very similar to that for Fe-Al back scattering. Only a single shell of O atoms was required to fit the data for samples pretreated in He and CO but two shells of O atoms were required to fit the data for samples pretreated in O_2. Table I shows that the coordination numbers and interatomic distances determined from a fit of the Fourier-filtered EXAFS data are virtually the same for samples of Fe-ZSM-5

Table I. *Fe K-edge EXAFS least-square fitting results for Fe-ZSM-5 with different Fe/Al ratios pretreated under different conditions.*

Pretreatment	shell	N^a	R (Å)^b	σ^2 ($\times 10^{-3}$ Å)^c	ΔE_0 (eV)^d	R-factor
Fe-ZSM-5 (0.33)

	Al	1.5	2.87	4.6	−4.4	
Fe-ZSM-5 (0.66)						
He	O	4.5	2.08	18.2	0.32	0.0417
	Al	1.1	2.88	1.8	−1.1	
O_2	O	0.4	1.40	5.3	3.2	
	O	2.4	2.02	4.9	3.2	0.0037
	Al	1.9	2.92	6.4	6.3	
Fe-ZSM-5 (0.80)						
He	O	4.6	2.11	12.9	−1.1	0.0159
	Al	1.9	2.82	5.3	−14.2	
O_2	O	0.4	1.44	7.7	4.1	
	O	2.4	2.03	3.8	4.1	0.0159
	Al	1.6	2.92	4.4	5.6	
CO	O	3.8	2.09	11.2	−1.3	0.0418
	Al	1.6	2.85	6.6	−9.7	

[a] Coordination number (±10%), [b] interatomic distances (±0.02 Å), [c] Debye-Waller factor, [d] energy shift and [e] R-factor gives a sum-of-squares measures of the fractional misfit, which is defined as

$$R = \sum_{i=1}^{N}\{[\mathrm{Re}(f_i)^2 + [\mathrm{Im}(f_i)]^2\} \Big/ \sum_{i=1}^{N}\{[\mathrm{Re}\,(\tilde{\chi}_{data}(k_i))]^2 + [\mathrm{Im}(\tilde{\chi}_{daai}(k_i))]^2\}$$

where $f_i = \tilde{\chi}_{data}(k_i) - \tilde{\chi}_{model}(k_i)$.

pretreated in He or CO, independent of the Fe/Al ratio. In all cases the coordination number of Fe with O is ∼4 and the Fe-O distance is approximately 2.1 Å. Both the coordination number and the bond distance are similar to that either $Z^-[Fe(O)_2]^+$ or $Z^-[Fe(OH)_2]^+$. The coordination number of Fe with Al ranges from 1.6 to 1.9, which is higher than that for either of the two model structures cited above. This apparent inconsistency could be a result of multiple scattering caused by the light O atoms lying along the scattering paths between Fe and Al.

5. Conclusions

The local structures of Fe in Fe-ZSM-5 with Fe/Al ratios between 0.33 and 0.80 were investigated with EXAFS. The RSF is characterized by two principal features located at 1.6 and 2.5 Å, irrespective of pretreatment conditions. The first of these peaks is associated with Fe-O scattering. Fourier analyses and EXAFS least-square fits indicate that the second peak originates from Fe-Al scattering, not from Fe-Fe scattering as has been proposed previously. The iron in Fe-ZSM-5, therefore, is present as isolated iron cations. For He- and CP pretreated samples, the structure of Fe in Fe-ZSM-5 is best described as $Z^-[Fe(O)_2]^+$ or $Z^-[Fe(OH)_2]_+$, where Z^- represents the charge-exchange site in the zeolite.

Received June 26, 2004; accepted November 4, 2004

Abstract

The Cr-containing mesoporous molecular sieves (Cr-HMS) operated as efficient photocatalyst for the decomposition of NO into N_2 and O_2 even under visible light irradiation ($\lambda > 450$ nm). This photocatalyst exhibited a sharp and intense preedge peak in the XANES region which was characteristic of Cr-oxide species in tetrahedral coordination. In the Fourier transform of EXAFS spectrum, only a single peak due to the neighboring oxygen atoms was observed and the curve-fitting analysis indicated that 4-coordinated Cr-oxide moieties having two terminal Cr=O bonds were present. The results obtained with XAFS analysis as well as the analyses with UV-VIS absorption and photoluminescence measurements indicate that the charge transfer excited state of the tetrahedrally coordinated Cr-oxide moieties play a significant role in the photocatalytic reaction under visible light irradiation.

1. Introduction

It is of special interest to design ion and/or cluster size catalysts within zeolites [1–8] because these fascinating supports offer unique nano-scaled pore systems, unusual internal surface topology, and ion-exchange capacities. The highly dispersed transition metal oxides incorporated within the zeolites and mesoporous molecular sieves show unique reactivities not only for various catalytic reactions, but also for photocatalytic reactions under UV light irradiation [1–4]. Recently, unique and efficient photocatalytic systems incorporating the transition metal oxides (Ti, V, Mo, etc.) have been designed and developed using the cavities and frameworks of zeolites and mesoporous molecular sieves [4–8]. Especially Ti-zeolites with tetrahedrally coordinated titanium oxide moieties showing unique reactivities for various photocatalytic reactions under UV-irradiation (220–260 nm) are the good candidates as the efficient and selective photocatalysts. Although these tetrahedrally coordinated Ti-oxide moieties can exhibit the unique photocatalytic reactivity, they can only adsorb and utilize UV light at around 220–260 nm to form the charge transfer excited state as active species. The design of photocatalytic systems which can operate under visible light irradiation have been desired. Previously, we have found that the metal ion-implantation of TiO_2 with highly accelerated transition metal ions is useful to design photocatalysts which can operate efficiently under visible light irradiation [9]. Although this metal ion-implantation technique can be applied to the metal oxides incorporated in the zeolites, it has been desired earnestly that the photocatalysts responsive under visible light irradiation should be prepared by conventional chemical processes.

In the present study, Cr-containing mesoporous molecular sieves (Cr-HMS) have been prepared by the conventional chemical method. Their photocatalytic reactivities under visible light irradiation were investigated and the local structure of Cr-oxide active sites were studied by spectroscopic techniques such as XAFS, UV-Vis absorption, and photoluminescence measurements.

2. Experimental

The chromium containing mesoporous zeolite molecular sieves (Cr-HMS)(Si/Cr = 50, 635 m^2/g) was synthesized using tetraethylorthosilicate and $Cr(NO_3)_3 \cdot 9H_2O$ as the starting materials and dodecylamine as a template [10, 11]. The chromium-silicalite (CrS-1, 190 m^2/g) microporous zeolite (Si/Cr = 100) was hydrothermally synthesized using tetraethoxysilane and $Cr(NO_3) \cdot 9H_2O$ as starting materials and tetrapropyl ammonium hydroxide (TPAOH) as a template in accordance with previous literature [12]. Imp-Cr/HMS zeolite (Si/Cr = 50, 615 m^2/g) were prepared by impregnating HMS with an aqueous solution of $Cr(NO_3)_3 \cdot 9H_2O$. Calcination of the sample was carried out in a flow of dry air at 773 K for 5 h. Prior to spectroscopic measurements and photocatalytic reactions, the catalysts were degassed at 723 K for 2 h, heated in O_2 at the same temperature for 2 h and then finally evacuated at 473 K for 2 h to 10^{-6} Torr.

The photocatalytic reactions of NO molecules were carried out with the catalysts (100 mg of the catalyst involving zeolite) in a quartz cell with a flat bottom (80 ml) connected to a conventional vacuum system (10^{-6} Torr range) [7]. The light irradiation of the catalysts in the presence of NO (135 μmol/g-cat) was carried out at 275 K under UV light ($\lambda > 270$ nm) or visible light ($\lambda > 450$ nm) using a high pressure mercury lamp through water and color filters. The reaction products were analyzed by gas chromatography.

XRD patterns were obtained with a Shimadzu XD-D1 using Cu Kα radiation. The XAFS spectra (XANES and EXAFS) were measured at the BL-9A facility [13] of the Photon Factory at the National Laboratory for High-Energy Physics, Tsukuba. A Si(111) double crystal was used to monochromatize the X-rays from the 2.5 GeV electron storage ring. The Cr K-edge absorption spectra were recorded in the fluorescence mode at 295 K. In a typical experiment, 50 mg of the sample pressed into a disc was loaded into the *in situ* cell having the Kapton windows. The normalized spectra were obtained by a procedure described in previous literature [14] and Fourier transformation was performed on k^3-weighted EXAFS oscillations in the range 3–10 $Å^{-1}$. The curve-fitting of the EXAFS data was carried out by employing the iterative nonlinear least-squares method and the empirical backscattering parameter sets extracted from the shell features of reference compounds. The diffuse reflectance UV-Vis absorption spectra were recorded with a Shimadzu UV-2200A spectrometer at 295 K. The in situ photoluminescence spectra the catalysts were measured at 77 K with a Shimadzu RF-501 spectrofluorophotometer.

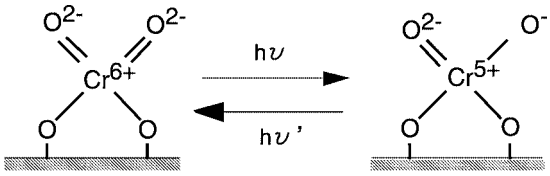
3. Results and discussion

Cr-HMS mesoporous molecular sieves exhibited a single peak at around 2° in the XRD patterns indicating that the Cr-HMS has the structure of the HMS mesoporous molecular sieves having pores larger than 20 Å and the Cr-oxide moieties are highly dispersed in the zeolite framework, while no other phases are formed [10, 11]. Also the results of XRD analysis indicated that imp-Cr/HMS keeps the mesoporous structure and CrS-1 has the MFI zeolite structure without a formation of crystalline Cr-oxide species.

Figure 1 shows the XAFS spectra of the pretreated imp-Cr/HMS, Cr-HMS and CrS-1. The imp-Cr/HMS exhibits a weak preedge peak in the XANES spectra and an intense peak due to the neighboring Cr atoms (Cr-O-Cr) in the Fourier transform of EXAFS, indicating that the catalyst consists of a mixture of tetrahedrally and octahedrally coordinated Cr-oxide species (Cr_2O_3-like cluster). Cr-HMS exhibits a sharp and intense preedge peak which is characteristic of Cr-oxide moieties in tetrahedral coordination [15–17]. In the Fourier transform of EXAFS, only a single peak due to the neighboring oxygen atoms (Cr-O) can be observed showing that Cr ions are highly dispersed in Cr-HMS. In the curve fitting analysis of the EXAFS of Cr-HMS, the best fitting was obtained with two oxygen atoms (Cr=O) in the shorter atomic distance of 1.57 Å and two oxygen atoms (Cr-O) in the long distance of 1.82 Å. CrS-1 also exhibits an intense preedge peak indicating the presence of Cr-oxide in tetrahedral coordination and only a single peak due to Cr-O bond can be observed. The peak position of Cr-O bond with CrS-1 is the longer than that of Cr-O bond observed with Cr-HMS. In the curve fitting analysis of the EXAFS of CrS-1, the best fitting was obtained with four oxygen atoms (Cr-O) in the atomic distance of 1.78 Å.

Figure 2 shows the diffuse reflectance UV-Vis absorption spectra of the degassed and hydrated Cr-HMS, degassed CrS-1, and K_2CrO_4 aqueous solution. The degassed Cr-HMS exhibit three distinct absorption bands at around 270, 370, 480 nm which can be assigned to the charge transfer from O^{2-} to Cr^{6+} of the tetrahedrally coordinated Cr-oxide moieties [18, 19]. The absorption bands assigned to the absorption of the dichromate of Cr_2O_3 cluster cannot be observed above 550 nm, indicating that tetrahedrally coordinated Cr-oxide moieties exist in an isolated state. On the other hand, the degassed CrS-1 exhibit two distinct absorption bands at around 280, 380 nm and the band in the visible light region ($\lambda > 450$ nm) can be hardly observed. These absorption bands are very similar to those of K_2CrO_4 aqueous solution which has the Cr^{6+} ions tetrahedrally coordinated by oxygen atoms in the same distance of Cr-O bond. In the hydrated Cr-HMS, the two bands in the region of UV light shift to the longer wavelengths (280, 380 nm) and the intensity of the band in the region of visible light (480 nm) decreases, indicating that the coordination geometry of Cr-oxide moieties in the hydrated Cr-HMS changes to be similar to those of CrS-1. These differences in the absorption spectra among the catalysts well reflect the changes in the coordination geometry of Cr-oxide moieties, as suggested in the XAFS analysis.

Cr-HMS evacuated at 473 K exhibited a photoluminescence spectrum at around 550–750 nm upon excitation of the absorption (excitation) band at around 250-550 nm. Figure 3 shows the photoluminescence spectra of Cr-HMS observed at 77 K upon the excitation at 280, 370, and 500 nm, respectively. The photoluminescence upon the excitation at these wavelengths observed at the same position, while the intensities of spectra depend on the wavelength of excitation. In the excitation spectrum



Scheme 1. Charge transfer processes on the tetrahedrally coordinated Cr-oxide moieties.

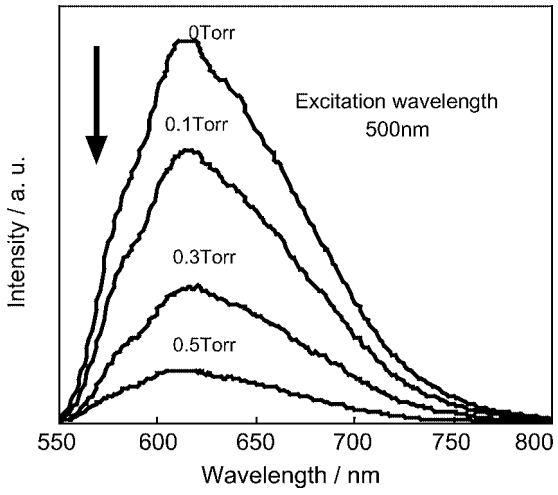


Fig. 4. Effects of the addition of NO on the photoluminescence spectra of the Cr-HMS at 77 K.

of Cr-HMS monitored at 640 nm, three excitation bands are observed at 280, 370 and 500 nm, which are almost corresponding to the absorption bands observed in the UV-Vis absorption spectra shown in Fig. 2. No change in the positions of these absorption bands is observed with changing the monitoring wavelength of photoluminescence, indicating that the photoluminescence occurs as the radiation decay process from the same excited state independently to the excitation wavelength. These absorption and photoluminescence spectra are similar to those obtained with well-defined highly dispersed Cr-oxides anchored on silica and can be attributed to the charge transfer processes on the tetrahedrally coordinated Cr-oxide moieties involving an electron transfer from O^{2-} to Cr^{6+} and a reverse radiative decay, respectively [20, 21]. These results indicate that the Cr-HMS mesoporous molecular sieve involves Cr-oxide moieties in tetrahedral coordination having two terminal Cr=O, being in good agreement with the results obtained by XAFS, and UV-Vis measurements. The estimated model for the local structure of the Cr-oxide moieties and the charge transfer processes are shown in Scheme 1.

Figure 4 shows the effects of the addition of NO on the photoluminescence spectra of the Cr-HMS at 77 K. The addition of NO onto the Cr-HMS leads to an efficient quenching of the photoluminescence in its yield, its extent depending on the amount of NO added. The observation of the efficient quenching by the NO addition indicates that the charge transfer excited state of the tetrahedrally coordinated isolated Cr-oxide moieties, $(Cr^{5+}-O^{-})^*$, easily interact with NO under UV light and visible light irradiation.

UV light irradiation ($\lambda > 270$ nm) of the Cr-HMS in the presence of NO led to the photocatalytic decomposition of NO and the evolution of N_2, N_2O and O_2 in the gas phase at 275 K. The Cr-HMS also shows photocatalytic reactivity even

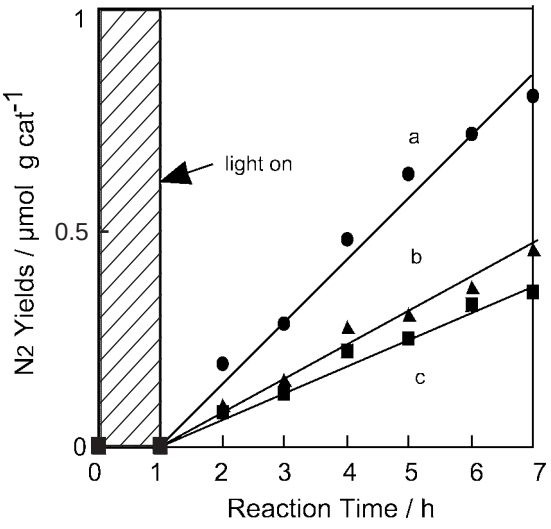

Fig. 5. Reaction time profile of the N_2 formation in the photocatalytic decomposition of NO on the Cr-HMS ($\lambda > 270$ nm) (a), imp-Cr/HMS ($\lambda > 270$ nm) (b), Cr-HMS ($\lambda > 450$ nm) (c) at 273 K.

under visible light irradiation ($\lambda > 450$ nm). As shown in Fig. 5, the N_2 yields increase linearly to the irradiation time. The formation of these reaction products were not detected in the dark conditions nor in irradiation of the HMS itself without Cr-oxide. These results clearly indicate that the presence of both Cr-oxide species included within HMS as well as light irradiation are indispensable for the photocatalytic reaction to take place and the direct decomposition of NO to produce N_2, O_2 and N_2O occurs photocatalytically on the Cr-HMS. Although the reaction rate under the visible light irradiation is smaller than under UV light irradiation ($\lambda > 270$ nm), the selectivity for N_2 formation (97 %) under visible light irradiation ($\lambda > 450$ nm) is higher than that of UV light irradiation (45 %). These results indicate that Cr-HMS can absorb visible light and act as an efficient photocatalyst under not only UV light but also visible light irradiation and especially Cr-HMS can exhibit the high selectivity to form N_2 under visible light irradiation. On the other hand, imp-Cr/HMS exhibit the smaller reactivity than the Cr-HMS and CrS-1 exhibited no reactivity under visible light irradiation. These results indicate that the presence of Cr-oxide having the tetrahedral coordination with the terminal Cr=O bond is essential to the demonstration of photocatalytic reactivity even under visible light irradiation.

4. Conclusions

The present results have clearly demonstrated that the Cr-HMS with mesoporous structure and tetrahedrally coordinated Cr-oxide moieties can exhibit the efficient reactivity for the photocatalytic decomposition of NO under visible light irradiation ($\lambda > 450$ nm). Cr-HMS contains tetrahedrally coordinated Cr-oxide moieties in the framework having two terminal Cr=O and that the charge transfer excited state of the Cr-oxide moieties are responsible for the efficient photoluminescence and photocatalytic reactivities. This photocatalytic system with tetrahedrally coordinated Cr-oxide moieties dispersed on mesoporous zeolite molecular sieves seems to be a good candidate to use abundant visible or solar light energy for the useful chemical synthesis.

Abstract

We report a near-edge X-ray absorption spectroscopy (NEXAFS) study of the C K-edge of C_{60} molecules interacting with Si(100) and Si(111) surfaces. Annealing the C_{60}/Si systems at 1050 K induces fullerene fragmentation and leads to SiC nucleation. Tuning the probing depth and studying polarization dependence, the NEXAFS results shed light on the evolution of the molecular states after thermal treatment, up to the fullerene fragmentation and SiC formation. The NEXAFS spectra of a single layer of C_{60} deposited at 670 K onto both surfaces show a strong C_{60}-substrate interaction. A polarization dependence of the spectra can be detected; this behaviour is similar to the results obtained on C_{60} covalently chemisorbed on Al surfaces. We find, for both substrates, that fullerene fragmentation starts at the C-Si interfaces, involving the C atoms lying close to the Si substrate, implying an increase of the number of C-Si bonds at the fragmentation stage.

1. Introduction

C_{60} interacts strongly with Si susbtrate atoms, forming a covalent C-Si bond. Decomposition of C_{60} takes place on Si(100) above $\cong$ 1000 K, and the SiC formation takes place by nucleation [1, 2, 3, 4]. STM results show that on both, Si(100) and Si(111) substrates, the fragmentation of the C_{60} cages starts locally. Large SiC islands are formed at temperatures higher than 1050 K, after cage decomposition. Under the appropriate growth conditions, it is possible to grow ordered phases on different Si substrates [5, 6] obtaining the cubic polytype 3C-SiC. A remarkable point is that with this procedure SiC can be grown at a temperature ($T \cong 1000$ K) significantly lower than with other methods ($T >$ 1300 K) and this could improve the structural quality of the interface between SiC and Si to integrate Si-SiC technology. Hamza *et al.* [1] showed that thermal fragmentation of C_{60} on Si(111)-(7 × 7) can lead to an ordered 3C-SiC thin film oriented in register with the substrate. X-Ray diffraction measurements [7] show that well ordered 3C-SiC can be obtained by depositing C_{60} precursors on Si(100) and demonstrate that the occurrence of extra-phases can be properly limited by choosing the appropriate substrate temperature and deposition rate during C_{60} deposition. Co-deposition of Si and C_{60} on heated Si substrate leads to higher quality SiC films.

NEXAFS is a mature technique to study the electronic structure of molecules deposited on surfaces [8]. Here NEXAFS spectroscopy is used to study the evolution of the C_{60} molecular empty states in C_{60}-Si interfaces as a function of the annealing temperature, up to the fullerene fragmentation and SiC formation. The study was performed by varying the probing depth by using different detection modes (Auger Yield and Total Yield with probing depth of 8 Å [9] and more than 50 Å, respectively), and by changing the light polarization direction with respect to the surface. The NEXAFS spectra of a single layer of C_{60} deposited at 300 K and annealed at 670 K onto both surfaces, show a strong C_{60}-substrate interaction, confirming literature results [10]. A polarization dependence of the spectra can be detected, similarly to the behavior observed when C_{60} is chemisorbed on Al surfaces [11]. In this latter case the C_{60} molecules interacted with the surface via a covalent bond, similar to the case studied here of C_{60} absorption on Si surfaces, even though for Si substrates the bond also involves the LUMO + 1 states. By changing the detection mode (Auger yield and total yield), we were able to distinguish the more external molecular states configuration with respect to the C-Si interface during thermal C_{60} fragmentation and SiC nucleation. Our results show that fullerene fragmentation starts from the C-Si interfaces, with the disruption of the C_{60} molecular states toward the bulk, i.e. involving the C atoms lying close to the Si substrate atoms. This result indicates the increase of the number of C-Si bonds at the interface during fragmentation.

2. Experimental

The C_{60}/Si systems were studied by XAS and photoemission spectroscopy. The preparation of Si(100) and Si(111) clean substrates and the C_{60} deposition from crucible were performed according the procedures of refs. [2] and [5]. Thermal treatments of C_{60} deposited on Si substrates were made for a time of 5 minutes at different temperatures in ultra high vacuum. Temperatures were measured by a pyrometer and thermocouple (experimental error about ±10 K). Islands of cubic SiC were produced by fullerene deposited on the Si(100) substrate and annealed at high temperature ($T >$ 1060 K) [1, 5, 6]. Measurements at the C absorption edge of C_{60} deposited on the Si(111) surface were taken at the ALOISA beamline of the ELETTRA synchrotron (Trieste, Italy) [12] by using the drain current detection mode. The energy resolution was 80 meV for the NEXAFS spectra, and the typical photon flux on the sample was of the order of 10^{11} photons/s. Spectra were recorded both in s and p incidence (with the $\boldsymbol{E}$ vector of the impinging light at respectively, 90° and 7° with respect to the surface normal).

NEXAFS of the fullerene interacting with Si(100) surface and 3C-SiC ordered films were performed on the BEAR beamline

*e-mail: pedio@tasc.infm.it

of ELETTRA [5]. The ***E*** light vector of the impinging photons was in the surface plane. The energy resolution was 80 meV for the XANES spectra, and the typical photon flux on the sample was of the order of 10^{10} photons/s. The NEXAFS spectra have been measured in total electron yield, drain current (sampling depth >50 Å) and Auger Yield modes. In the Auger Yield mode, a CMA analyser was tuned at the C LVV Auger line of Kinetic Energy ≈270 eV, estimated sampling depth ≈8 Å [9].

Photoemission from the C 1s and Si 2p and valence bands were measured by an electron analyser (an angular integrated CMA for BEAR and an angular resolved Hemispherical analyzer for ALOISA) for a deeper characterization of the systems.

All the spectra were measured at room temperature and normalized to the incident photon flux obtained by measuring simultaneously the current drained by a tungsten grid inserted in

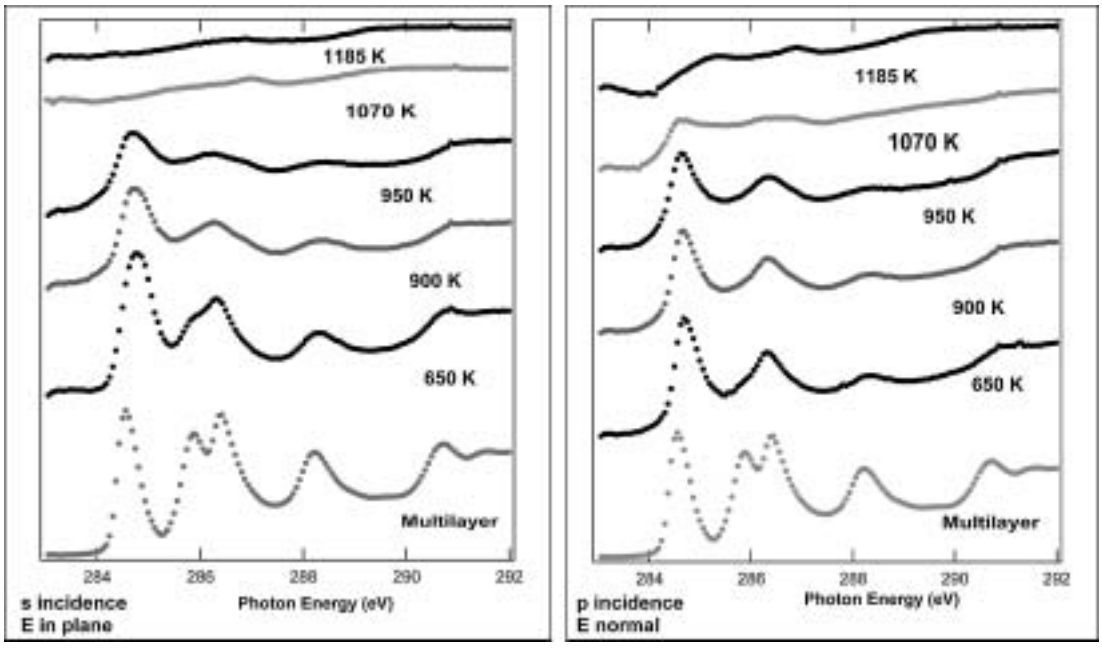

Fig. 1. The evolution of the C K-edge NEXAFS spectra (drain current) measured in s and p incidences for the C_{60}/Si(111) system as a function of annealing temperature. A thick C_{60} film (multilayer) is shown for comparison.

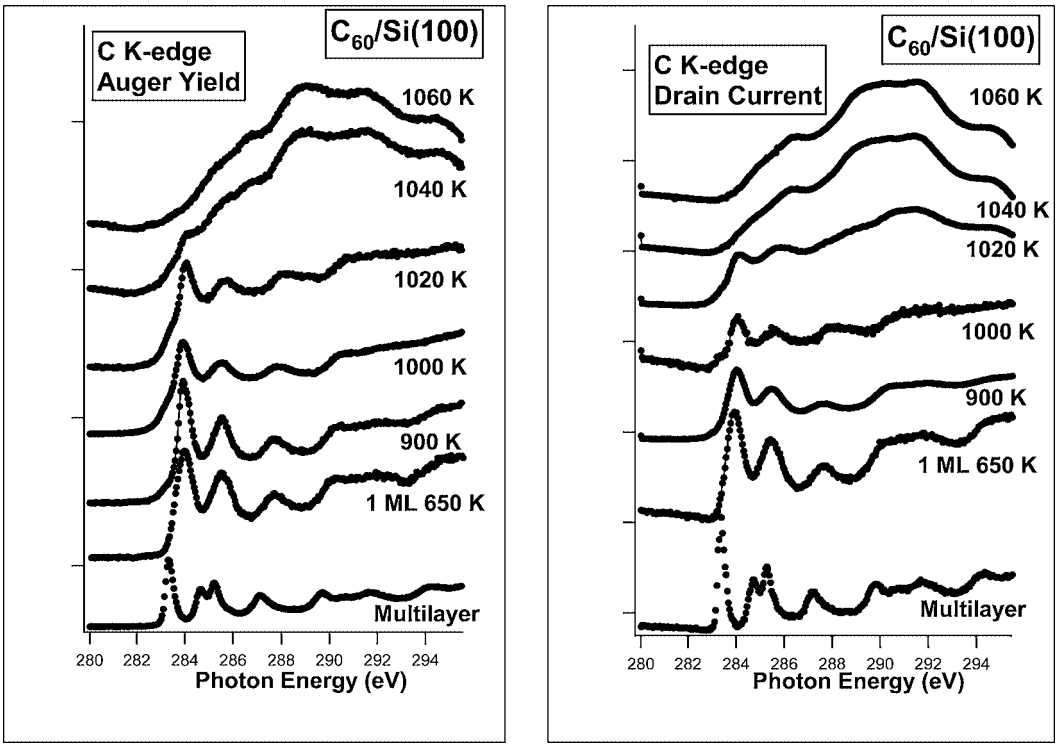

Fig. 2. Evolution of the C K-edge NEXAFS spectra for the multilayer C_{60} and 1 ML of C_{60}/Si(100) system after different annealing treatments as measured simultaneously in two detection mode: the most surface sensitive Auger Yield (left) and Drain Current (right). The geometry was such that the ***E*** light vector of impinging photon was in the surface plane. The temperature is indicated in Kelvin. Thick C_{60} film (multilayer) is shown for comparison.

the beam path. The tungsten grid was previously heated at high temperature to remove contaminants.

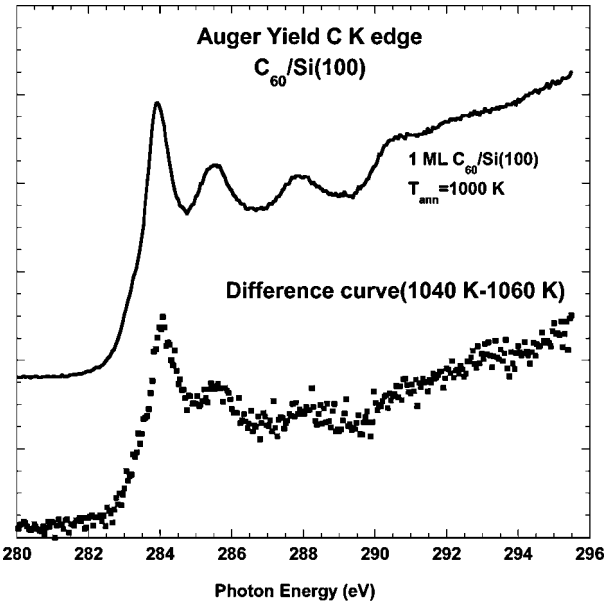
3. Results and Discussion

The NEXAFS spectra of the C K-edge of the C_{60}/Si(111) system as a function of annealing temperature are reported in Fig. 1. The multilayer C_{60} spectrum is shown for comparison. The evolution of the molecular empty states of the fullerene molecules as a function of annealing temperature was studied both in s (left panel) and p (right panel) light incidence mode, with the E vector of the impinging light at respectively, 90° and 7° with respect to the surface normal. Fig. 2 shows the C K-edge NEXAFS spectra for the 1 ML C_{60}/Si(100) system as a function of annealing temperature, measured in the two detection mode (Auger yield, left panel, and drain current, right panel) up to the molecule fragmentation and the SiC island formation. A C_{60} multilayer spectrum is shown for comparison. The spectra of the C_{60} multilayer are largely independent of the light incidence (s or p), the probing depth and the Si substrates. The first four peaks of the C_{60} multilayer NEXAFS correspond to molecular states with π character (ref. [10] and refs therein).

The NEXAFS spectra of a single layer of C_{60} deposited at 300 K on both surfaces and annealed at 670 K (Fig. 1 and Fig. 2), show a strong C_{60}-substrate interaction with a broadening of the transition involving mainly the LUMO and LUMO + 1 π character states, confirming literature results [10]. This behavior is similar to the one observed when C_{60} is chemisorbed on Al surfaces [11], where the C_{60} molecules interact with the surface with a bonding similar to the case here studied. In the case of Si substrates the effect of the anisotropy of the fullerene molecular states toward the bulk and out of the surface appears even more pronounced and involves also the LUMO + 1 state (see spectra annealed at 670 K), as already found by authors in ref. [10]. Similar results are found for the C_{60}/Si(100) single monolayer. The study of the connection between the NEXAFS data and the C_{60} orientation will be discussed in a forthcoming paper. Increasing the annealing temperature the molecular states become even broader and above 1060 K the SiC island formation takes place, with the gradual vanishing of molecular features. A polarization dependence of the spectra can be detected when the spectra are measured in s or p incidences for the C_{60}/Si(111) system (Fig. 1). The LUMO molecular state has a different broadening in the two different incidences (i.e. it is broader in s incidence) and at 1070 K it can be distinguished only in p incidence.

The NEXAFS spectra in both systems show that molecular states during fragmentation are more intense in p incidence geometry. Comparing the high annealing temperature spectra of C_{60}/Si(111) system, spectra obtained in p incidence show more pronounced features. This can be taken as evidence that the final state of the transitions have π character, pointing outward the surface.

The thermal treatment of the C_{60}/Si(100) system in the high temperature range of 950–1070 K (Fig. 2) induces a further broadening of the C_{60} molecular features, that still remain distinguishable, up to 1040 K. Fragmentation of the molecule starts for an annealing temperature above 1020 K. By varying the probing depth additional information is obtained. In fact, in the spectra obtained in the surface sensitive mode (Auger Yield probing depth of 8 Å, of the order of the fullerene dimension 7 Å), C_{60} features are recognizable, while they are washed out when using a higher probing depth, of the order of 50 Å. This result is shown by the data in Fig. 3a, where the NEXAFS spectrum taken with a probing depth of 8 Å for 1 ML C_{60}/Si(100) after annealing at 1000 K is compared with the difference curve obtained by subtracting the NEXAFS spectra after 1040 K minus



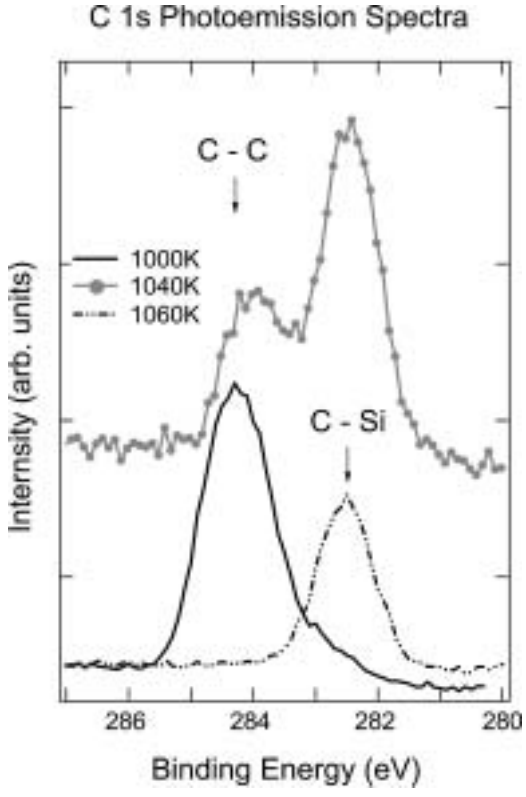


Fig. 3. (a) NEXAFS difference curve of the spectra taken in Auger yield mode on the C_{60}/Si(100) systems after 1040 K and 1060 K annealing temperature. The difference spectrum is compared with the spectrum in AY taken after an annealing treatment at 1000 K in Fig.2. (b) C 1s XPS spectra of one C_{60} ML annealed at different temperatures, measured at photon energy of 380 eV. In the bottom are shown the C 1s spectrum of the C_{60} ML annealed at 1000 K (straight line), where almost carbon are in the C-C bond, and the spectrum of the C_{60} ML annealed at 1060 K (dotted line), where all the C atoms reacted with the substrate to form SiC. The spectrum of the top (system annealed at 1040 K) clearly shows the two components due to C-C and C-Si bonds.

1060 K annealing temperature taken at the same probing depth. The difference curve was calculated in order to make evident the molecular features that are present in the 1040 K spectrum and completely vanish in the 1060 K spectrum, taken as reference for C in the SiC state. Note that the geometry was such that the E light vector of the impinging photon was parallel to the surface plane. This means that the set of C atoms in the external layer of the C_{60} cage is the last to be perturbed by the annealing and that C_{60} decomposition first takes place at the C atoms in contact with the Si substrate atoms with a gradual increase of the number of Si-C bonds [2, 5].

Photoemission results reported in Fig. 3b, indicate that two C inequivalent bonds are present after having annealed at 1040 K. The two different bonds are assigned [4] to the C-C bond at 284.2 eV and to the C-Si bond at 282.6 eV.

Summarizing our data indicates that the C_{60} fragmentation starts at a temperature of about 1020 K. By changing the probing depth of NEXAFS, after thermal C_{60} fragmentation and SiC nucleation, we found that the residual molecular states of the fragmented C_{60} cage are localized on the topmost surface layer, i.e. they are at the more external site with respect to the C-Si interface. The feature intensities behaviour of the electric field direction for the $C_{60}/Si(111)$ system show that the molecular fragment have π character and are likely directed almost orthogonal to the surface. This topic will be discussed in a forthcoming paper.

4. Conclusions

We studied the molecular state evolution of C_{60} deposited on silicon (100) and (111) surfaces. The study was based on optical absorption at the C K-edge and on its dependence on the direction of the electric field at the surface. Additional information was obtained by using different probing depths in the acquired spectra.

The NEXAFS C K-edge results on both systems during annealing show that the outer molecular states of the C_{60} cage endure up to annealing temperature as high as 1040 K. These residual fragment molecular states are π orbitals directed normal to the surface.

Abstract

EXAFS and XANES at the Pd and Sn K-edges have been used to characterise a novel palladium doped Sn/SnO_x nanocomposite that have found application in a new type of high performance solid-state gas sensor. The spherical nanoparticles (10 to 65 nm diameter) prepared either by co-decomposition of Sn and Pd organometallic precursors (doping in volume) or by decomposition of a palladium precursor on preformed Sn/SnO_x core-shell nanoparticles (doping in surface) consist of a tin metallic core surrounded by some small platelets of a well-crystallised material embedded in an outer layer of amorphous tin oxide. In this layer tin atoms in an oxidation state close to +IV, are four-fold coordinated to oxygen with bond distances slightly larger than in bulk cassiterite SnO_2. In both samples palladium was found to be always in a metallic state, only surrounded by Sn and Pd atoms located at unusually short distances. The two samples that differ mainly by their Pd coordination number present very different morphologies and electrical properties when fully oxidised. A possible location of the Pd atoms in these two materials is proposed.

1. Introduction

A new high performance gas sensor using the integrated circuit technology [1, 2] has been designed by depositing a drop of a suspension of a novel Sn/SnO_x nanocomposite [3, 4] doped with Pd onto a silicon die. This drop is then heated up to 600 °C using the integrated heater and a thin film of highly sensitive Pd doped nanostructured SnO_2 is generated onto the surface of the silicon wafer [2]. The suspension of monodisperse nanoparticles of Pd doped Sn/SnO_x [5] is prepared by a new chemical method based on the decomposition of Sn and Pd organometallic precursors in a controlled water/anisole mixture. Two different synthesis routes have been investigated: co-decomposition of Sn-based and Pd-based organometallic precursors (doping in volume) and decomposition of a palladium precursor on preformed Sn/SnO_x nanoparticles (doping in surface). A subsequent heat-treatment of these colloids carried out at 600 °C leads in all cases to Pd-doped SnO_2 nanoparticles that retain the same size and morphology. If the surface doping leads to a big improvement of the conducting properties of the oxidised sensor material, the volume doping produces a material that features poorer electrical properties than the undoped one. These contradictory results show that a detailed investigation of the structure and electronic properties of these nanocomposites is crucial to achieve a full understanding of the relationship between their structure and electrical properties. Mössbauer spectroscopy, XPS, HRTEM and X-ray diffraction have been already applied to characterise these colloids [4] but these techniques have shown some limitations due to the complex nature of these materials.

We report here an EXAFS and XANES study carried out both at the Sn and Pd K-edge of these two Pd doped Sn/SnO_x samples prepared by two different methods. The aim of this investigation is to complement the characterisation methods already used by a local order sensitive probe in order to better characterise the local structure and the electronic properties as well as to determine the dopant location in these colloids, precursors of the SnO_2-based sensor nanomaterials. This should allow for a better monitoring of the synthesis process that is essential to develop a reproducible low-cost synthetic method for large-scale production.

2. Experimental

2.1. *Preparation of the nanocomposites*

2.1.1. *Preparation of Pd doped in surface [Sn/SnO_x] colloidal suspension.* Preparation of the pure tin colloid from the $[Sn(NMe_2)_2]_2$ precursor in anisole containing traces of water follows the route described previously [3, 4]. The palladium precursor $[Pd(dba)_2]$ in anisol was added to a colloidal suspension of pure Sn/SnO_x ($[Pd]/[Sn] = 4\%$). After exposition to 1 bar of CO during 20 mn, depressurisation, decantation, filtration and drying under vacuum, a black powder was obtained and sampled by TEM.

2.1.2. *Preparation of Pd doped in volume [Sn/SnO_x] colloidal suspension.* The palladium precursor $Pd(OAc)_2$ was added to a solution of $[Sn(NMe_2)_2]_2$ in anisole containing traces of water in a Pd/Sn ratio of 8 wt%. The solution was then heated at 135 °C for 3 hours under magnetic stirring and a black suspension was obtained. After decantation the black precipitate was washed with anisole and sampled by TEM.

2.2. *Electron microscopy*

Samples for HRTEM studies were prepared in a glove box by slow evaporation of a drop of suitably diluted colloidal suspensions deposited on holey carbon-covered grids. The HRTEM experiments were performed at the "Service Commun de Microscopies de l'Université Paul Sabatier" on a JEOL JEM 2010 electron microscope working at 200 kV.

2.3. *X-ray Absorption Spectroscopy*

X-ray absorption data were collected on beamline 9.2 (CLRC Daresbury Laboratory, UK), operating under beam conditions of 2 GeV, 200 mA using a Si (220) double-crystal monochromator. XAS signals were measured in transmission mode at the Sn K-edge and in fluorescence mode using a 13-channel solid-state detector at the Pd K-edge. The spectra were recorded at 80 K by

*E-mail: D.Grandjean@chem.uu.nl

cooling the samples with a cold finger liquid-nitrogen cryostat. Appropriate amounts of sample were finely ground with boron nitride and pressed into 13 mm pellets producing a suitable edge jump. Data reduction of experimental X-ray absorption spectra was performed using the program EXBROOK [6]. EXAFS refinements with k^2 weighting were carried out with EXCURV98 [6] using Fourier filtering techniques with the same filter windows (0.8–4.0 Å).

3. Results and discussion

3.1. *Electron Microscopy*

Figure 1a shows the HRTEM image of a typical surface-doped nanoparticle in colloidal suspension that is clearly composed of a crystallised core of ca. 12 nm diameter surrounded by some small platelets of a well-crystallised phase embedded in an outer layer of amorphous material of ca. 4 nm thickness. XRD and Mössbauer results are consistent with the presence of an amorphous tin oxide surface layer surrounding a β crystallised tin core [4]. However, the coordination and oxidation state of tin in this layer as well as the exact nature of the platelets that are absent in the pure Sn/SnO_x material remain unclear. Figure 1b displays a HRTEM image of a typical volume-doped particle [5]. It is obvious that the particle size has increased dramatically to reach ca. 65 nm in diameter. As in the case of surface doped particles, the core of the particle appears to be surrounded by platelets of a rather crystalline material embedded in an outer amorphous layer.

3.2. *XANES*

3.2.1. *Sn K-edge.* Background corrected and normalised XANES of the two nanocomposites that are presented in Figure 2 along with Sn metal and bulk SnO_2 taken as references, show that the two nanomaterials have a very similar XANES profile. They both feature the white line characteristic of the oxide species but with a lower intensity than for the SnO_2 reference compound showing that the average oxidation state of Sn in this material is lower than in bulk SnO_2. Compared to SnO_2, the nanocomposites XANES spectra are also characterised by damped resonance peaks that usually shows the presence of a disordered phase and/or a large number of surface atoms. A mixture of an amorphous SnO_2 phase and a tin metallic phase is a possible explanation of the shape of this XANES profile.

3.2.2. *Pd K-edge.* Figure 3 shows the background corrected and normalised XANES of the two nanomaterials along with bulk PdO and bulk Pd presented as references. The two XANES spectra are almost identical and seem to have the same average electronic structure. The general profile of the spectrum of the Pd doped samples is similar to the one of bulk metallic Pd but with very much damped resonance peaks indicating the presence of disorder in the material and/or nanosize structures. The PdO spectrum has a totally different shape and its edge position is obviously shifted towards the higher energies as one might expect it for a higher oxidation state. The XANES analysis can already show that the Pd doped Sn/SnO_x samples are not oxidised and have an electronic

structure close to the metallic state but with very small particle size and/or an amorphous character.

3.3. *EXAFS*

Results of the EXAFS structural refinements for the Sn and Pd K-edges measurements are summarised in Table I.

3.3.1. *Sn K-edge.* The phase corrected Fourier transforms (FT's) of the two Pd doped-samples are gathered in Figure 4. As the XANES data already showed, both nanocomposites feature a very similar FT. The first peak could be fitted for both samples with 3.3 O located at 2.071–2.073 Å from the central atom (Table I). This is similar to the values found for the undoped Sn/SnO$_x$ materials [7]. If we take into account the part of the Sn that belongs to the core of the colloid, the tin atoms in the oxidised phase are then likely to be 4 fold coordinated to oxygen [7]. The corresponding bond distances are only slightly larger than in bulk SnO$_2$ (2.045 Å) indicating that Sn has an oxidation state close to +IV. The second peak in the FT could be fitted with ca. 1 Sn atoms located at 3.00–3.010 Å from the Sn scatterer atom. This distance does not correspond to the Sn-Sn distance in SnO (3.515 Å) or SnO$_2$ (3.187 Å) tin oxides but to the bond distances in the tin metallic phase (3.022 Å) [8]. The relative amount of metallic tin atoms in the colloid was estimated using the Sn coordination number at ca. 25% [7]. The low intensity of the peaks beyond the metal tin shell show that the tin oxide phase is mainly in a disordered and/or amorphous state confirming the presence of a dispersed matter pointed out by HRTEM. The general fit of the surface-doped sample was slightly improved when a shell of ca. 0.1 Pd atoms located at 2.58 Å was added to the EXAFS model.

3.3.2. *Pd K-edge.* The Fourier transforms of the two nanomaterials presented in Figure 5 are different from one another. The results of the EXAFS refinement (Table I) show that the environment around the Pd atoms is composed for both samples of ca. 2.7 Sn atoms, located at a distance of 2.55 Å in the case of the volume-doped sample, and at a distance of 2.58 Å, consistent with the Sn K-edge fit results, in the surface-doped sample. These distances are shorter than tin-palladium bond lengths in alumina supported catalysts (ca. 2.63 Å) already reported by Choi *et al.* [9] and Pd-Sn distances in the Pd$_2$Sn phase (Pd-Sn 2.608 Å) [8]. Both samples feature a second shell of palladium atoms consisting of 2.3 atoms located at 2.77 Å for the surface-doped sample and of only 0.5 atoms located at 2.71 Å for the volume-doped sample. No other peaks could be detected indicating together with the XANES results that the Pd phase is rather amorphous and/or that this phase is composed of very small particles that are not oxidised but part of a metallic phase. The Pd-Pd distances found in these two samples (2.71–2.77 Å) are slightly different than the typical

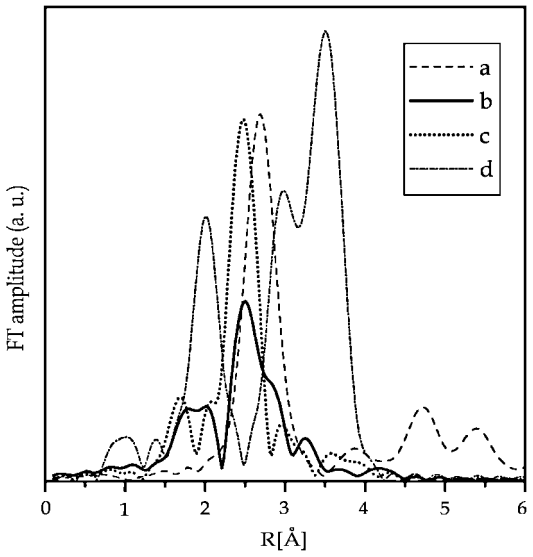

Fig. 5. Fourier Transforms of the k^3-weighted (references) or k^2-weighted Pd K-edge EXAFS of **a**: bulk Pd; **b**: Pd surface-doped Sn/SnO_x; **c**: Pd volume-doped Sn/SnO_x; **d**: bulk PdO.

bond distance of the palladium metallic phase (Pd-Pd 2.751 Å) [8]. The small discrepancy observed in the bond distances (ca. 1–2%) between the two samples may indicate that Pd atoms are in different locations and have different environments in each sample. The very low value of the Pd coordination number found for the volume-doped sample indicates that a better mixing of the Sn and Pd atoms occurs during the preparation process.

By combining the EXAFS results with the TEM images it is possible to propose two locations of the Pd dopant atoms in these nanomaterials. The first one is in small platelets of pure Pd surrounded by a tin/tin oxide interface located around the tin metallic core. These platelets were observed in both samples but mainly in the surface-doped one. The second location is in the Sn metallic core of the particle in which they form a bulk alloy with Sn and/or an Sn/Pd phase. A combination of these two locations seems to occur in the volume-doped sample.

Pd doped samples have been tested for their electrical properties after a full oxidation at 600 °C, in the working conditions of the gas sensor. The two Pd doped samples feature very different electrical properties. If the sample doped in surface shows an approximately 2-fold increase in its sensitivity to gases like CO compared to the undoped SnO_2 samples [10], the volume-doped sample features very poor electrical properties with a very high resistivity. The high amount of Pd (8 wt%) that has been used in this case as well as the different morphology could explain the dramatic change of the electrical properties in this sample.

4. Conclusion

The EXAFS and XANES results showed that the major part of tin in both Pd doped Sn/SnO_x nanocomposites is forming an amorphous oxide phase in which Sn atoms in an oxidation state close to +IV, are four-fold coordinated to oxygen atoms with an average bond distance slightly longer than in bulk cassiterite SnO_2. The presence of a metallic core estimated at ca. 25% of the total amount of tin atoms could also be pointed out. Pd is always in a metallic state and is surrounded by Sn and Pd atoms located at unusually short distances that vary according to the sample. A possible location of the palladium into the small crystalline platelets around the Sn core of the particle has been suggested for the sample doped in surface. For the sample doped in volume the formation both of a bulk Sn/Pd phase in the core part of the particle that could explain the huge increase in the particle size, together with the presence of Pd platelets around it has been suggested. When oxidised, the sample doped in surface features a large increased in its gas sensitivity compared to the pure one, whilst a very high resistivity have been measured in the sample doped in volume. This XAS study has allowed us in complement to the other techniques used, to fully characterise the structure of these materials by pointing out more specifically the location of the doping element in the two methods. These results should lead to significant improvement in the optimisation of the preparation method of these nanocomposites.

Abstract

Thermal treatment of Cd and Se doped borosilicate glass yields CdSe nanoparticles that are interesting for applied and fundamental studies of quantum and size effects in semiconductors. Using X-ray absorption spectroscopy at both the Cd and Se K-edges, we have studied the local atomic structure for each of these reactants at several stages of particle growth. When the doped glass is quenched from 1050 °C, the Cd neighbor is mostly oxygen and the Se neighbor is mostly Zn. With heat treatment at 600–750 °C, the concentration of nearest neighbor Cd-Se bonds increases and becomes dominant while the optical spectrum evolves toward that of a composite containing CdSe.

II-VI semiconductor nanoparticles grown in glass have long been model systems for the study of quantum confinement and other size effects. Deep understanding of the environment of the reactant atoms is important for two reasons. First, interpretation of optical properties requires knowledge of the crystal order or disorder, defects, and interface bonds. Second, control of nucleation and growth of nanoparticles requires an understanding of the bonding of reactants both before and after particles are formed.

An often-cited, but untested, model of CdSe particle formation in glass is described by Weyl [1]. In this model, Se and Cd are present in the melt as ZnSe and CdO and should be predominant in quenched glass. At lower temperature CdSe is more stable than ZnSe and CdO. At the heat treatment temperature of 500–700 °C, ZnSe and CdO dissociate and Se and Cd diffuse through the glass and aggregate onto CdSe particles. The details of the precursor phases were not discussed by Weyl. We have addressed the question of the local bonding of Cd and Se atoms at various stages of particle growth using X-ray absorption spectroscopy near the respective K-edges. Optical absorption and resonant Raman spectroscopies were used to characterize particle size and composition [2].

Samples were prepared from commercial RG695 filter glass from Schott Glass Technologies. The base glass has as major components, SiO_2, B_2O_3, Na_2O, CaO, ZnO, and K_2O. Cd and Se are added. Glass composition was determined by the self-consistent interpretation of X-ray fluorescence, X-ray absorption, and electron microprobe measurements.

As-received RG695 glass has been heat-treated after quench to grow relatively large ($d > 5$ nm) nanoparticles with an absorption edge close to the bulk band gap of CdSe (1.8 eV). We prepared glass with nanoparticles in various stages of growth by dissolving the nanoparticles in commercial glass by heating to 1050 °C, followed by quenching. A 5 mm thick slab, contained by Pt shim stock, is typically quenched within 30 seconds to below 500 °C. Prior to cutting, the slab is annealed for one hour at 450 °C to reduce thermal stress. Many samples were cut from a single large ($40 \times 40 \times 5$ mm) slab of each glass to suitable thickness (3 mm for Cd edge XAS, 0.3 mm for Se edge XAS, and 0.5 mm for optics), polished, and heat treated. We focus in this paper on two samples i) as-received (heat treated) RG695 and ii) a sample quenched from 1050 °C.

X-ray absorption spectra were acquired by transmission using in-line gas ionization chamber detectors with the sample at 77 °K. The incident X-ray energy was scanned using a Si(220) "two bounce" monochromator on beamlines 4-2 and 10-2 at the Stanford Synchrotron Radiation Laboratory. Our optics yielded a resolution of 12 eV FWHM at the Cd K edge. The X-ray absorption spectra were reduced and analyzed using standard techniques [3].

In Fig. 1 we show the optical absorption spectra of heat treated and quenched glasses along with the scaled absorption spectrum of bulk CdSe. The absorption edge of commercial RG695 glass ("heat treated") is blue-shifted by ∼100 meV compared to bulk CdSe. This shift could be due to any combination of quantum confinement, composition variation from pure CdSe, or strain. The vibrational Raman scattering spectrum contraindicates substantial alloying ($Zn_xCd_{1-x}S_ySe_{1-y}$) or strain. (We have previously shown that Zn alloying can be significant in commercial CdS-doped glasses [4].) Assuming that the entire blue shift of the heat treated sample is due to quantum confinement yields an estimate of 6 nm for the particle diameter, consistent with broadening observed in X-ray diffraction. The sample that was quenched from 1050 °C exhibits extremely little absorption below 3.5 eV. Assuming that the edge is representative of quantum-confined CdSe particles, we estimate that there are very few particles with diameter larger than

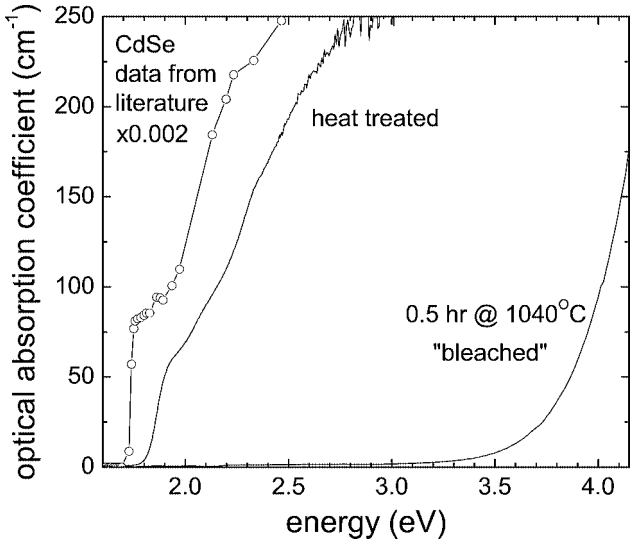

Fig. 1. The optical absorption coefficient α is shown as a function of photon energy for heat treated (as-received) RG695 glass, glass quenched from 1050 °C, and bulk CdSe.

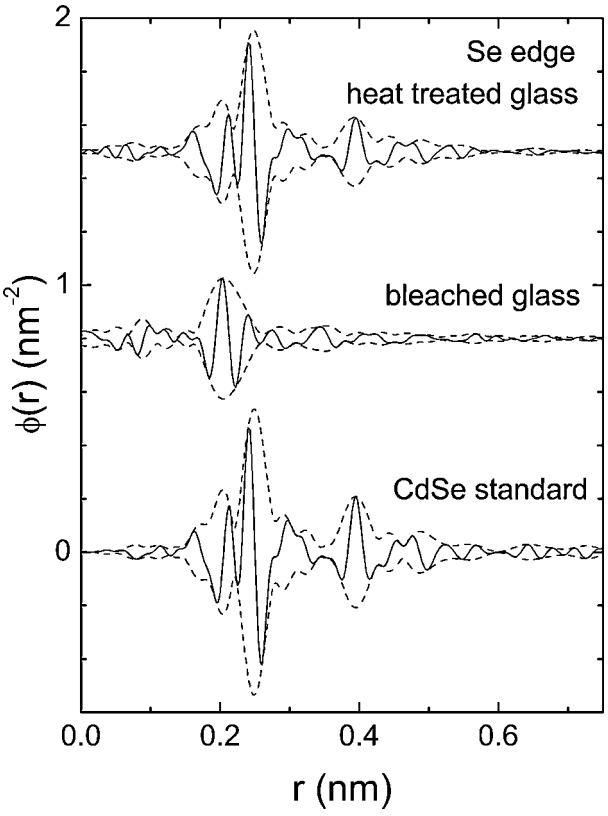

Fig. 2. The real part (solid line) and magnitude (dashed line) of $\phi(r)$, the Fourier transform of $k\chi$, extracted from the XAS data Se edge of three samples as labeled in the figure.

1.5 nm. Optics can tell us little else about the state of the particles or reactants in bleached material.

From XAS measurements we know that the Cd and Se concentrations in both glass samples are nearly equal, with 8.2×10^{19} Cd atoms/cm^3 and 6.5×10^{19} Se atoms/cm^3. The near balance of reactants makes it possible to perform meaningful XAFS analysis on both edges. In Fig. 2 we show the real part (solid line) and magnitude (dashed line) of $\phi(r)$, the Fourier transform of $k\chi$, measured at the Se edge for the heat treated glass, the bleached glass, and a CdSe standard. The CdSe standard exhibits two significant peaks in ϕ at 0.25 nm and 0.4 nm, corresponding to the Cd nearest neighbor and the Se second neighbor respectively. Similar structure is observed for the heat treated glass. The ϕ spectrum of the bleached glass is very different, with a single peak in ϕ centered close to 0.2 nm.

We fit the first neighbor region for Se using FEFF3 [5] signatures for Zn and Se. We fit the first neighbor region for Cd using signatures for O and Se. When possible, FEFF signatures were adjusted by fitting them to standards including CdSe, Se, and CdO.

Analysis of XAFS both edges gives the following results. In the bleached glass: 20% of the Se is bound to Cd and 60% of the Se is bound to Zn. The remainder of the Cd in the bleached glass is bound to O. In the heat-treated glass: 80% of the Se is bound to Cd in an ordered environment. The remainder of the Cd is bound to O. In both glasses, there is a 20% deficit in observed Se neighbors, presumably due to a very disordered environment for this phase.

We conclude that most of the Se is indeed bound to Zn and most of the Cd is bound to O in the quenched glass, consistent with the conventional model of Weyl [1]. A recent XAFS report identifies Se as the predominant first neighbor for Se in a similar quenched glass [6]. We have made a careful comparison of the fits for both Se and Zn first neighbors and conclude that Zn yields a significantly better fit. In the quenched glass, 20% of the Se is in CdSe, but optical absorption results demand that the CdSe must be in particles smaller than 1.4 nm diameter. Heat treatment causes the formation of CdSe in an ordered environment at the expense of ZnSe and CdO. In commercial glass, most of the available Se is incorporated into CdSe particles larger than 6 nm in diameter. There is no evidence for the formation of ZnSe and CdSe pseudobinaries.

Abstract

Oxidation of the $[Au_6Ni_{32}(CO)_{44}]^{6-}$ cluster anion in acetonitrile solutions by air and by Me_3NO has been monitored using Ni K- and Au L_{III}-edge XAFS spectroscopy. EXAFS data for the pristine cluster correspond reasonably well to its known crystal structure and point to a formation of bimetallic Ni-Au nanoparticles in the oxidation products. Air oxidation of the acetonitrile solutions without additional oxidants/promoters goes very slowly whereas addition of Me_3NO results in immediate precipitation. The nanoparticles formed upon the oxidation are suggested to have a core of gold atoms and an outer shell of nickel oxide.

1. Introduction

Transition metal nanoparticles have attracted significant attention over the last decade [1–3]. Their potential application areas encompass, among others, catalysis, medicine, and electronics. One of the most promising synthetic approaches to metal nanoparticles is a controlled chemical transformations of well-characterized molecular precursors, *e.g.* high-nuclearity cluster compounds [2]. Up to date, a wealth of stoichiometric cluster compounds with cluster cores ranging from highly ordered fragments of close packings to loose irregular agglomerates are known [3], which can be used as building blocks in a design of new metal-based nanostructured materials. An especially important class of these materials consists of bimetallic nanoparticles, which allow fine tuning of the materials' properties due to a variability of their chemical compositions and spatial distributions of the component metal atoms in cluster cores [4].

Recently, a new high-nuclear stoichiometric bimetallic carbonyl cluster $[Au_6Ni_{32}(CO)_{44}]^{6-}\cdot 6PPh_4\cdot 4.5CH_3CN$ was synthesized, isolated, and characterized by single-crystal X-ray diffraction by L. F. Dahl and his group [5]. According to the crystallographic data, the core of the cluster anion (Fig. 1) is built up of an inner Au_6 octahedron surrounded by a Ni_{32} shell. In the idealized D_{3d} point symmetry of the Au_6Ni_{32} bimetallic moiety, five types of Ni atoms are symmetrically non-equivalent (meanwhile, the crystallographic symmetry of the core is P-1 such that 16 Ni atoms are crystallographically independent). In overall, the structure is characterized by broad distributions of all interatomic contacts. Upon mild heating or chemical oxidation, this cluster readily loose its carbonyl ligands to form higher-nuclearity species. Therefore, it may be a convenient precursor in preparation of bimetallic Ni-Au nanoparticles.

XAFS spectroscopy is an important tool to study chemical transformations, which lead to a formation of nanoclusters, *e.g.* colloid metals [1, 6, 7]. Earlier, the oxidative aggregation of various stoichiometric palladium carbonyl-phosphine clusters exposed to air in toluene solutions, giving rise to f.c.c. Pd_n nanoparticles (where n is *ca.* 900) was monitored by us using Pd K-edge EXAFS and XRD [8].

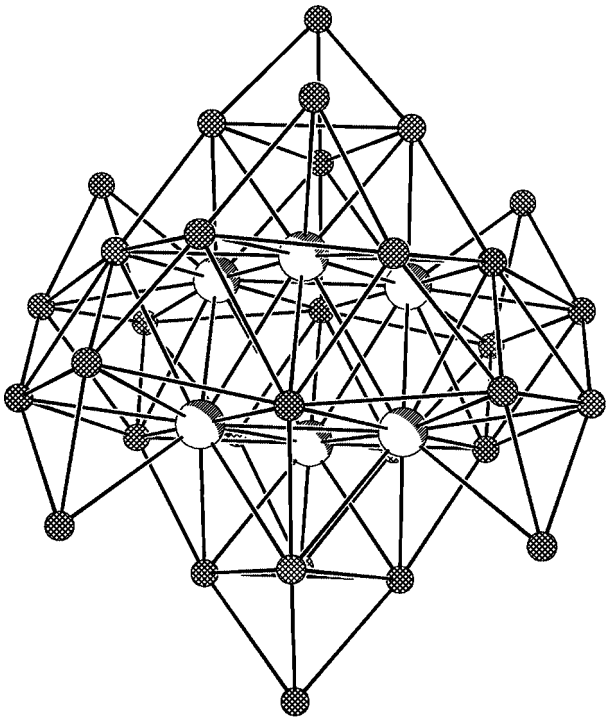

Fig. 1. Cluster core of the initial Au_6Ni_{32} cluster according to the X-ray crystallographic analysis [5]. Large spheres denote Au atoms, small spheres denote Ni atoms.

In this paper, we report on Au L_{III}- and Ni K-edge XAFS monitoring of the evolution of the $[Au_6Ni_{32}(CO)_{44}]^{6-}$ cluster anion in acetonitrile solutions upon oxidation. As it was shown elsewhere [9], Me_3NO readily transfer an oxygen atom to carbonyl ligands to form CO_2 and thus strongly promotes the overall oxidation of transition metal carbonyls in the presence of air. Thus, both oxidation routes with and without the promoter were studied.

2. Experimental

Polycrystalline cluster compound $[Au_6Ni_{32}(CO)_{44}]^{6-}\cdot 6PPh_4\cdot$ 4.5MeCN (hereinafter, referred to as Au_6Ni_{32}; 25 mg) was provided by Prof. Lawrence F. Dahl (University of Wisconsin-Madison, USA). Commercially available acetonitrile was further purified from air by Ar bubbling for 10 min. Two samples of dark brown acetonitrile solutions with a concentration of *ca.* 20 g/l for

*e-mail: obelyak@ineos.ac.ru

the first solution (**1**) and *ca*. 30 g/l for the second solution (**2**) were prepared by ultrasonication (1 min) of the respective amounts of Au_6Ni_{32} in *ca*. 0.5 ml of MeCN. For measurements, *ca*. 0.1 ml of both solutions were placed in small plastic cells, which were open to air. The rest of the two solutions, kept closed from air, maintained brown colour with some brown precipitate formed. In order to promote the oxidation, 3 mg of a mild oxidant Me_3NO (*ca*. 10 : 1 excess with respect to the initial cluster) dissolved in several drops of EtOH/MeOH mixture was added to the fraction of the solution **2** kept in a closed vessel for 10 hours. The brown colour of the solution immediatly disappeared and a brown flake-like precipitate evolved, which was separated afterwards onto a paper filter.

The polycrystalline powder of the initial Au_6Ni_{32} cluster (in Ar-blown polyethylene bags), solutions **1** and **2**, and the resulting precipitate were studied by XAFS in the fluorescence yield mode at the BL-9A bending magnet beamline of the Photon Factory synchrotron facility (KEK, Tsukuba, Japan) operated at 2.5 GeV with the electron current stored of 300 mA. The beam was focused on a sample by a system of conical Rh-coated mirrors to give a spotsize of $0.35 \times 1\,mm^2$. Intensity of the primary beam monocromatized by a Si(111) double crystal monocromator was measured by an ionization chamber filled with nitrogen; X-ray fluorescence yield was measured using a Lyttle detector. XAFS data for the air-exposed solutions **1** and **2** were collected repeatedly every 15–20 minutes (XANES) or 2–2.5 hours (EXAFS) with a total duration of 10 hours. The standard processing of EXAFS spectra was performed using the UWXAFS [10] software package with *ab initio* scattering amplitude and phase functions calculated by FEFF [11]. Normalized EXAFS curves $k^3\chi(k)$ over the k ranges of 2.6–12 $Å^{-1}$ for most of the spectra and 2.6–15 $Å^{-1}$ for the Au L_{III} spectrum of the precipitate were used in the curve-fitting.

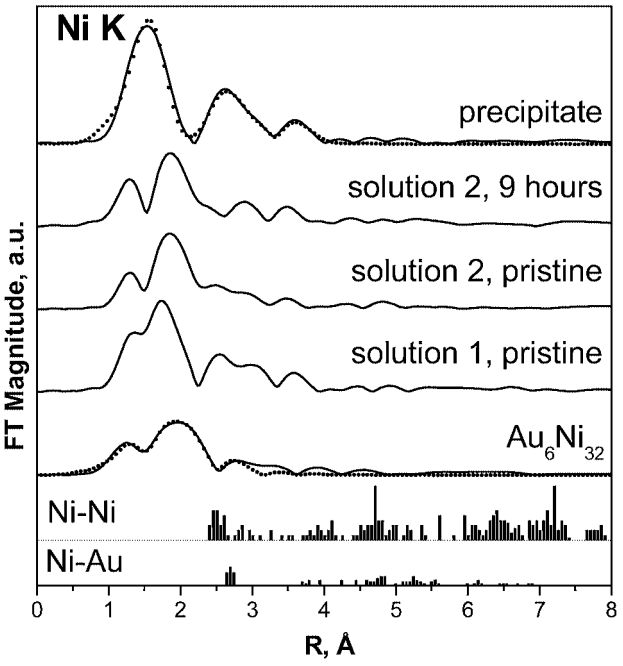

Fig. 2. Fourier transforms of Ni K-edge EXAFS spectra for the initial Au_6Ni_{32} cluster, pristine acetonitrile solutions **1** and **2**, solution **2** exposed to air for 9 hours, and the precipitate: experiment (solid lines) and best-fits (dots). Histograms of Ni-Ni and Ni-Au interatomic distances in the initial Au_6Ni_{32} cluster are shown for comparison.

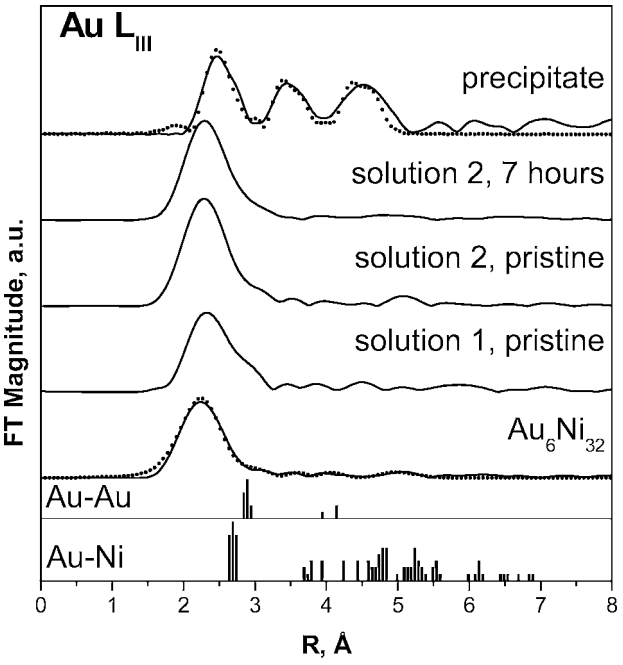

Fig. 3. Fourier transforms of Au L_{III}-edge EXAFS spectra for the initial Au_6Ni_{32} cluster, pristine acetonitrile solutions **1** and **2**, solution **2** exposed to air for 7 hours, and the precipitate: experiment (solid lines) and best-fits (dots). Histograms of Au-Ni and Au-Au interatomic distances in the initial Au_6Ni_{32} cluster are shown for comparison.

3. Results and discussion

Typical Fourier transforms (FTs) of Ni K- and Au L_{III}- edge EXAFS for the studied samples are shown in Figs. 2 and 3, respectively. Best-fit curves for the initial cluster and the resulting precipitate, are shown in dotted lines. Values of structural parameters corresponding to the best-fit structural models are summarized in Table I.

Due to the low symmetry of the Au_6Ni_{32} core in the initial cluster (see histograms of metal-metal distances shown in Figs. 2 and 3), fitting procedure of EXAFS spectra is challenging, especially in the case of Ni K-edge data. Nevertheless, a minimum required model of Au_6Ni_{32} composed of two Ni-C (Ni-C1 and Ni-C2), Ni-Ni, Ni-Au, and Ni . . . O spheres showed a pronounced similarity to the experimental Ni K-edge FT. The obtained best-fit values for the interatomic distances lie within the distribution limits of the respective parameters known from crystallographic data (see Table I). The FT pattern at Au L_{III}-edge even better corresponds to the structural model; its main peak is formed by overlapping contributions from closest Au-Ni and Au-Au distances. The pattern of relatively weak peaks at 3–5 Å can be well fitted to a set of outer spheres including non-bonding Au . . . C as well as Au . . . Ni and Au . . . Au separations in a good agreement with the crystallographic data.

The FTs of the precipitate are drastically different from those of the initial compound indicating a deep rearrangement of both the cluster core and the ligand shell due to the oxidation. The first dominant peak in the Ni K-edge FT can be well simulated with Ni-O scattering path at 2.03 Å that strongly suggests that a substitution of carbonyl ligands by oxygen atoms occurred. The shortest Ni-Ni distance is 2.93 Å according to the fitting results. Both these values are close to corresponding Ni-O and Ni . . . Ni distances in cubic crystalline nickel oxide NiO of NaCl type [12]. At Au L_{III}-edge, the FT is composed of three distinct peaks at *ca*. 2.45 Å, 3.45 Å, and 4.52 Å (not corrected for the phase shift). The high intensities of these peaks

assume a relatively big cluster core with a well-ordered local environment of gold atoms [13]. According to the fitting results, both gold and nickel contribute to these three peaks with the gold contribution dominating. Furthermore, Ni-Au interatomic distances independently determined from Ni K- and Au L_{III}-edge data (Au-Ni1/Ni-Au1 and Au...Ni2/Ni...Au2 in Table I) are consistent. No fitting-improving Au-A contributions (where A denotes oxygen or other light atoms) were found.

In Ni K-edge XANES (Fig. 4), the pattern of the precipitate with a weak pre-edge feature and an intense main component ("white line"), is totally different from that of the initial cluster compound, which has a strong pre-edge peak and a weak white line. The pre-edge feature, which appears due to a forbidden $1s \rightarrow 3d$ electronic transitions is always prominent for compounds with direct Ni-Ni bonds. A strong reduction of this feature gives an evidence that a substantial part of Ni-Ni bonds was broken as a result of the oxidation in accordance with EXAFS data, where only non-bonding Ni...Ni closest distances are observed.

Therefore, our XAFS data indicate that nanoparticles composed of an Au core and a NiO outer shell are most probably formed upon the chemical oxidation of the initial $[Au_6Ni_{32}(CO)_{44}]^{6-}$ cluster anion with Me_3NO. It has to be mentioned that Au-Au interatomic distances (2.70 Å, 3.59 Å, and 4.58 Å) are significantly shorter than in the bulk f.c.c. gold (2.88 Å, 4.07 Å, and 4.99 Å, respectively) that may point to a different, *viz.* non-f.c.c, arrangement of Au atoms in cores of the Au-Ni nanoparticles. The Au-Au interatomic distances as short as 2.70 Å were also found in high-nuclearity gold cluster compounds by single crystal X-ray diffraction [14].

A comprehensive quantitative analysis of the FT patterns of acetonitrile solutions is too complicated since a lot of scattering

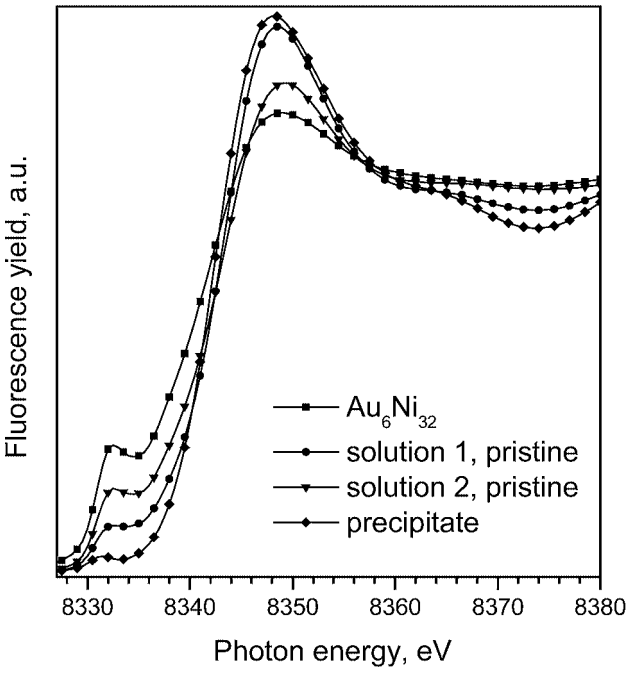

Fig. 4. Ni K-edge XANES spectra of the initial Au_6Ni_{32} cluster, pristine acetonitrile solutions **1** and **2**, and the precipitate.

paths has to be taken into account. Qualitatively, both pristine solutions show some differences in the shape of the first peak in Ni K-edge FT pattern as compared to that of the initial Au_6Ni_{32} cluster assuming a partial replacement of carbonyl ligands by oxygen species at Ni atoms. On the other hand, the two Au L_{III}-edge FTs of the solutions closely resemble that of Au_6Ni_{32} indicating that the Au_6 octahedron remains intact upon dissolution. Upon exposure to air for several hours, both solutions do not show any prominent changes as evidenced by time-resolved EXAFS and XANES series at Ni K- and Au L_{III}-edges (as a typical example, FTs for the solution **2** after 7–9 hours of air exposure are shown in Figs. 2 and 3). The changes, if any, can be reduced to an increase in the fraction of the unreacted Au_6Ni_{32} cluster. The most probable reason of that is a very slow oxidation of Au_6Ni_{32} in small amounts of MeCN solution by air (possibly, due to a formation of a thin film of oxidation products at a surface, which prevents further air access). Therefore, all the initial oxidation of the solutions **1** and **2**, most probably, takes place in a dissolution step, and thus the state of pristine solutions depend largely upon the preparation details, such as solvent pre-treatment. During air exposure, a slow precipitation withdraws insoluble oxidation products from the monitored area of the solution. In contrast, addition of Me_3NO causes immediate oxidation and precipitation of Au/Ni nanoparticles.

4. Summary and outlook

- An analysis of Ni K- and Au L_{III}-EXAFS spectra for the initial cluster compound $[Au_6Ni_{32}(CO)_{44}]^{6-}\cdot 6PPh_4\cdot 4.5CH_3CN$ yields values of structural parameters in a reasonable agreement with crystallographic data despite the heavy static disorder of the cluster core, which demonstrates applicability of EXAFS to similar high-nuclearity stoichiometric cluster compounds (see also [7, 8]).
- The oxidation product precipitated from the acetonitrile solution of the initial compound by Me_3NO was identified as a nanostructured material containing a core of Au atoms covered with a nickel oxide shell.

- Without addition of Me_3NO, the air oxidation of the acetonitrile solutions goes very slowly. A partial oxidation, most probably, occurs upon the preparation or ultrasonication of the solutions.
- In order to achieve a controlled oxidation of the initial cluster in a solution, chemical conditions of the reaction have to be adjusted (selection of protonic-aprotonic solvents mixtures, air blowing, or utilization of other mild oxidation promoters).
- Supplementary physical methods like XRD, IR, and HRTEM will be applied to verify the suggested structure of the final oxidation product.

Acknowledgements

Authors are indebted to Professor Lawrence F. Dahl (University of Wisconsin-Madison) who has kindly provided us with the initial Au_6Ni_{32} cluster and inspired this study. We are also grateful to Professor Edward Stern and Professor John Rehr (University of Washington, Seattle) for the UWXAFS and FEFF software, respectively. Authors also thank the KEK administration for the beamtime allocation and assistance in data collection. This work was supported by the Russian Foundation for Basic Research (grant #02-03-33225).

Abstract

Magnetoelectric materials may be applicable in magnetic and ferroelectric devices, because they exhibit both magnetic and electrical ordering over a range of temperatures. One of the few magnetoelectic materials is $BiFeO_3$. Large particles of (bulk) $BiFeO_3$ have a perovskite structure, a Neel temperature (T_N) of 380 °C, and a ferroelectric transition temperature (T_C) of 810 °C. Changing the particle size of $BiFeO_3$, to nanometer scale has been demonstrated to affect the magnetoelectric properties of this material. These changes may result from the small particle size of the nanoparticulate $BiFeO_3$ or may be due to local structural changes caused by the decrease in particle size. Nanoparticles of $BiFeO_3$ with a narrow size distribution are not easy to prepare. Nanoparticles were synthesized by using wet chemical techniques and were characterized by X-ray diffraction and scanning electron microscopy. Fe K-edge X-ray-absorption fine structure (XAFS) measurements were made of bulk and nanoparticulate $BiFeO_3$ to determine the local atomic structure about Fe. The XAFS results from the nanoparticulate $BiFeO_3$ show that the local structure about the Fe atoms to approximately 4.0 Å is the same as in the bulk $BiFeO_3$ sample. This result indicates that the decrease in the Neel Temperature (400° to 339 °C for these samples) with the decrease in particle size (1.4 μm to 20 nm) is not due to local structural changes about the Fe atoms as a result of the decrease in particle size.

1. Introduction

Magnetoelectric materials, also called multiferroics, exhibit both ferroelectric and magnetic ordering. Recent interest in these materials is driven by their potential application in sensors and memory devices. $BiFeO_3$ is one of the few magnetoelectric materials. The ferroelectric properties of $BiFeO_3$ exist in a wide range of temperatures vanishing at a high Curie temperature (T_C) of 820 to 850 °C [1, 2]. This material is also antiferromagnetic below the Neel temperature, T_N = 380 °C, exhibiting very weak magnetism at room temperature due to the presence of a residual moment arising from a canted spin structure [3, 4]. The structure of $BiFeO_3$ deviates from the ideal cubic perovskite structure due to displacement of the Bi sublattice, and a deformation and twist of the FeO_6 octahedra [5–8]. At room temperature, $BiFeO_3$ possesses rhombohedral symmetry ($a = b = c = 5.6343$ Å, $\alpha = 59.348°$), containing two formula units per unit cell. An alternative hexagonal unit cell [5–8] contains six formula units of $BiFeO_3$ ($a = 5.5787$ Å, $c = 13.8688$ Å) (Figure 1).

Studies of the effect of finite particle size on the physical properties of oxides and in particular ferroelectric oxides have attracted much attention [9], although most early studies were restricted to ceramic particles with micrometer grain size [10, 11]. The recent development of several wet chemical techniques (solgel, microemulsion, coprecipitation, spray-pyrolysis, etc.) have made it possible to produce many oxides in a pure phase with a narrow size distribution of ultrafine particles. In this study

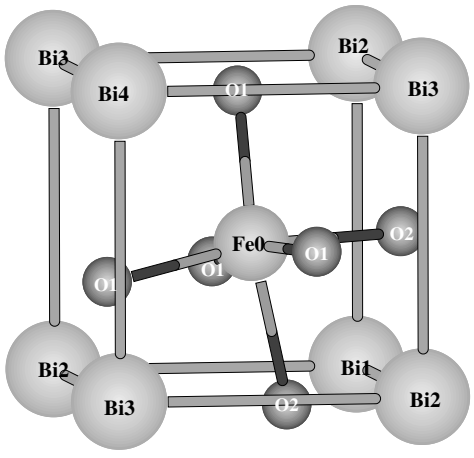

Fig. 1. Ball and stick model of one $BiFeO_3$ formula unit.

the coprecipitation technique was used to prepare the $BiFeO_3$ particles. $BiFeO_3$ is a partially covalent oxide. Previous studies have shown that as the particle size decreases for partially covalent oxides, there is an increase in unit cell volume and a distortion so that crystal symmetry increases [12]. In many of these compounds the physical properties are also affected by the decrease in particle size [13]. Size effect studies of nanoparticulate $BiFeO_3$ (23 to 80 nm) indicate that as the particle size decreases (a) the lattice expands, (b) the Neel temperature (T_N) decreases from 400 to 339 °C, and (c) the antiferromagnetic to paramagnetic transition becomes increasingly diffuse [14]. To understand these changes in the physical properties of $BiFeO_3$ as the particle size decreases, XAFS measurements have been made at the Fe and Bi edges at several temperatures and on several samples with varying particle sizes. This paper reports our first results on this large collection of data, where we compare the Fe K-edge data collected at 20 K for the BULK (1400 nm) and NANO (20 nm) $BiFeO_3$. Previous EXAFS studies of a similar material $BaTiO_3$ showed that the magnitude of the Ti atom's off-center displacement does not depend on particle size [15]. We are not aware of any previous EXAFS studies of nanoparticulate $BiFeO_3$.

2. Experimental Section

Pure single-phase particles of $BiFeO_3$ were prepared by using a wet-chemistry coprecipitation technique. Briefly, bismuth trioxide (Bi_2O_3) and ferric oxide (Fe_2O_3) of 99.9% purity were measured in stoichiometric proportions and dissolved in concentrated nitric acid. The solution was diluted with deionized water to bring the concentration level to 10% weight/volume. Bi and Fe cations were simultaneously coprecipitated with

*soma@agni.phys.iit.edu

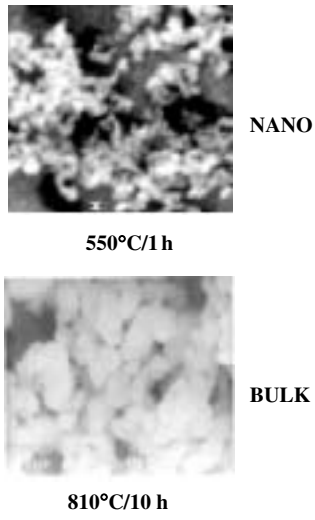

Fig. 2. SEM image of the NANO and BULK samples.

ammonium hydroxide. The precipitate was filtered and washed with deionized water until the pH reached 7. The washed precipitate was dried under an infrared lamp and thermogravimetric analysis (TGA) on the resultant precursor determined its calcination temperature. Weight loss was found to be complete by 500 °C, implying that the precursor should be heated above 500 °C to obtain $BiFeO_3$. Nanoparticulate (NANO 20 nm) and bulk (BULK 1400 nm) $BiFeO_3$ were synthesized by heating the precursor to 550 °C for 1 hour and 810 °C for 10 hours, respectively. The bulk heating temperature was chosen because Bi volatizes above 850 °C.

The samples were characterized with high-resolution X-ray diffraction (HR XRD) and scanning electron microscopy (SEM) measurements (see Fig. 2). HR XRD measurements (MRCAT ID-10 beamline at the Advanced Photon Source) verified the purity of the sample, and accurately determined the lattice parameters and particle sizes of the samples. The samples were packed in capillaries (2 mm diameter) that were rotated during the measurement in transmission mode. LaB_6 was used as a calibration standard. The size of the fine particle and the bulk samples was determined from full width at half maxima of the (012) peak using Scherrer's formula [16]. SEM measurements were used to determine the morphology of the particles.

The Fe K-edge EXAFS measurements were performed at the MR-CAT beamline [17] 10-ID at the Advanced Photon Source, Argonne National Laboratory. The samples were spread on tape. Several layers were stacked so that the thickness x of the samples corresponding to $\Delta\mu x = 0.5$, where $\Delta\mu$ is the jump of the absorption coefficient at the Fe K-edge energy. The samples were then loaded in a displex and cooled to 20 K. The energy of the monochromator was calibrated by simultaneously collecting the XAFS spectra from an iron foil. The undulator parameters (taper and gap) were optimized to obtain a large photon flux with nearly constant intensity within the scanned energy range of 6900 to 8400 eV. The Si(111) double crystal monochromator was scanned continuously so that the data was collected in quick EXAFS mode. A Rh harmonic rejection mirror was used to eliminate X-rays of higher harmonic energies. The incident and transmission photon intensity was measured by using ion chambers filled with the following gas mixtures, 80 : 20 $He : N_2$ and N_2, respectively. The size of the incident X-ray beam on the sample was 1 mm^2. The transmission measurements were collected over the scanned energy range of 6900 to 8400 eV with a step size of 0.4 eV and a dwell time of 0.5 s. For each sample, 10 scans were taken and then averaged.

Table I. *Size and lattice parameters for the fine particle sample (NANO) and the bulk sample (BULK) based on HR XRD measurements.*

SAMPLE	SIZE (nm)	a (Å)	c (Å)	Volume (Å^3)
BULK	1400	5.5789	13.8689	431.66
NANO	20	5.5824	13.8644	432.06

The data was processed using the FEFFIT package [18]. Background subtraction and data merging was done with Athena [19]. Theoretical models were constructed with the program FEFF7 [20] and the crystallographic atomic positions of $BiFeO_3$.

3. Results and Discussion

High resolution XRD data showed that the samples are phase pure. Table I gives the lattice parameters for the NANO and

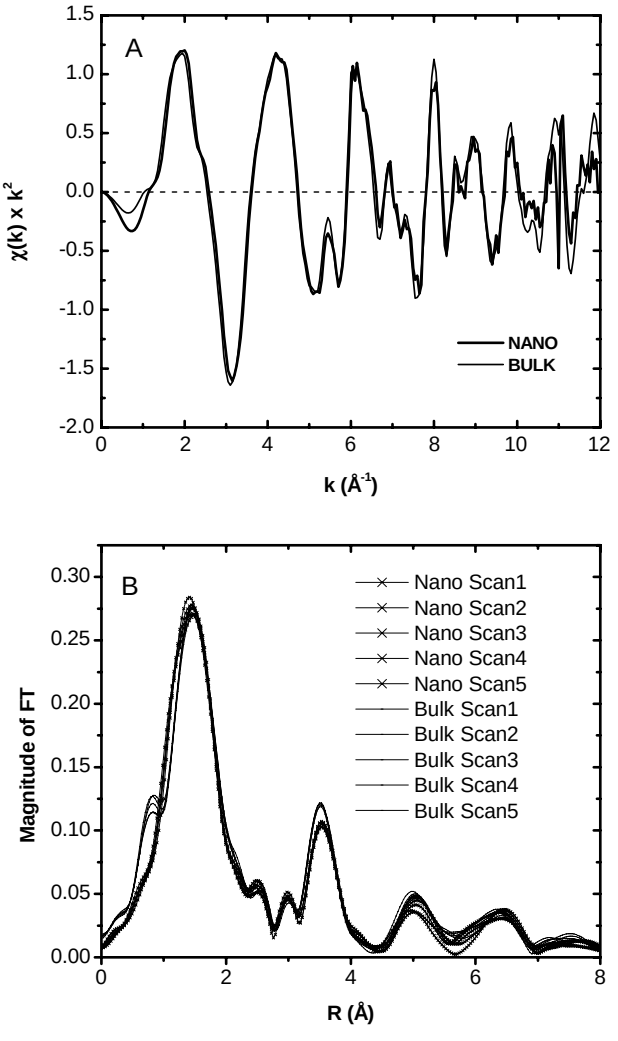

Fig. 3. Comparison of the EXAFS data from the NANO and BULK data sets. Panel A shows the average $\chi(k)$ data of 10 scans for the NANO and BULK data. The data ranges from 3.0 to 10.0 and 3.0 to 14.0 Å^{-1} are used for the fits to the NANO and BULK data sets, respectively. Panel B shows the magnitude of the Fourier transform (FT), k-weight of 1, for 5 of the Bulk and the NANO data sets using the data range from 3.0 to 10 Å^{-1} and a k-weight of 1. There is a systematic decrease in the second peak of the FT of the NANO data set as compared to the BULK data set.

BULK samples. These results show an expansion of the unit cell volume with the decrease in particle size from the BULK to NANO samples. However, for the first 7 coordination spheres this expansion corresponds to changes in distances between the Fe atoms and the neighboring atoms (0.000 to 0.002 Å) that are too small to resolve in an XAFS measurement. This result is confirmed by comparing the average $\chi(k) \cdot k^2$ data from the NANO and BULK samples (Fig. 3). Both data sets show the same phase (as the data sets cross zero at the same points) indicating that the distance between the Fe atoms and its neighbors are the same for both samples, but there is a systematic reduction in the amplitude of the signal from the NANO sample as compared to the BULK sample. This reduction in amplitude is small but reproducible for each of the 10 scans collected on both the NANO and BULK samples. To demonstrate the reproducibility of the data, Figure 3b shows the magnitude of the Fourier transform (FT) from 5 of the individual scans from the NANO and BULK data set showing a consistent and systematic decrease in the second peak height. Since each of the individual scans clearly shows a grouping that is tighter than the differences in the NANO to BULK data sets we are confident that this decrease in the amplitude of the EXAFS signal for the NANO data set relative to the BULK data set is larger than the uncertainty in the measurements.

Both data sets were fit simultaneously in *R*-space by using a *k*-weighting of 1, 2 and 3 in the FT of the data. The model for the data contains all paths from the reduced $BiFeO_3$ unit cell (Figure 1). Table II lists these paths and the EXAFS parameters. The model includes a $S_0{}^2$ value, a single third cumulant for the first and second oxygen shells, four energy shift values for each of the atom types and six σ^2 values grouped depending on the atom types and distances. This model has a total of 13 variables. The need for a third cumulant was tested by modeling the data with and without the third cumulant. The reduced-chi square value decreased by approximately 40% with the inclusion of a third cumulant (53 to 32); therefore it was included in the model. To test the NANO data for any changes relative to the BULK data, the model was simultaneously optimized to both data sets with exactly the same parameters. The magnitude and real part of the data and model are shown in Figure 4. Overall the model can describe most of the features in both data sets simultaneously, but the amplitude of the model is too large for the second peak in the FT for the NANO particulate data. The model can be corrected by fitting the second peak from 2.8 to 4.0 Å with an additional scaling factor for the coordination numbers of the Bi, Fe and O_3 shells for the NANO particulate data set. Parameters from shells in this region were re-optimized while parameters determined from the first shell were held to the values previously determined. The fit results for both of these fits to the data are listed in Table III. The coordination numbers were determined to be $7 \pm 4\%$ smaller in the NANO particulate sample than predicted by the $BiFeO_3$ crystal structure. The magnitude and real part of the data and model are shown in Figure 5.

The results of the simultaneous fit to the BULK and NANO data sets show very similar local structure for the nanoparticulate $BiFeO_3$ data relative to the bulk $BiFeO_3$ structure. The identical

Table II. *List of paths included in the XAFS model of the $BiFeO_3$ data. The path description includes the atom types (Path), the number of paths (Number), and the initial half path length (Reff). The XAFS parameters include a change in the half path length (Δr), the mean-square displacement of the half path length (σ^2), and an energy shift (ΔE). Changes in the half path lengths are parameterized in terms of a single expansion coefficient α. The values in Bold are the first occurrence of each parameter. In addition to the parameters listed an $S_0{}^2$ value and a third cumulant for the first two oxygen shells were determined in the fit. There are a total of 13 parameters for this model.*

Table III. *Best fit values from the simultaneous fits to the NANO and BULK data sets. For the first fit from 1.0 to 4.0Å there is an average of 7 variables for the model and 15 and 20 independent points for the NANO and BULK data sets. The best-fit value for $S_0{}^2$ is 0.80 ± 0.05, and for alpha is 0.003 ± 0.001, and for the third cumulant is 0.0003 ± 0.0001 Å^3 for both the data sets. The NANO data set has an additional energy shift relative to the BULK data set of 0.8 ± 0.4 eV. For the second fit from 2.8 to 4.0Å there is an average of 4 variables. The best-fit value for the reduction in amplitude of the Bi, Fe and O_3 shells is 7 ± 4%. Values without uncertainties were not determined in the fit but held at the values determined from the first fit.*

model applied to both data sets as shown in Table III and Figure 4 illustrates the similarities in the data sets as the model describes both very well without the need of any independent parameters. This model only fails to reproduce the second peak height in the NANO data set by approximately 5%. By allowing the shells that contribute in this region to have reduced coordination number the model is able to describe both data sets (See Fig. 5). The decrease in the coordination number of $7 \pm 4\%$ for the NANO data set is consistent with the expected decrease in coordination number expected for 20 nm particles. A 20 nm particle should have an average coordination number of 7.6 Bi atoms at approximately 3.5 Å as compared to the bulk value of 8.0 Bi atoms. This calculation was made by assuming a uniform density of Fe atoms within a spherical particle with a 20 nm diameter and also with the assumption that the Fe atoms on the surface are coordinated with half as many (4) Bi atoms. So we infer that, though a decrease of particle size from 1400 nm to 20 nm is sufficient to bring about a decrease in the antiferromagnetic Neel temperature of the $BiFeO_3$ nanoparticles, it fails to affect the local structure of the Fe atoms in the NANO samples. We presume that this is a consequence of the presence of only ∼7% of the atoms on the surface of the material. With further decrease of the particle size and hence with increase in the number of surface atoms, it might be possible to see distinguishable changes in the local structure around Fe atoms and thereby further changes in the magnetic and electric properties of the material.

4. Conclusion

In conclusion, we have shown from our XAFS studies of the magnetoelectric $BiFeO_3$ system that, with decrease in particle size, there is no measurable change in the local structure within 4.0 Å of the Fe atoms in these samples. A more detailed study, currently in progress, which incorporates XAFS at the Bi L_{III} edge and multiple temperature measurements, may enable us to determine structural changes, if any. The results from this limited data set indicate that the changes in the physical properties of $BiFeO_3$ are likely due to the decreasing particle size rather than changes in the local structure about the Fe atoms.

Abstract

The recent adoption of copper interconnect technology by the semiconductor industry, has led to great interest in understanding the mechanisms of copper metal deposition onto silicon wafer surfaces from ultra pure water (UPW) solutions. We have studied these processes by using total reflection X-ray fluorescence (TXRF) and X-ray absorption near edge spectroscopy (XANES) in a grazing incidence geometry to determine the surface concentration and chemical state of copper atoms on intentionally contaminated Si surfaces. These measurements established that in deoxygenated UPW, copper is deposited on the silicon surface in the form of metallic nanoparticles with sizes up to 16 nm. However, in non-deoxygenated UPW, the copper is incorporated uniformly into the silicon surface oxide as Cu oxide.

1. Introduction

For over 30 years, the device density of silicon integrated circuits has been increasing, leading to more stringent requirements for surface cleanliness. Metallic impurities on the silicon surface can degrade the performance of the ultra-thin SiO_2 gate dielectrics that form the heart of the individual transistors resulting in reduced process yields and decreased device reliability. In particular, transition metals such as Co, Cu and Fe can introduce deep level traps that lead to threshold voltage shifts of MOS transistors and a reduction of minority carrier lifetimes [1]. Moreover, metals such as Cu and Au are fast diffusers in silicon and can spread into active device areas during various silicon processing steps [2–4]. Presently, transition metal impurities must now be reduced to concentrations lower than the mid-10^9 atoms/cm^2 region in order to achieve acceptable yields with current processing technologies [5].

Various cleaning solutions are used to remove metal atoms, particles and organics from practical silicon surfaces. Most silicon cleaning methodologies are based on the RCA clean which was originally developed by Kern [6]. In this process, silicon wafers are first immersed in a high-pH solution consisting of 5 H_2O: 1 H_2O_2: 1 NH_4OH to remove organics. This is followed by an HF dip to strip any oxides from the silicon surface, and finally the wafers are submerged in a low-pH solution consisting of 6 H_2O: 1 H_2O_2: 1 HCl to remove metallic ions. Between cleaning steps, the wafers are rinsed with ultra-pure water (UPW). It is vital that the chemicals, and more importantly the UPW used in the rinse steps, be very clean as any contaminants present in the solutions will be deposited on the silicon surface.

Since cleaning solutions, especially UPW, can often be a source of contamination, understanding how metal species in solution interact with silicon surfaces is vital. An especially important contaminant is copper, particularly since the implementation of copper interconnect technology has increased the presence of copper in the process environment. Copper contamination on silicon surfaces from solution is affected by a variety of factors including defects on the surface, doping in the semiconductor, and pH value [7]. For metal contamination during the wet cleaning process, there are two alternative reaction pathways determined by the pH value of the solution. In lower pH solutions, metal ions are electrochemically reduced and deposited on the surface as metallic particles [8]. Conversely, in higher pH solutions which grow an oxide on the silicon surface, metal ions are precipitated and included in the forming oxide layer as a metal oxide/hydroxide [9]. Since UPW has a neutral pH, both reaction mechanisms are available for deposition of copper, therefore it would be expected that other factors, such as the amount of dissolved oxygen, would play an important role in the deposition of Cu on silicon surfaces from UPW solutions.

In this study, the effect of dissolved oxygen in UPW on the deposition of Cu on Si wafer surfaces is examined by using a variety of techniques. By using total reflection X-ray fluorescence with a synchrotron X-ray source (SR-TXRF) it will be shown that the dissolved oxygen content influences the amount of copper deposited from UPW solutions. In addition, it is possible to ascertain whether the deposited copper is atomically dispersed or particle-like in nature by measuring the copper fluorescence signal as a function of the angle of incidence of the incoming X-rays. Finally, the chemical state of the deposited copper is determined with X-ray absorption near edge spectroscopy (XANES).

2. Experimental

Samples were prepared by cleaving silicon wafers into 20 mm $\times$ 10 mm pieces, which were subsequently cleaned using a 4 : 1 sulphuric acid/hydrogen peroxide mixture ($H_2SO_4 = 96$ vol%; $H_2O_2 = 30$ vol%) for 10 minutes followed by a rinse in UPW. These samples were then dipped into a solution of 0.5% HF for 1 minute to prepare a clean, hydrogen terminated surface. In order to study the influence of oxygen in UPW rinses, de-oxygenated UPW was prepared by Argon sparging, reducing the dissolved O_2 content to 0.3 ppm. The non-deoxygenated UPW contains about 3 ppm of dissolved oxygen. Copper in a 2% nitric acid matrix was then introduced into the UPW at concentration levels ranging from 0.01 ppb to 1000 ppb and surface contamination was then accomplished by immersing the hydrogen terminated silicon samples into these solutions for 5 minutes.

To determine the resulting surface concentration of copper, these samples were analyzed with SR-TXRF at the wiggler beam line 6-2 at the Stanford Synchrotron Radiation Laboratory (SSRL). The details of the experimental apparatus and procedures have been published elsewhere [10]. Briefly, X-ray fluorescence in a glancing incidence geometry (0.1° angle of incidence) is used for both elemental quantification and XANES measurements. In addition, the detailed shape of the fluorescence intensity as a

function of angle is used to distinguish between contaminants that reside in a uniform surface layer versus those that exist as particles on the surface [11].

The XANES spectra were obtained between 8.940 keV and 9.2 keV at increments of 0.5 eV between 8.97 keV and 8.99 keV near the copper K edge, 1 eV above the edge between 8.99 to 9.060 keV, and 5 eV between 9.06 and 9.2 keV. The signal was integrated for 10 seconds per point for each scan and up to 30 scans were accumulated on the low concentration samples to achieve a high signal to noise ratio. Reference spectra for Cu metal, CuO and Cu_2O were obtained from bulk samples. The bulk spectra were then used in a least squares fitting procedure to determine the percentage of each copper species present in the copper contaminated silicon samples. The energy calibration was maintained by simultaneously measuring the spectrum of a Cu foil behind the sample using the part of the beam that passed over the wafer without being reflected.

3. Results and Discussion

Figures 1a and 1b show SR-TXRF measurements on two sets of silicon samples contaminated in deoxygenated and non deoxygenated UPW with copper concentrations of 10 and 100 ppb, respectively. These results clearly demonstrate that the amount of copper deposited on the silicon surface strongly depends on whether the UPW has been deoxygenated or not. When the copper in solution is below approximately 15 ppb, less copper is deposited for the deoxygenated UPW, however, at solution concentrations greater than 15 ppb, more copper is deposited when the UPW is deoxygenated. This suggests that the mechanism for copper deposition is clearly different between deoxygenated and non-deoxygenated solutions.

In addition, the Cu 1s XANES results in figures 2a and 2b provide insights into the chemical state of the deposited copper. These spectra were obtained from silicon samples that were contaminated in non-deoxygenated (figure 2a) and deoxygenated (figure 2b) UPW solutions with an intentional copper concentration of 100 ppb. A linear background subtraction

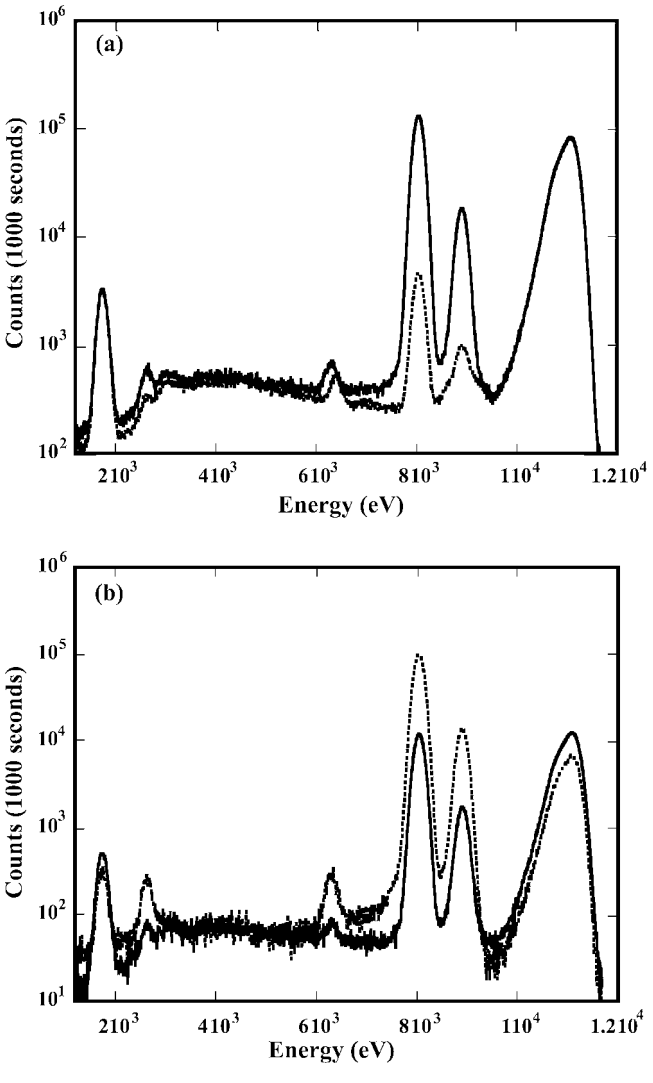

Fig. 1. TXRF spectra of silicon samples dipped in deoxygenated (dashed line) and non-deoxygenated (solid line) UPW contaminated with (a) 10 and (b) 100 ppb Cu. Note that at 10 ppb, less copper is deposited in the deoxygenated UPW and at 100 ppb, less copper is deposited in the non-deoxygenated UPW.

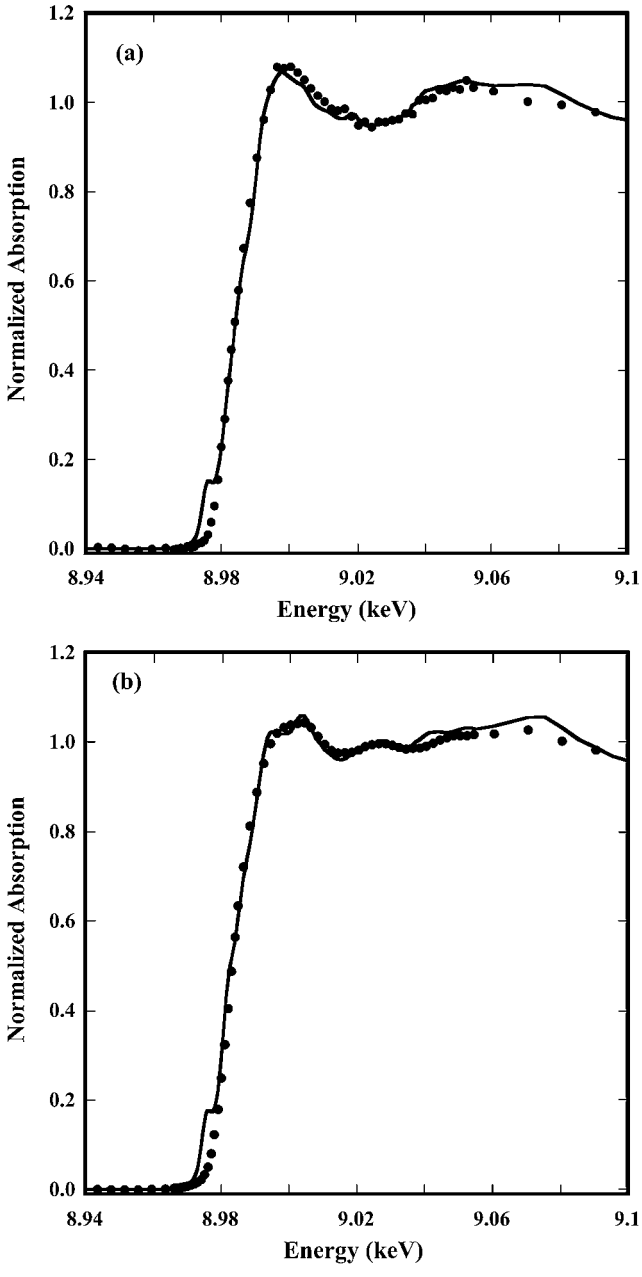

Fig. 2. Copper K-edge XANES spectra for silicon samples dipped in non-deoxygenated (a) and deoxygenated (b) UPW solutions that were contaminated with 100 ppb Cu. The overall fits are plotted as solid lines.

Table I. *Fractional contributions for the XANES fits shown in figure 2 for samples dipped in deoxygenated and non-deoxygenated UPW contaminated with 100 ppb Cu.*

	Deoxygenated	Non-deoxygenated
Cu metal	0.53	0.33
Cu (I) Oxide	0.30	0.27
Cu (II) Oxide	0.17	0.41

and normalization using a spline fit to the post edge region was conducted. Least squares fits were made between these spectra and the reference samples to determine the percentage contribution of copper metal, copper (I) oxide, and copper (II) oxide using the WinXAS program [12]. The numerical results of these fits are shown in table I. From these fits, it can be seen that the Cu deposited onto the silicon surface for the deoxygenated UPW has more metal character than that deposited from the non-deoxygenated UPW which contains less Cu metal and more of the Cu oxides. This provides evidence that, in the absence of dissolved oxygen, copper species in UPW will deposit reductively onto the silicon surface resulting in surface species that have significant metal character. On the other hand, the presence of dissolved oxygen inhibits reductive deposition and the copper species are preferentially incorporated into the growing oxide, resulting in surface species that are more oxide in character.

These results are further supported by measurements of the angular distribution of the fluorescence intensity as function of incidence angle which show that copper particle growth occurs in the deoxygenated UPW solution whereas the sample prepared in non- deoxygenated UPW gives a profile indicative of atomically dispersed copper near the silicon surface. A fit of the angle scan for the deoxygenated sample suggests the presence of nanoparticles with a mean diameter of 16 nm. This result is further confirmed by AFM measurements that show a large density of 20 nm high particles on the samples immersed in deoxygenated UPW.

In de-oxygenated solutions, our results confirm that the primary mode of Cu deposition is reductive, resulting in Cu metal cluster formation, while in non-deoxygenated solutions, Cu precipitates into the growing oxide as Cu oxide/hydroxide. However, at low concentrations such as 10 ppb, the concentration in the UPW is not high enough for metal cluster growth in deoxygenated solutions, and any deposited Cu is re-dissolved by the UPW solution. Therefore, the only Cu that is deposited at 10 ppb occurs by precipitation into the oxide. This mechanism results in higher amounts of deposited Cu for the air saturated solution, since an oxide grows more readily when compared to the deoxygenated solutions. Alternatively, at higher concentrations, such as 100 ppb, Cu cluster growth via the reductive mechanism can occur and therefore the amount of Cu deposited is higher for the de-oxygenated solutions since Cu is deposited both reductively and incorporated into the oxide.

4. Conclusion

It has been demonstrated that the deposition of copper onto silicon surface from ultra pure water solutions is strongly influenced by the presence of dissolved oxygen. TXRF measurements revealed that there is a concentration, above which the amount of copper deposited in deoxygenated UPW solutions was greater than that of non-deoxygenated UPW. Below this concentration threshold the reverse is true and the copper deposited is less for deoxygenated solutions. These differences suggest that the deposition mechanisms are influenced by the presence of dissolved oxygen and that reductive deposition occurs predominantly in deoxygenated UPW, while oxidative deposition primarily occurs in non-deoxygenated UPW. In addition, by measuring the Cu fluorescence as a function of angle, the presence of copper particles on the silicon surface was established for samples immersed in deoxygenated UPW. Finally, the chemical state of the deposited copper was determined using XANES. Samples immersed in deoxygenated UPW had a high metal Cu content, demonstrating that reductive deposition is the principal mechanism for deposition, while samples immersed in non-deoxygenated UPW had a high Cu(I) and Cu(III) oxide content, indicating that most the Cu deposited on the silicon surface was incorporated into the oxide.

Abstract

The electronic structure of two different samples of single wall carbon nanotubes (SWCNs) have been investigated using X-ray absorption near edge spectroscopy (XANES). The XANES data, detected around the C K edge, have been compared with that of a pure HOPG sample used as structural standard. The measurements have been carried out at the photoemission 4B9B beamline (Synchrotron Radiation Facility of the Institute of High Energy Physics of Beijing) using a surface-sensitive total electron yield technique. The samples were previously characterized using Raman spectroscopy, electron microscopy (SEM), and tunneling microscopy (STM). The bonding properties of C atoms (π^* and σ^* bands of sp^2–coordination) and the structural characteristics are identified by looking at the changes in both pre-edge and multiple-scattering regions of the XANES spectra.

The single-wall carbon nanotubes (SWCNs) were discovered in '93 [1] and are made purely of carbon atoms on a single sheet of graphite wrapped around a cylindrical axis. The same material with slight variations in the geometrical arrangement yields different electronic properties, ranging from metallic to semiconducting behavior. These nanosystems have fascinating chemical, mechanical and electrical properties which are remarkably different from those of any other carbon-based material and which suggest enormous potential applications in many technological areas, as catalysis, energy and gas storage, electron emitters, sensors, fast acting switches, molecular electronics, etc. [2–6]. In this contest it is very important to know and to control the electronic and chemical characteristics of the produced SWCNs.

Different methods were proposed to fabricate carbon nanotubes. The approach to the production of SWNCs used for this work relies on metal-catalysed reactions between atomic H and C nanopowders [7]. The amorphous C nanoparticles (diameter 40 ± 20 nm) are produced by cw-CO_2 laser-assisted pyrolysis of ethylene/acetylene mixtures in a flow-reactor [8]. The carbon nanotubes are generated using a CVD (Chemical Vapour Deposition) apparatus connected to a powder-flowing system formed by a powder reservoir, a mass flow controller and a final Mo nozzle which can be translated and rotated around the longitudinal axis. A scheme of the apparatus can be found in [9]. The C nanopowders are swept from the reservoir by Ar streams, and homogeneously distributed by the nozzle across the active area of the substrate where interaction with atomic H takes place. The main parameters of the synthesis process are: H_2 flowing rate 200 sccm; Ar flowing rate 40–60 sccm; substrate temperature 800–900 °C. The samples analyzed in this paper are representative of different kind or material which can be obtained by varying Ar flow rate and substrate temperature.

The produced nanotubes were deposited onto Si plates coated by a submicron dispersion of Fe particles.

Structural and morphological characterizations of SWCNs were carried out using Raman spectroscopy, electron microscopy (SEM), and tunneling microscopy (STM).

The SEM micrographs of Figs. 1 a) and b) show the morphology of two deposits formed by self-organized nanotubes joined together in bundles.

The STM analysis has been performed on a scanning probe microscope Jeol JSPM-4210, in low-vacuum conditions, at

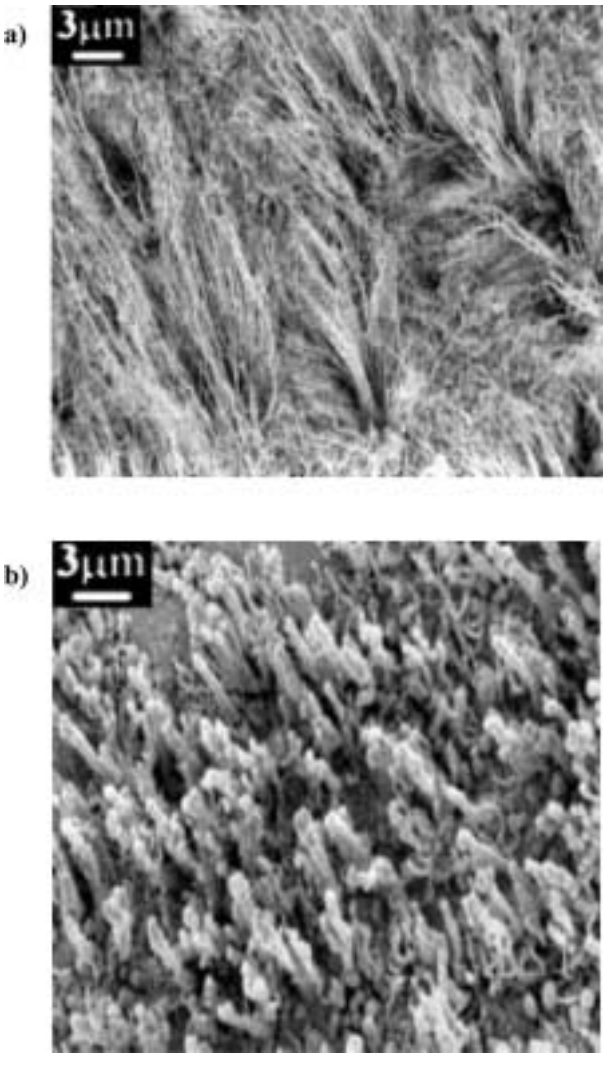

Fig. 1. SEM image of SWCNs deposits: a) sample 1; b) sample 2.

tunneling currents in the range 0.100–0.300 nA and at biases in the range 0.100–0.300 V.

STM image (Fig. 2) obtained from the same deposits of Fig. 1 a), allows to evidence a bundle formed by single wall carbon nanotubes aligned on a nanometric scale.

Further information about the structure of the nanotubes has been obtained by Raman analysis in the 80–400 cm^{-1} spectral region related to the Radial Breathing Mode (RBM) of SWCNs. The spectra were taken at room temperature in the backscattering configuration using an Ar^{-} ion laser beam (wavelength: 514.5 nm; laser power 10 mW; spectral resolution: 3 cm^{-1}). The analysis of the Raman spectra taken in the RBM region shows that under our catalytic growth conditions SWCNs are the dominant product (Fig. 3).

X-ray absorption spectroscopy (XAS) is a local structural technique of analysis based on the excitation of electronic transition from an inner level to outer unoccupied states. The photoabsorption process yields information on the local electronic structure and coordination environment around the absorbing atom. XAS techniques such as EXAFS (Extended X-ray Absorption Fine Structure) and XANES (X-ray Absorption Near Edge Structure) have been used extensively to investigate the local structure in the interior and at the surface, as well as bonding formation of a variety of solid-state materials [10–12].

The experimental set-up for the investigation of absorption spectra at the C K-edge is described in [13]. Samples were loaded in an ultrahigh vacuum chamber and maintained in a background pressure of $\sim 8 \times 10^{-8}$ Pa, although during the data acquisition the pressure rise up to $\sim 1 \times 10^{-7}$ Pa. The spectra are detected using the total electron yield (TEY) mode, a surface-sensitive detection method with a typical probing depth of a few nm. The photon energies used to record the C K-edge absorption spectrum range from 275 to 320 eV, and the experimental resolution at these photon energies is about 0.3 eV.

The C K-edge XANES spectra of the carbon nanotubes (samples 1 and 2) in TEY are reported in Fig. 4. According to the dipole-allowed transition selection rule, all spectral features are due to transitions from the carbon 1s core level to p-like final unoccupied states. The spectra show above the threshold well-resolved transition features (peaks *A* to *D*). From previous work [14–19], the two prominent transition features *A* and *C* at 285.5 and 293 eV may be associated with the existence of unoccupied π^* and σ^* bands, respectively. The behavior of transition peaks in both spectra are quite similar indicating that the short-range environment in both samples has the same structure. The spectral features *B* may be an indication of the σ^* resonance characteristic of C-H bonds [20–22] and are consistent with the growing conditions of our carbon nanotubes.

From the spectrum it is evident that the peaks of sample 2 are smoother compared to those of sample 1, which implies that the "medium-range" structure of SWCNs of sample 2 is more distorted and/or amorphous on the surface.

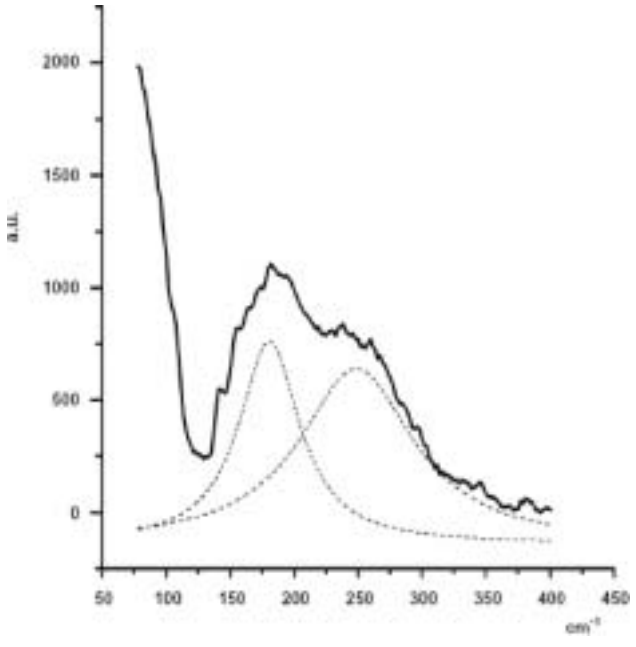

Fig. 3. Raman spectrum in the RBM region of a typical sample: the dashed line is the Lorentian fit to the experimental spectrum.

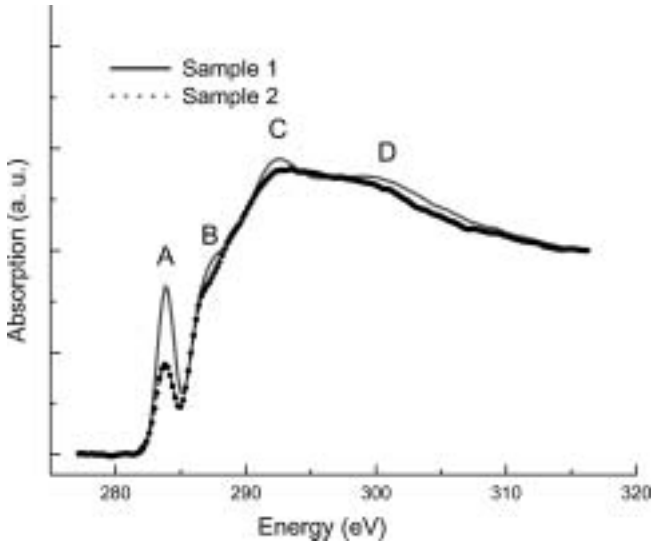

Fig. 4. The C 1s X-ray absorption spectra of sample 1 and sample 2 in total electron yield.

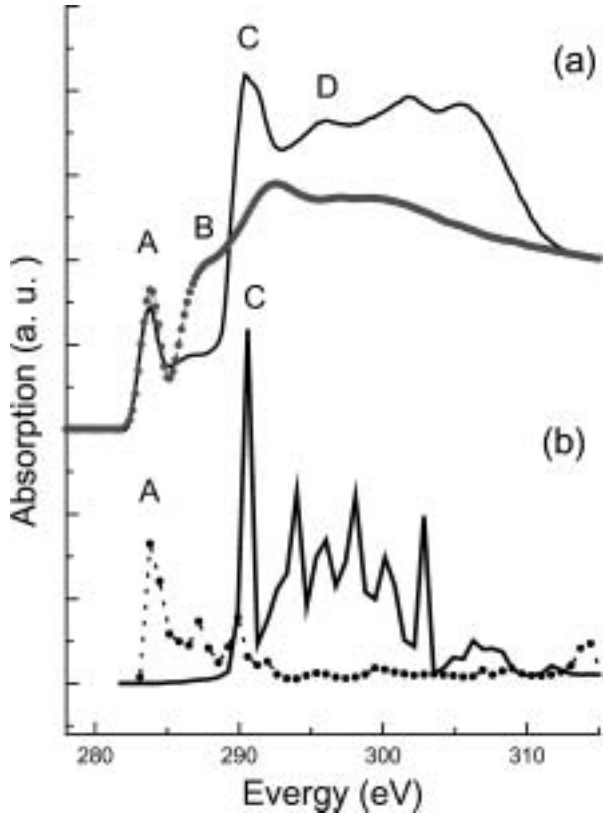

Fig. 5. (a) Comparison of the C K-edge XANES spectra of sample 1 (dot line) and highly oriented pyrolytic graphite (HOPG) in TEY (panel a). (b) Polarized multiple-scattering calculations of the C K-edge XANES of graphite: Z-component (dot line) and XY-components (solid line).

In Fig. 5(a) we present the comparison of the C K-edge XANES of sample 1 of SWCNs and the spectrum of highly oriented pyrolytic graphite (HOPG) in TEY. This latter spectrum exhibits a reasonable agreement with previous published data [14–18], i.e., as spectrum composed by three main features: an almost atomic contribution at about 285.5 eV, a peak (*A*) at about 293 eV (*C*) and the main large MS resonance centred at about 305 eV (*D*). The weak feature near 287.5 eV (*B*) was generally observed in the X-ray absorption spectra of graphite and attributed to the free-electron-like interlayer states in the graphite [23, 24]. If we look to the *A* structure, the intensity of this feature does not change significantly between CNT and HOPG, indicating that the structure just above the Fermi level is mainly a molecular interaction between the central atom and its nearest neighbour coordination shell (short-range effects), which addresses also a reasonable ordering of the carbon matrix. However, a difference between the spectra of SWCNs and HOPG can be recognized looking at the 289–320 eV region: the transition 1s $\rightarrow$ σ*-like states is less intense and fairly broadened in the SWCNs. This behaviour implies that the "long- or medium-range" atomic order deviates from graphite one (e.g. disorder and/or distortion effects). Actually in a bundle of self assembled nanotubes, carbon atoms experience an anisotropic geometry due to the fact that each C atom is bonded to the C atoms of the same graphene sheet and to the C atoms of the adjacent tubes. The anisotropic environment of the atoms can be certainly one of the causes of the distortion of the original trigonal structure. This mechanism, in turn, increases the number of distinct photoelectron scattering paths in a nanotube, yielding a broadening of the XANES spectrum. These effects may be due to a random phase decoherence among each set of closely similar multiple scattering paths and the variation in the threshold E_0 in the absorption coefficient [25]. Such effects could be also ascribed to the fact that the tubes in the bundles are not infinitely long neither perfectly straight. However, also the compositional disorder, i.e. the presence of H atoms of others impurities, leads to the smearing of near-edge features.

In Fig. 5(b) we present for comparison, the polarized XANES calculation of graphite using 215-atom cluster within a sphere of radius 7.5 A in the framework of the multiple scattering theory [26–30]. It is clearly evidenced in the dot line that the π* states (peak *A*) are reproduced in the Z-polarized component which corresponds to C $2p_x$ and $2p_y$ orbitals. This resonance is strong at grazing X-ray incidence, when the X-ray electric field vector has a large projection along the direction of the p orbital, and it is the weakest at normal X-ray incidence, when the electric field vector is perpendicular to the p orbital [19]. The corresponding 1s to σ* transitions around 293 eV appear in the XY-polarized calculation which contains the C $2p_z$ orbital and exhibits the opposite trend as expected since the σ* is orthogonal to the π*. It is work to notice that the position of σ* feature in SWCNs shifts towards higher energy than those in graphite indicating than the C-C distances in SWCNs are shorter than the one in graphite. The quantitative simulation are in progress and will be presented in a forthcoming paper.

The data at the C K edge in SWCNs and comparison with graphite show that structural and bonding configurations can be recognised looking at the characteristic pre-edge features. Moreover the investigation of the different features in the multiple-scattering region is found to be of fundamental importance to better understand topology and degree of order of these materials. These measurements can also be used to choose the chemical environment (i.e. H atmosphere) for the selected growth of SWCNs with specific properties.

Abstract

Recent progress in synthesis of "giant" polyoxomolybdate (POM) molecules that have a structure of hollow spheres or wheels and size of several nanometers in diameter has emphasized the need in their accurate structural investigation. Our temperature-dependent EXAFS studies demonstrated that the first generation POM molecules containing 132 Mo atoms, undergo irreversible structural transformations at ca. 500 K, while the recently synthesized second generation POM at ca. 400 K. The number of different structural units in these molecules can be accurately obtained from EXAFS analysis and compared with model structure calculations. In our method of analysis, we use theoretical calculations of pair radial distribution functions from the model structures as initial approximations to analyze the structures of these molecules. Our analysis allowed us to identify the new POM structure as a giant sphere, similar to the $\{Mo_{132}\}$ structure but containing 522 Mo atoms. Our results also demonstrate that the structural rigidity of different building blocks of these molecules can be quantitatively probed by EXAFS.

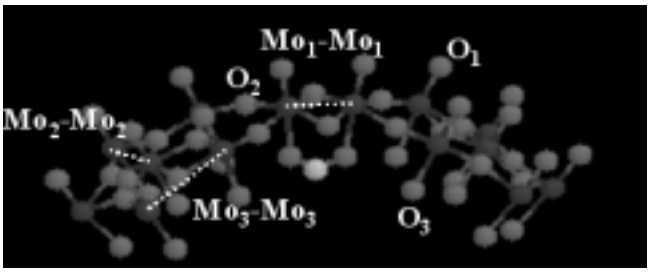

Fig. 1. Building blocks of the $\{Mo_{132}\}$ structure. Shown are $\{(Mo)Mo_5\}$ pentagons that have two types of Mo-Mo bonds: Mo_2-Mo_2 and Mo_3-Mo_3, and the $\{MO_2^{V}O_4\}$ bridges that have the third type of Mo-Mo bonds, denoted as Mo_1-Mo_1. Shown also are three types of oxygen atoms that belong to three distinct bond types: Mo-O_1, Mo-O_2, and Mo-O_3.

1. Introduction

In polyoxomolybdate (POM) molecules, that belong to a class of structurally underconstrained systems, a number of fascinating physical properties are expected. For example, in an analogous framework system, ZrW_2O_8, the presence of "rigid unit modes" (RUMs) was proposed to be the driving force of the recently discovered negative thermal expansion (NTE) [1]. These RUMs are a special class of "floppy modes" that were recently observed in amorphous and crystalline silicates, the transverse acoustic modes of a framework structure composed of rigid SiO_4 tetrahedra [2].

The building blocks of the $\{Mo_{132}\}$ structure can be visualized (Fig. 1) as containing 12 $\{(Mo)Mo_5\}$ pentagons with longer Mo-Mo distances and 30 $\{Mo_2^{V}O_4\}$ bridges that have shorter Mo-Mo bond lengths [3]. The structural data available from X-ray crystallography were processed by our software program that computes pair radial distribution functions (PRDF) $g_{AB}(r) = dN_{AB}/dr$ for A-B pairs (where element A is a central (absorbing) atom and element B is its neighbor. In the present case, the distributions were calculated for Mo-O and Mo-Mo neighbors. As it will be shown below, these calculations were essential to adequately analyze EXAFS data in the reference $\{Mo_{132}\}$ structure and apply the same analysis procedure to the unknown $\{Mo_N\}$ structure.

2. Synthesis and characterization of the 1st and 2nd generation "giant spheres"

The synthesis of the C_{60}-like $\{Mo_{132}\}$ and another even larger, hollow, spherical POM (likely to have the structure of 2nd generation of C_{60}-like) have been reported in literature [4, 5]. It is very easy to synthesize and grow $\{Mo_{132}\}$ single crystals that can be used for structure determination by single crystal X-ray diffraction experiments. However, for the larger POM, the final products are usually powders or tiny crystals. Small-angle X-ray scattering measurements showed ordered 5.2-nm primitive cubic packing of the single POM molecules, indicating the new POM molecules are extraordinarily large (for comparison, $\{Mo_{132}\}$ has the size of 2.9 nm), but the molecular structure of the new POM cannot be directly determined. We describe here that convincing evidence can be obtained from EXAFS measurements by realizing that the basic building units for various POMs are the same.

3. EXAFS measurements and analysis of the nano-spheres

EXAFS measurements were performed at the beamline X16C of the National Synchrotron Light Source (NSLS). Both types of samples, the $\{Mo_{132}\}$ and the 2nd generation $\{Mo_N\}$ spheres, were measured in transmission at different temperatures (from 140 K to 473 K) under nitrogen flow, using a custom-designed and built catalyst cell. Above ca. 500 K, the $\{Mo_{132}\}$ samples underwent irreversible structural transformations. The onset of the irreversible changes was lower (ca. 400 K) for the $\{Mo_N\}$ samples. Irreversibility was checked by comparing the data measured at 300 K before and after thermal treatment.

Different groups of Mo-O and Mo-Mo bonds can be observed in Fig. 2 that shows raw EXAFS data. Next to the horizontal axis in Fig. 2 (B), the PRDF plots are also shown. Comparison between the *r*-space data and X-ray crystallography results visualized by the PRDF plots demonstrates that EXAFS contains unique information on each of the structural groups (3 Mo-O groups and 3 Mo-Mo groups, Fig. 1). For example, the peak at ca.1.2 Å in Fig. 2 (B) corresponds to the Mo-O_1 axial pair in

*e-mail: frenkel@bnl.gov

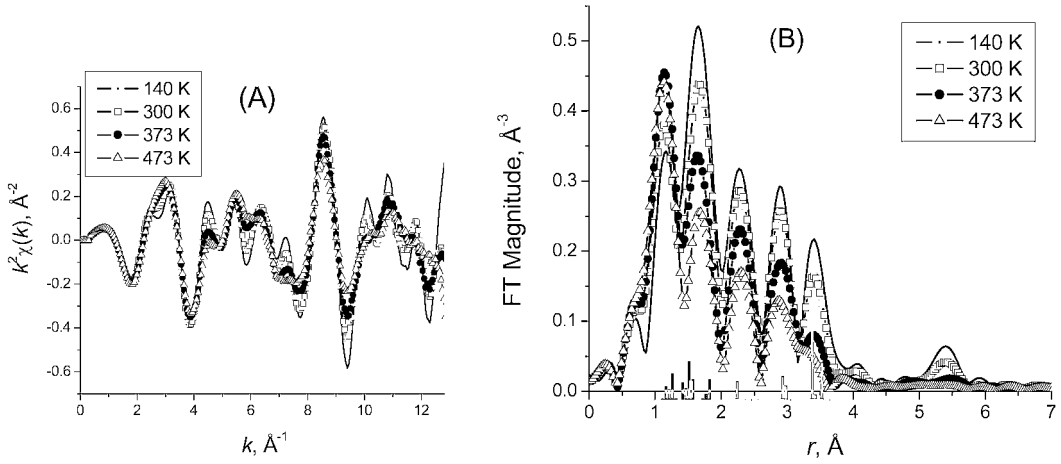

Fig. 2. EXAFS data (in k- and r-spaces) of the $\{Mo_{132}\}$. The radial distribution functions of Mo-O and Mo-Mo pairs, shifted toward lower r by 0.5 Å and 0.3 Å, respectively, are shown next to the horizontal axis in (B).

MoO_6 octahedra. The second peak, at ca. 1.7 Å corresponds to another axial Mo-O_3 and the equatorial Mo-O_2 bond groups of MoO_6 octahedra. From visual observation (the first peak intensity increases with temperature while that of the second peak decreases with temperature), one can hypothesize that the MoO_6 octahedral environment is not rigid. Rather, it should become progressively distorted at elevated temperatures.

FEFF6 [6] was used to calculate model Mo-O and Mo-Mo theoretical contributions to EXAFS. The theory that included three Mo-O and three Mo-Mo single-scattering paths was fitted to the data in r-space using FEFFIT [7]. The coordination numbers of each type of bond were dictated by the $\{Mo_{132}\}$ structure and fixed in the fits to be equal to the values obtained by our PRDF calculations. The bond lengths and disorders were varied independently for all bonds. Fit quality is shown in Fig. 3 for the lowest and highest temperatures analyzed.

The EXAFS data in the unknown sample, $\{Mo_N\}$ (Fig. 4) look strikingly similar to the $\{Mo_{132}\}$ standard (Fig. 3). Indeed, the peak positions align well for the Mo-O and Mo-Mo bonds between the two samples. Since the r-space data in the case of Mo_{132} structure mimics the PRDF obtained for a spherical particle that has $\{(Mo)Mo_5\}$ pentagons and $\{Mo_2^VO_4\}$ bridges with characteristic Mo_1-Mo_1, Mo_2-Mo_2 and Mo_3-Mo_3 bond lengths, the fact that

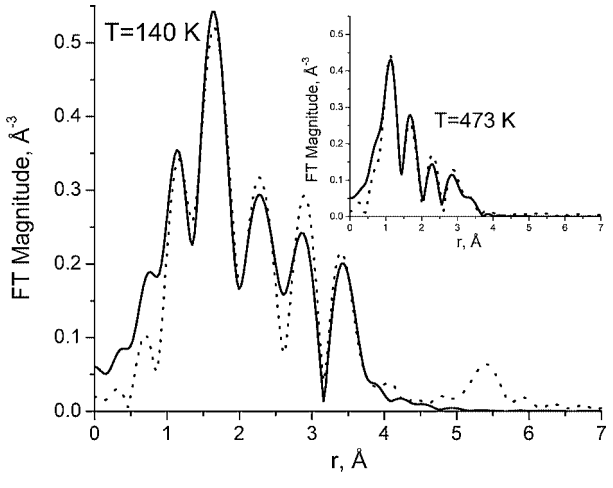

Fig. 3. Fourier transform magnitudes of EXAFS data and fits of the $\{Mo_{132}\}$ at 140 K and 473 K.

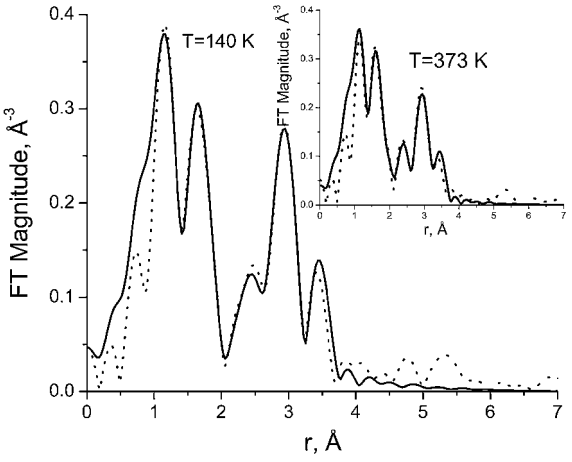

Fig. 4. Fourier transform magnitudes of EXAFS data and fits of the 2nd generation sphere at 140 K and 373 K.

our data for the unknown samples has signatures of the same groups indicates that the topological properties of the two types of particles, $\{Mo_{132}\}$ and $\{Mo_N\}$ should be very similar. In literature, one of the possible candidates for a spherical cluster that is larger in size than Mo_{132} is the 522-atom cluster that also has pentagons and bridges like the $\{Mo_{132}\}$ [8]. That justifies our analysis approach as nearly identical to that of the $\{Mo_{132}\}$ reference structure: we fixed the coordination numbers of each type of bond in accordance with the $\{Mo_{522}\}$ structure and varied the bond lengths and their disorders. The data and best fits are shown in Fig. 4 for the lowest and highest temperatures analyzed.

4. Results

σ^2 for the axial Mo-O_1 and Mo-O_3 bonds were found to be almost the same ($\sim$0.004(1) Å^2) throughout the temperature range (140 K to 473 K). The σ^2 for the equatorial Mo-O_2 bonds increased three-fold from 0.0050(9) Å^2 to 0.0142(15) Å^2 in the same temperature range.

The best fit values for the bond lengths for $\{Mo_{132}\}$ (shown by solid vertical lines in Fig. 5) were consistent with the PRDF calculations. The best fit results obtained in the 2nd generation sphere sample were also consistent with the same distance ranges for the three Mo-O bond groups and three Mo-Mo bond groups (shown by dashed vertical lines in Fig. 5), as in $\{Mo_{132}\}$ structure.

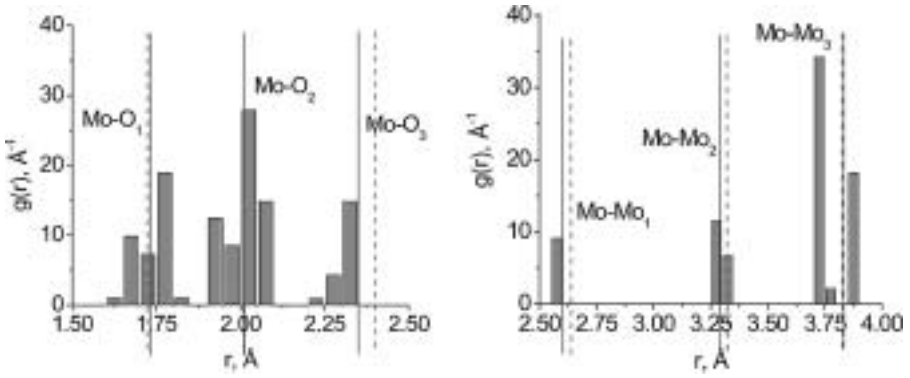

Fig. 5. PRDFs calculated from the crystallography data for Mo-O and Mo-Mo pairs. Shown by vertical lines are the best-fit EXAFS results for each group of distances obtained for the 1st and 2nd generation spheres.

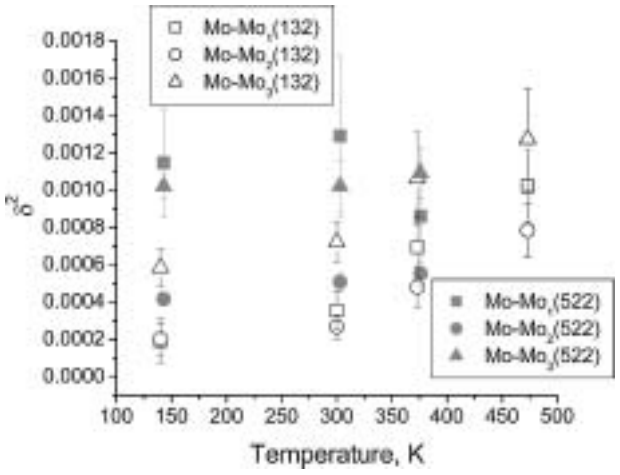

Fig. 6. Bond-length-normalized mean square displacement δ^2.

Figure 6 shows the normalized bond length disorder parameter, $\delta^2 = \sigma^2/R^2$ (where R is the bond length) that we calculated based on the best fit results obtained for σ^2 for each of the three Mo-Mo bonds in the both samples. The use of δ^2 is preferred because longer bonds may have larger σ^2 than shorter bonds not only due to the longer bonds' larger disorder but also due to the smaller correlation between the vibrations of their atoms. If σ^2 is normalized by R^2, the ambiguity caused by the Mo-Mo bond length differences in different structures will be partially lifted when the rigidities of the two structures are examined.

5. Discussion and Conclusions

The fit results for σ^2 of Mo-O bonds confirmed our hypothesis that the MoO_6 octahedra are not rigid in $\{Mo_{132}\}$. From the trend described above we infer that the MoO_6 octahedra are progressively distorted at elevated temperatures. This property has a familiar ring from the NTE materials where an asymmetric "tentpole" distortion of what previously was believed to be a rigid unit, a ZrO_4 tetrahedron, was proposed to be an alternative scenario to transverse O vibration in the W-O-Zr linkages in ZrW_2O_8 [9].

For the structure of the 2nd generation molecule, our results show that the topology of this molecule is analogous to that of $\{Mo_{132}\}$, as we assumed based on preliminary visual observation of the data. Because the number of Mo^V-Mo^V bonds (denoted by Mo_1-Mo_1 in Fig. 1) is much larger in this molecule (as determined by UV/vis. spectrometry, $\sim 87 \pm 8\%$ of Mo atoms in the POM are Mo^{VI}, compared to 55% in $\{Mo_{132}\}$) than in $\{Mo_{132}\}$, and due to the uniqueness of the topological characteristics of various POMs, the structure of this molecule must be that of $\{Mo_{522}\}$.

The non-monolithic nature of POMs has been discussed previously. As pointed out by A. Müller, *et al.* [10], most POMs consist of different $\{MO_x\}$-type building-block units that are highly stable. However, the linkages that connect these building blocks directly or via other coordinating centers [10] may be fragile and break even at moderate temperatures. As predicted by the different stability ranges of temperature in the $\{Mo_{132}\}$ and $\{Mo_{522}\}$ molecules, their structural rigidities should be different. Our EXAFS results indicate that the dominating factor responsible for this effect is the rigidity of the Mo^V-Mo^V bridges that connect the building blocks in these two structures. Figure 6 demonstrates that in Mo_{132}, these bridges are less disordered and therefore, more stiff than in Mo_{522}. We believe that the relative rigidity of these bond types, which serve as bridges between the $\{(Mo)Mo_5\}$ pentagon building blocks, revealed in our analysis of $\{Mo_{132}\}$ EXAFS data is the origin of these molecules' enhanced stability over the $\{Mo_{522}\}$ particles.

Abstract

Preparation of catalysts in molten salt has great possibilities for producing excellent catalysts because the reaction in molten salt is quite different from that in water. MoO_3 dissolves in molten salt and finally becomes molybdate via intermediate oxoanions as catalytic active species. The structure of the oxoanions and the mechanism of stabilization on zirconia in the preparation process remain unknown. In the previous study, we have clarified the changes in the composition of molybdate species during the catalyst preparation procedures by quenching the samples. In the present paper, the structure of Mo oxoanions in molten nitrates at different temperatures was investigated by *in situ* XAFS.

Samples were prepared from MoO_3 in molten nitrate ($NaNO_3$). The mixture was heated up to various temperatures from 298 to 773 K. The *in situ* XAFS spectra of the molted samples were measured on Mo K-edge using an *in situ* cell at the BL-10B in the Photon Factory.

The EXAFS was analyzed quantitatively to obtain the structure and composition of Mo oxoanions in the molten nitrates by multi-component fitting based on a linear combination of $\chi(k)$ of reference samples and simulation using FEFF8 code in consideration of the Debye-Waller factor. The results show a change of composition of oxoanions in molten nitrate during the reaction.

1. Introduction

Catalyst preparation by the molten salt method has been shown to produce novel catalysts with high surface areas. In the preparation of molybdenum catalysts, MoO_3 is at first dissolved in the molten nitrate and subsequently transforms into some intermediates before completely changing to MoO_4^{2-} anions [1–4]. However, the structures and the reaction mechanisms of the intermediates have not been clarified yet. Because these intermediates do not have long-range ordered structures, we applied XAFS to the structural analyses involving composition determination of molybdate species in mixed KNO_3 and $NaNO_3$ salt [5]. In the previous study, we have clarified the changes in the composition of molybdate species during the catalyst preparation procedures [6].

In the present report, the reaction behavior of the preparation of unsupported molybdate catalysts in molten nitrate was investigated by *in situ* EXAFS. For this purpose, XAFS measurements were done using an *in situ* cell at various temperatures between 298 and 773 K.

2. Experimental

Unsupported molybdenum oxide catalysts were prepared from a MoO_3 precursor (5 mg) with 150 mg of $NaNO_3$ in an *in situ* cell of a quartz reactor with a thin window of 0.5 mm thickness to transmit X-rays. The cell tapers off at the bottom like a wedge to adjust X-ray path length by changing beam position. The amount of molten nitrate corresponds to a 10–20 fold molar excess. The mixture was heated up to 773 K at a heating rate of 1 K/min being kept for 1 h stepwise at 473, 523, 573, 623, 673, and 723 K and for 2 h at 773 K during an XAFS measurement as shown in Fig. 1. The Mo K-edge XAFS measurements were performed at the Photon Factory using BL-10B with a Si(311) channel-cut crystal monochromator. Fourier transformation was performed for $\Delta k = 80\,\mathrm{nm}^{-1}$ of Mo K-edge EXAFS. The phase shift and backscattering amplitude factor were corrected by using the calculated values of FEFF8 [7] for Mo as an absorber and O as a scatter in crystalline $Na_2MoO_4.2H_2O$.

Multi-component fitting of spectra was done using linear combination of experimental data of reference samples under non-negative constraint conditions. In particular, the k^3 weighted measured spectra were compared with synthesized spectra of reference spectra in k-space ($k = 30$–$110\,\mathrm{nm}^{-1}$) using the chemical composition as the parameter. MoO_3, $Na_2MoO_4.2H_2O$, and $Na_2Mo_2O_7$ were chosen as references.

3. Results and Discussion

It is not easy to *in situ* measure XAFS of molten salts because they are highly reactive with emission of NO_x gas and fundamentally heterogeneous in molten state. Figure 1 shows XANES spectra of Mo K-edge of $MoO_3/NaNO_3$ at 298–773 K plotted vs. time. A disturbance of the spectra occurred around the melting point. After the melting point, a precipitate was found in molten salt and a little NO_x gas bubbles rose up from the molten salt. Therefore temperature as increased very slowly. The X-ray beam irradiated on the precipitate. The color of the precipitate changed from yellow to white with the increase of temperature. The edge shape changed from that of MoO_3 to that of MoO_4^{2-} at the melting point indicating the change of dominant species.

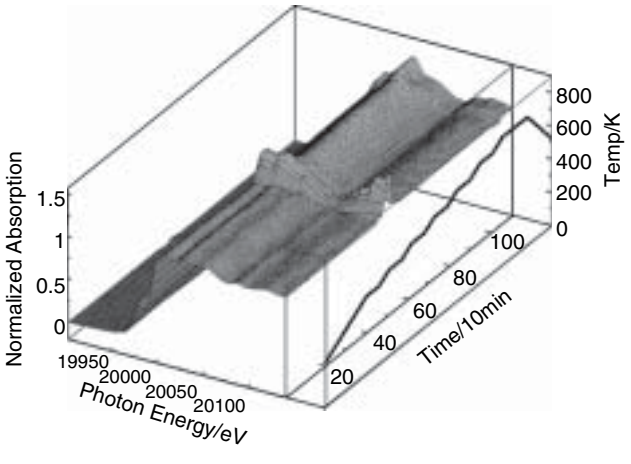

Fig. 1. In situ XANES spectra of Mo K-edge of $MoO_3/NaNO_3$ at 298–773 K.

*e-mail: n-matsubayashi@aist.go.jp

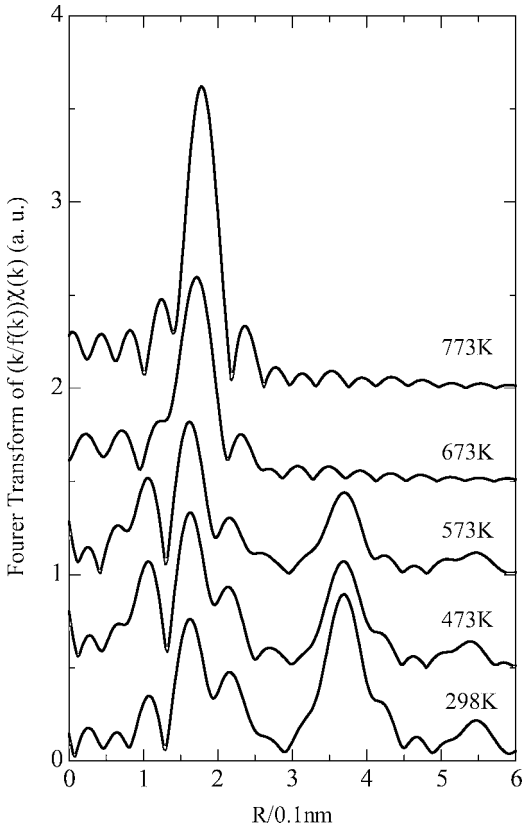

Fig. 2. Fourier transforms of $(k/f(k))\chi(k)$ of Mo K-edge EXAFS of $MoO_3/NaNO_3$ measured at 298–773 K.

Figure 2 shows the Fourier transforms of $(k/f(k))\chi(k)$ of Mo K-edge EXAFS of $MoO_3/NaNO_3$ measured at 298–773 K. The peak at 0.36 nm is assigned to Mo-Mo scattering of the MoO_3 structure. This indicates that the local structure of MoO_3 precursor remains intact before melting. With increasing temperature, the intensities of the peaks at 0.36 nm decrease, whereas the intensities of the peaks at 0.18 nm corresponding to Mo-O scattering in the highly symmetrical tetragonal MoO_4^{2-} structure increase. These results show that the MoO_3 precursor transforms into MoO_4^{2-} with increasing temperature.

In the reaction process of MoO_3 in the molten salts, many species of molybdenum oxides coexist as an amorphous state that seems to be important in catalyst activity. However, a quantitative analysis in a general idea of a crystal structure that has long range order measurable by X-ray diffraction is difficult. So, quantitative analysis according to local structure of a circumference of molybdenum by XAFS was attempted.

In the local structure around Mo of typical molybdenum oxides, the distance of Mo-O of four coordinates in tetrahedral MoO_4^{2-} is 0.18 nm and the distances of Mo-O of six coordinates in distorted octahedral MoO_3 are distributed in a range of 0.17–0.23 nm. The EXAFS signal of 6 coordinates in MoO_3 is smaller due to distortion than that of 4 coordinates in MoO_4^{2-}. In $Mo_2O_7^{2-}$, both structures coexist and the intensity of EXAFS is intermediate. This means that it is difficult to analyze quantitatively from the intensity of EXAFS signal in mixture of these oxide species.

In usual curve fitting analysis of EXAFS, three structural parameters of distance, R, coordination number, N, and Debye-Waller factor, σ, for each coordination shell are used mainly. The coordination shell should be ideally selected with a unique distance, but practically the coordination shell is often selected with intermediate distances such as six coordinates in a distorted octahedron. In this case, the distances are assumed to be distributed in gauss distribution to be fitted to a Debye-Waller factor. However, the assumption is obviously wrong for interatomic distances from crystal data.

The curve fitting for 4 coordinates in MoO_4^{2-} is easy. But in the curve fitting for 6 coordinates in MoO_3, if the coordination number is fixed to 6, the Debye-Waller factor would be large. Therefore the usual curve fitting analysis of EXAFS for a mixture of molybdenum oxides is difficult.

We have analyzed the $\chi(k)$ spectra using multi-component fitting with a linear combination of Mo species in mixtures consisting of $Mo_2O_7^{2-}$, MoO_4^{2-}, and MoO_3 according to the following formulas.

$$\chi_{cal}(k) = a\chi_a(k) + b\chi_b(k) + c\chi_c(k) + \cdots,$$

$$(\chi_{\exp}(k) - \chi_{cal}(k))^2 \rightarrow \min,$$

$$a, b, c \cdots \geq 0,$$

$$a + b + c + \cdots = 1.$$

Each $\chi(k)$ was weighted by k^3 in the fitting.

Correction with a Debye-Waller factor is necessary to compare the data of the *in situ* measurement at different temperatures. In the linear combination fitting, the correction was done by the data measured at the temperatures. We assumed that the static contribution of the Debye-Waller factor to the EXAFS amplitude is constant with temperature and the thermal contribution can be expressed as second and forth order cumulants. To interpolate for temperature, indexes σ_{2t}^2 and σ_{4t}^4 of exponential function like a Debye-Waller factor including anharmonic term ($\exp(-2\sigma_{2t}^2k^2 + 2\sigma_{4t}^4k^4/3)$), which are relative to $\sigma_{2t}^2 = 0$, $\sigma_{4t}^4 = 0$ at 298 K was introduced as fitting parameters to the $\chi(k)$ data of MoO_3, $Na_2Mo_2O_7$, and Na_2MoO_4 at each temperature using that at 298 K instead of a Debye-Waller factor of each coordination shell. The fitting parameters were increased with increasing temperature as shown in fig. 3.

In the fitting, some possible reference data including ammonium molybdate ($(NH_4)_6Mo_7O_{24}.4H_2O$) and phosphomolybdic acid ($P_2O_5.24MoO_3.nH_2O$) were attempted. The data that give a minus coefficient or large uncertainly were removed. As a result, fitting by reference data of MoO_3 $Na_2Mo_2O_7$, and MoO_4 was the best in the attempted data.

Figure 4 shows results of fitting of linear combination of $\chi(k)$. Since spectra around 600 K, the melting point indicated by a dashed line, are disturbed, stability of fitting is not good. However, just after the melting point, MoO_3 decreases, $Na_2Mo_2O_7$ increases at 673 K, and Na_2MoO_4 becomes a dominant species at 723 K.

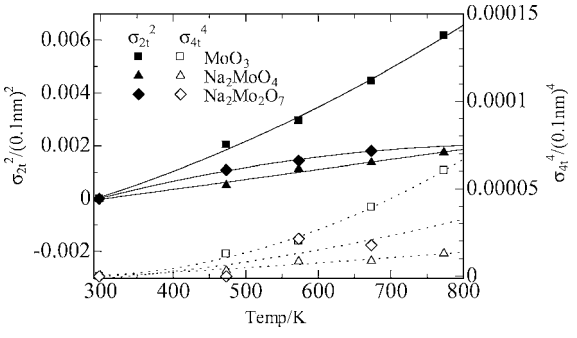

Fig. 3. Temperature dependency of total correction parameters for Debye-Waller factor, σ_{2t}^2 and σ_{4t}^4, experimentally determined by fitting on MoO_3, $Na_2Mo_2O_7$ and Na_2MoO_4.

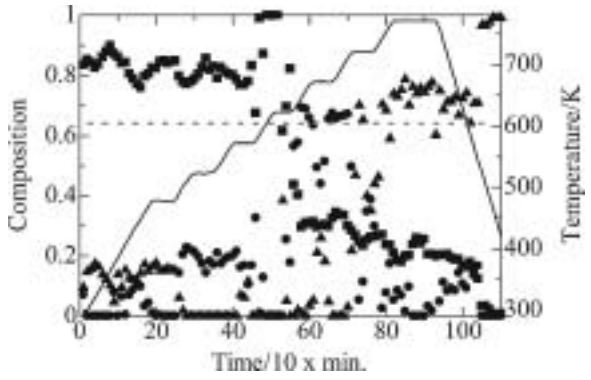

Fig. 4. Results of fitting of composition of Mo species in molten sodium nitrate obtained by EXAFS data fitting. ■ MoO_3, ● $Na_2Mo_2O_7$, ▲ Na_2MoO_4.

This tendency agrees with previous results obtained by quenching method. But the result of the *in situ* measurement revealed that MoO_3 and $Mo_2O_7^{2-}$ remained by about 15% in 773 K in a molten state and they become almost perfectly MoO_4^{2-} after freezing by cooling. Other molybdenum oxide species than the above three species may have formed in the mixture. The local structure of other polymolybdate species seemed to be similar to $Mo_2O_7^{2-}$, thus $Mo_2O_7^{2-}$ is a typical species of polymolybdate as a result. Thus, the total composition of the three species is normalized to 100%. Strictly speaking, the percentage obtained by this procedure does not necessarily correspond to the real percentage of components, but it indicates the relative contribution of the signal of the model to the EXAFS signal. Many other molybdenum oxide species, of which crystal data are not available, seems to coexist in the molten salt. It is necessary to add simulation models produced from the residual in the linear combination fitting to the reference data but the reliability of this procedure depends on the propriety of the model. At the next step, we will build reasonable models to explain the EXAFS results by combination with molecular mechanics and dynamics.

4. Conclusions

The *in situ* XAFS measurements of molten salts were performed by slowly increasing the temperature. A new fitting method of linear combination of reference $\chi(k)$ data was proposed for quantitative analysis by local structure around Mo of mixture system and estimated a change of composition of molybdenum oxide species with increasing temperature. MoO_3 and $Mo_2O_7^{2-}$ remained by around 15% as local structure even in 773 K after reaction in molten salt, and they were almost completely transformed to MoO_4^{2-} by cooling. This means that the analysis by quenching method does not exactly reflect the molten state.

Acknowledgment

This study was carried out under the collaboration between IRC and AIST in the PICS program. The XAFS measurements were performed under the approval of the Photon Factory Program Advisory Committee (Proposal 2001G327).

Abstract

Ni-Raney catalysts have a sponge-like structure and are largely applied in reactions of organic hydrogenation. The industrial production has the advantages of low cost and simple process, however this catalyst has the inconvenient of the easy deactivation. The understanding of the deactivation mechanism has motivated several studies, some of them identifying a surface restructuration and loss of the active sites. In this work, we present XRD and XAS measurements at the Ni K edge of Ni-Raney samples obtained before and after an industrial reaction of olefin hydrogenation. We show that in the deactivation process, the porous structure of Ni grains becomes closer to the massive structure, presenting a higher number of first neighbors and an increase of the crystalline coherence. These results call into question the usual hypothesis of collapse of the porous structure.

1. Introduction

Ni-Raney catalysts are largely used in industrial processes of olefins and carbonyl groups hydrogenation reactions [1, 2]. Due to the easy deactivation of the catalyst, many efforts have been dedicated to elucidate the mechanism of this process [3]. The accumulation of organic species in the pores has been considered as a weak reason for the deactivation, and the main effect has been attributed to the collapse of the pore structure [4].

The main line of business of GETEC Guanabara Química Ind. S/A is the conversion of sugars into polyols by means of hydrogenation processes. X-ray absorption spectroscopy (XAS) and X-ray diffraction (XRD) were combined to analyze samples of freshly prepared and deactivated catalysts produced at GETEC.

2. Experimental

XAS, and XRD measurements have been performed at the LNLS (Laboratório Nacional de Luz Síncrotron), Campinas, Brazil. XAS samples were sealed with kapton tape immediately before the measurements. XAS spectra were performed at the Ni K edge in transmission mode. The X-ray beam was monochromatized with a "channel cut" Si (111) crystal. The instrumental resolution was 2.9 eV. The WINXAS program [5] was used for EXAFS data analysis. In XRD measurements, a sample holder with 5 mm window was used in an upside down position, aiming to minimize the interference of the water present in the fresh catalyst. XRD patterns were obtained at 8,200 eV, using a double crystal monochromator (Si (111)) with a sagital focusing in the second crystal.

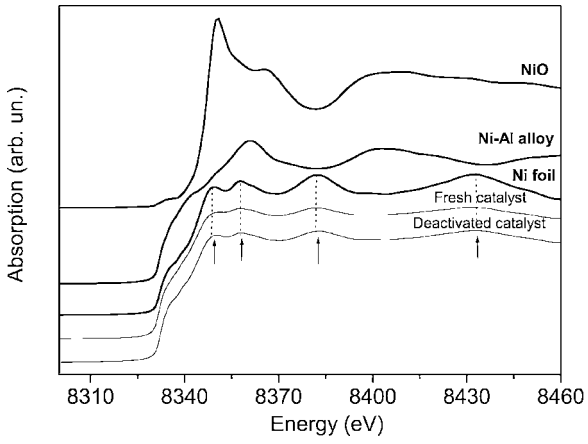

Fig. 1. XANES spectra at Ni K edge.

3. Results and discussion

3.1. *XAS measurements*

Figure 1 shows the XANES spectra of the freshly produced and deactivated catalyst at the Ni K edge. The XANES spectra demonstrate clearly that the chemical environment around the Ni atoms in the catalysts are identical to the metallic Ni foil, in which the structure on the threshold is related to the electronic transition from 1s level to the hybridized 3d-4p level [6]. The agreement of the energy position at the absorption edges (Ni K edge = 8,333 eV) demonstrates that even after the deactivation, the catalyst do not suffer changes in oxidation state, remaining in the metallic form of Ni^0. The structures indicated by the arrows (Figure 1), characteristic of nickel in FCC (face-centered cubic) packing, are preserved in the catalyst spectra, but with a reduction in amplitude of the oscillatory structures.

The Fourier Transform (FT) of the EXAFS oscillations (Figure 2) over the range 2.9–12.8 Å shows the decrease in the intensity of the peaks for the catalysts when compared to the metallic nickel. It can be related to the presence of a smaller average number of neighbors or a large increase of the disorder. The contribution of the first shell is selected by back Fourier filtering over the range 1.8–2.8 Å. Electronic parameters have been obtained from the metallic foil and used in the k-space least square fitting of the catalysts. This procedure certifies high reliability in the comparison of the structural parameters of the catalyst to those of the bulk nickel (Table I). The agreement between the experimental and adjusted curves is excellent. The σ^2 value is low, indicating a low disorder, with no lattice distortion or strain in the catalysts crystalline structure. The number of neighbors is reduced (around 6) in agreement to the XANES

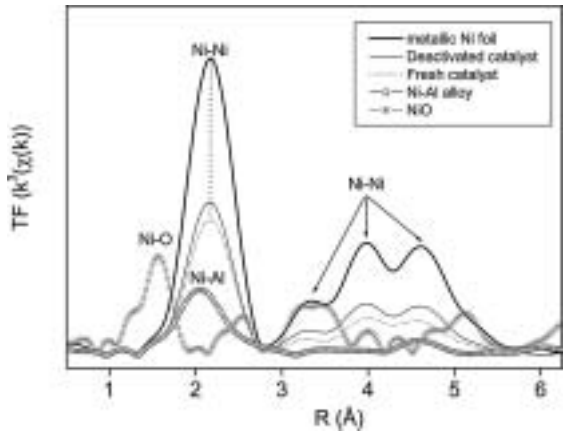

Fig. 2. FT of the EXAFS signal.

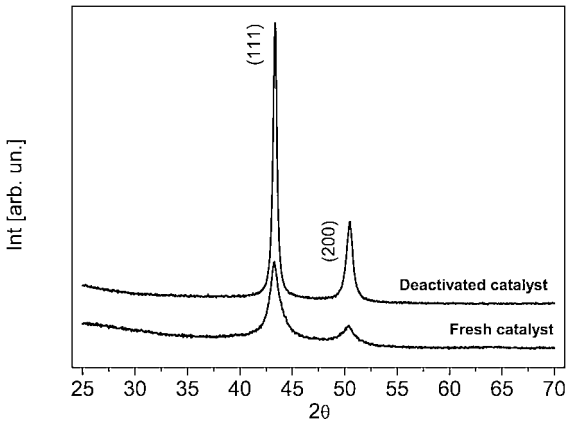

Fig. 3. X-Ray diffraction patterns.

Table I. *Quantitative analysis results of the coordination shell. N = number of neighbors, R = distance, $\Delta\sigma^2$ = Debye Waller factor in comparison to metallic Ni foil pattern.*

Sample	N	R (Å)	$\Delta\sigma^2$ (Å^2)
Fresh catalyst	5.90 ± 0.02	2.494 ± 0.003	0.0012 ± 0.0005
Deactivated catalyst	6.63 ± 0.03	2.495 ± 0.004	0.0014 ± 0.0004
FCC Ni foil	12	2.49	

results. There is no significant change in the Ni-Ni distances for the catalyst.

These results seem surprising since they do not obey the bond valence sum rule, in which low number of neighbors implies shorter distances. In spite of the fact that there is no evidence of aluminum or oxygen atoms participating on the chemical environment around the Ni atoms, it sounds reasonable to consider a surface with passivated dangling bonds.

We note that there is a significant increase of N after the deactivation effect that should be correlated to a decrease in the superficial area in the deactivated catalyst.

3.2. *XRD measurements*

The figure 3 shows the diffraction patterns of the catalyst samples. We observe broad peaks in the case of fresh catalyst and higher and sharper peaks after the deactivation [7]. This result indicates that in the deactivation process, the nickel framework not only gain more neighbors in a local order as demonstrated by XAS, but also gains crystalline coherence in a long-range order.

As demonstrated by XAS results, the broadness of the fresh catalyst can not be attributed to effects of lattice strain. Moreover, due to the morphological characteristic of the sponge-like structure, the calculation of crystallite sizes is fundamentally unfair. Even so, considering the approximations of the Scherrer equation [8], we can estimate the crystalline coherence length in the catalyst before and after the deactivation. This length is 7 nm for the fresh catalyst, and 17.5 nm for the deactivated one, in agreement to the hypothesis of enhancement of the crystalline coherence.

4. Conclusions

XAS and XRD measurements indicated that in the deactivation process, the porous Ni particles, become more close to the massive structure, presenting a higher number of first neighbors and an increase of the crystalline coherence length. With these evidences we propose the occurrence of a modification in the tridimensional connectivity of the solid during the deactivation process, that causes an increasing of the structural crystallinity of the catalyst. The precise mechanism involved is still an opened question, but the results presented in this work refuse the current hypothesis of pore collapse.

Abstract

Nanosized spherical silver particles were formed in silicate glass by sodium/silver ion exchange and subsequent annealing in air or hydrogen atmosphere at elevated temperatures. Furthermore, the sol-gel procedure was used to prepare embedded Ag particles. Structural characterisation of these composite materials by temperature dependent EXAFS-spectroscopy with transmission and fluorescence experiments revealed distinct differences of the particle/matrix interaction across the interface. The Ag-O and Ag-Ag correlations could be separated by fit procedures. The Ag-Ag bond length of the crystalline particles sensitively reflects their state of stress depending on the formation conditions. It was found an increase as well as a decrease of the Ag-Ag distance, i. e. tensile and compressive stress states were formed, for ion-exchanged glasses as a result of different cooling procedures and after hydrogen treatments, respectively, and for sol-gel samples. The combination with high-resolution electron microscopy (HREM) experiments yields the confirmation of such effects. Furthermore, the size-dependent parameters of nanoparticles could be determined. The results can be interpreted by the size effect of nanoscaled particles and the influence of the surrounding matrix.

1. Introduction

Glasses containing metal nanoparticles were investigated mainly because of the specific optical absorption (see for example [1]). Recently, the preparation and characterization of such composites has been further stimulated by peculiar non-linear optical properties, especially an increased third-order susceptibility, making such glass a promising candidate for application in integrated optics and photonics [2]. Previous studies indicated that the optical properties of nanoparticle/glass composites strongly depend on the size, the structure and the concentration of the embedded nanoparticles as well as their interaction with the host matrix [3]. Therefore, different preparation methods like ion implantation, ion exchange, reducing atmosphere treatment, ion and laser irradiation and sol-gel technique have been used to fabricate specific configurations of nanoparticles in glasses. Structural information down to the atomic scale on the nanoparticulate composites may be obtained by high resolution electron microscopy (HREM) [4]. This does not only allow to determine size, size distribution, external shape and internal structure of metal particles, but also to evaluate surface/interface effects on their lattice parameter. X-ray absorption spectroscopy is another structure-sensitive method. From the extended X-ray absorption fine structure (EXAFS) spectra [5–7] of the corresponding metal atoms the lattice parameter may be determined, even with more accuracy than HREM. However, the EXAFS results are averaged parameters of atom-atom correlations summed up for all detected particles, different from data determined by HREM for individual particles. The combination of both methods should be advantageous for a precise structural characterization.

Here, the results of EXAFS spectroscopy will be demonstrated for silver nanoparticles prepared by different methods and with that by different thermal histories. The data of transmission and fluorescence techniques were used to evaluate the lattice parameters in comparison with bulk Ag materials. The HREM experiments should allow to confirm the variation of the lattice constants that are less than 0.001 nm. With that the nature and the origin of the stress state of nanoscaled particles as well as of interface effects should be discussed.

2. Experimental procedures

Commercial soda-lime glasses containing SiO_2 and Na_2O as main components were used either as base glass for ion exchange or as substrate for sol-gel layers. At first, glasses containing a large amount of iron oxide (0.865%) of small thickness (0.15 mm) were prepared by a long duration of exchange period (310–426 hours) and applying a two-step annealing procedure in the temperature range of 380 to 600 °C. This enables to produce a nearly homogeneous distribution of Ag species throughout the glass sample as well as a narrow size distribution of nanoparticles. That allows the application of transmission experiments as well as a precise comparison with HREM data. The particle sizes were between 2.8 and 7 nm. For a second set of glasses of a thickness of 4 mm, the silver ions were introduced into the glass matrix by immersing the samples in a mixed silver nitrate/sodium nitrate melt at 400 °C for 2 hours. The subsequent thermal treatment at 635 °C yields the formation of Ag particles of 3 nm mean size in a surface-near region only. That gives the possibility to test the influence of temper stresses within the glass surfaces that could be formed by quenching the samples. The reference sample has been cooled down slowly. The third part of samples was prepared by an ion exchange process (thickness of 0.15 mm) in nitrate mixed melts (330 °C, 310 hours) and a thermal treatment in reducing hydrogen atmosphere at 500 °C. This procedure results in the formation of particles of sizes of 2 to 11 nm. The sizes were determined by electron microscopy. The proportion of multiply twinned particles to single crystalline particles was increased compared with that of the ion-exchanged glasses. A fourth set of embedded silver particles was prepared by the sol-gel technique. The sols were prepared from tetraethoxysilane orthosilicate by adding dissolved silver nitrate. The sol-gel samples were produced via hydrolysis under acidic conditions and subsequent drying at 200 °C. The mean size of particles was found to be 6 nm.

Ag K-edge (25.514 keV) EXAFS at beam line X1 of HASYLAB (Hamburg, Germany) were measured in transmission mode utilizing Si (311) double-crystal monochromator. Harmonic

*e-mail: dubiel@physik.uni-halle.de

rejection was achieved by detuning the monochromator crystals between 40 and 50%. The Ag K-edge EXAFS spectra of Ag foil as a reference and Ag-containing glass were systematically measured in the temperature range from 10 K to 300 K using a liquid helium vapour flow cryostat equipped with an electric heater. The spectra measured in fluorescence mode were recorded at the ESRF at the beam line BM08/GILDA between liquid nitrogen and room temperature. The incident X-ray intensity was measured with an ionisation chamber, whereas the fluorescence intensity was collected by a plastic scintillator. Harmonic rejection was achieved by detuning the monochromator crystals at the mid point of the reflectivity curve. The parameters characterizing the Ag-O and Ag-Ag coordination shells (bond lengths, Debye-Waller factor, coordination number, third cumulant) were evaluated by fitting the EXAFS function by means of UWXAFS program package [8] by means of theoretical amplitude and phase functions calculated by FEFF 7 [9]. The data of the transmission experiments were calculated on the basis of the cumulant expansion technique up to third-order term to include also anharmonic vibrations [6, 10]. The procedure of data evaluation is described in detail in [6].

3. Experimental results and discussion

Fig. 1 shows the Fourier transformed EXAFS oscillations of the ion-exchanged glasses containing 0.865% Fe_2O_3, so-called green glasses. These spectra indicate the existence of crystalline silver particles incorporated into the glass matrix that can be confirmed by electron microscopy. Besides the Ag-Ag correlations, a small contribution of Ag-O environment is observed for glass samples. This part can be assigned to isolated silver ions, which are not incorporated in silver particles. This oxygen environment is well known from ion-exchanged samples. For the interesting Ag-Ag correlations, four neighbouring spheres were considered. The data of the first shell is shown in Fig. 2 together with the data of Ag foil as reference material. This data were calculated after Fourier transformation (k range of 2.6–18.6 $Å^{-1}$ for Ag foil and 2.6–16 $Å^{-1}$ for the glass samples) into the real space using a Hanning window function. The fit range was in each case 1.6–4 Å. The coordination number, the damping factor by many-body effects and the edge shift parameter were fitted at 12 K only. For higher temperatures this values were fixed. The parameters of Ag-Ag

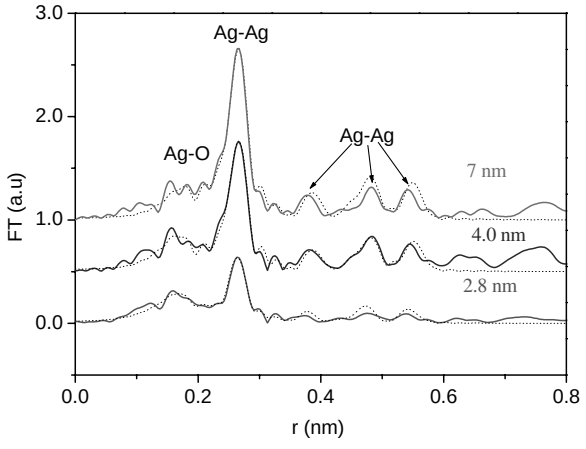

Fig. 1. Fourier transforms of the EXAFS oscillations of glass samples containing Ag particles of sizes of 2.8, 4 and 7 nm measured at 12 K and the corresponding fits (dashed lines) calculated by UWXAFS 3.0.

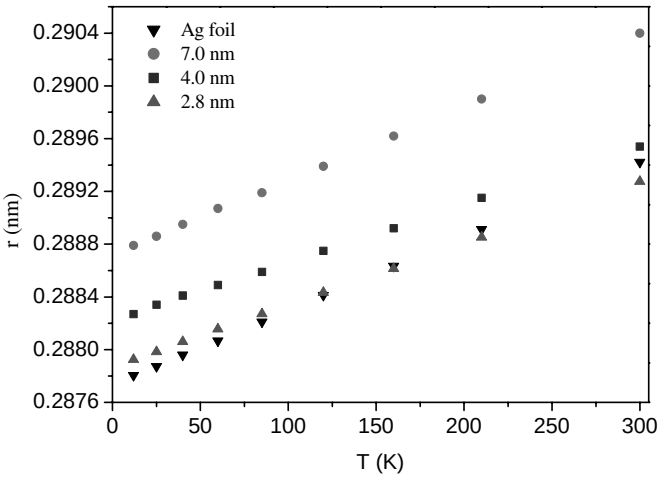

Fig. 2. Calculated Ag-Ag distances of Ag foil and of glasses represented in Fig. 1 in dependence on the temperature.

distance, Debye-Waller factor and third cumulant were fitted from 12 to 300 K. The EXAFS data for particles of 2.8 nm particles are similar to Ag foil values or slightly increased for larger particles (4 and 7 nm). These data demonstrate a lattice dilatation up to 0.001 nm for small particles after slowly cooling (duration of cooling was 24 hours) as investigated here. That means the typical lattice contraction of small particles is not observed in these glasses. High resolution electron microscopical investigations on this glass system confirm this effect for the parameters determined at 300 K [11]. However, the uncertainty of distance parameters determined by EXAFS resulting from the fit procedure is better (Δr = 0.0003 . . . 0.0005 nm) than the uncertainty of HREM data (Δr = 0.0006 . . . 0.0010 nm) resulting from the distribution of measured lattice parameters. The formation of such tensile stresses within the silver particles, i. e. the observed lattice dilatation, can be induced during the cooling procedure after the formation of silver particles at elevated temperatures due to the low thermal expansion coefficient of the silicate glass compared with that of bulk particles [6]. Furthermore, the starting temperature of cooling has to be considered [12]. Using the thermal expansion coefficient of Ag particles determined on the basis of third cumulant of EXAFS data (see [6]), such a behaviour can be explained quantitatively. It should be noted here, that there are small differences in interatomic distances determined by X-ray diffraction and EXAFS procedures for Ag foil [6]. Some authors [13–15] proposed that this effect originates from mean-squared vibrational disorder perpendicular to the line between the average position of the observed pair of atoms, here Ag-Ag. That requires theoretical calculations of vibrational disorder of Ag structures. However, the conclusions concerning the change of lattice parameters can be drawn without this because of the similar effect in bulk material and in nanoparticles.

Based on the previous results, the data of the other systems can be interpreted. Fig. 3 shows the Fourier transforms of EXAFS oscillations after strongly different cooling procedures, i. e. the formation of temper stresses inside the glass surface [16]. The compressive stress amounts to approximately 93 MPa. The experiments were performed by fluorescence method at 81 K because of the small concentration of particles. The data evaluation yield a reduced lattice parameter by 0.0005 nm for the quenched sample compared with the slowly cooled one and with the bulk sample too. That means, the expected compressive stress could be detected by the EXAFS method. The HREM experiments

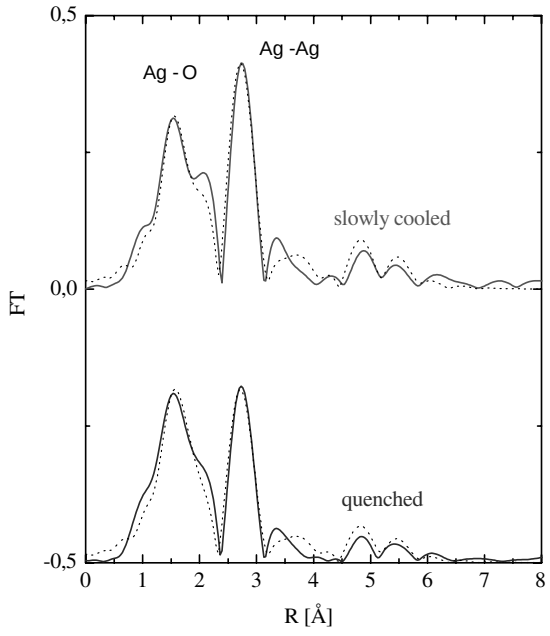

Fig. 3. Fourier transforms of EXAFS data measured by fluorescence method of quenched and slowly cooled samples together with the fitted curves (dashed lines).

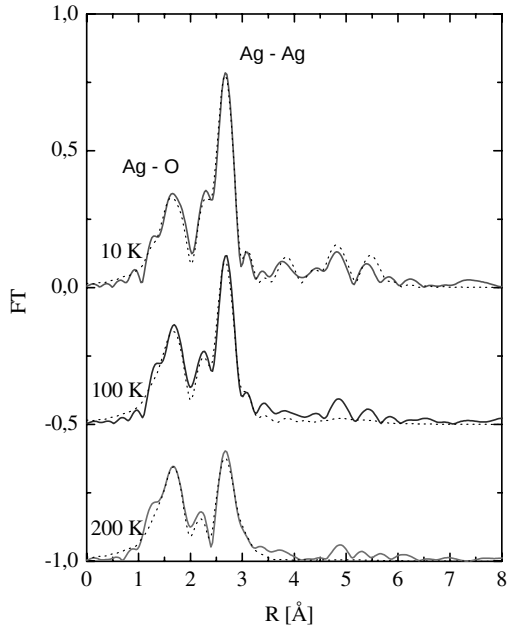

Fig. 4. Pair correlation functions as a result of particle formation due to treatment in hydrogen atmospheres. The dashed lines represent the fitted spectra.

do not allow to prove this effect. In the case of hydrogen treatment, the strongly increased concentration of silver particles enabled to perform absorption experiments. The corresponding spectra are represented in Fig. 4. The calculated Ag-Ag distances show a lattice dilatation up to 0.0001 nm for all temperatures. This increase of the Ag-Ag bond length is to explain by both the thermal expansion mismatch of particles and matrix and by the existence of twinned crystal structures. Fig. 5 shows the Ag-O and Ag-Ag spheres of the sol-gel glass containing Ag nanoparticles measured by fluorescence. The first Ag-Ag sphere shows a distinctly reduced bond length by 0.002 nm determined at 103 K. This lattice contraction corresponds to the behaviour of non-embedded nanoparticles that is caused by the increased number of surface atoms.

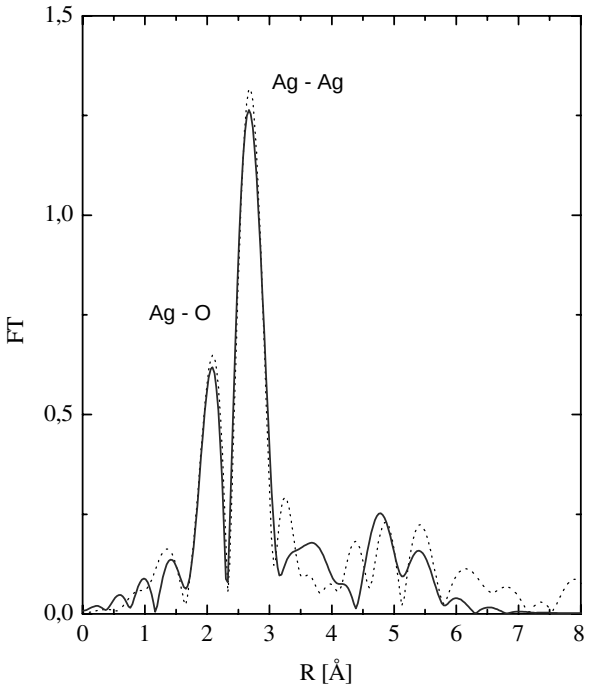

Fig. 5. Fourier transforms of fluorescence data of Ag nanoparticles prepared within a sol-gel layer and the corresponding fits (dashed lines).

Usually, small particles show reduced lattice parameters in comparison with bulk material due to the influence of surface atoms as mentioned above. This could be confirmed for isolated silver particles [17, 18] as well as for silver particles which were formed by precipitation processes in a sodium silicate glass as discussed before [19, 20]. Recently, similar results were obtained by EXAFS spectroscopy in fluorescence mode for particles formed by annealing, ion beam and laser beam irradiation [21]. In the same way, the local structure of silver clusters containing $8\,Ag^{+}$ ions or $6\,Ag^{0}$ atoms in the channels of a zeolite showed a slightly reduced lattice parameter compared with bulk material [22]. However, there are some experimental investigations that show the opposite behaviour of small particles of other types, i. e. a lattice dilatation has been measured. This was explained by interactions with ligands, the formation of oxide shells or the lattice mismatch between the particles and surface layers [23, 24]. Here, such explanations can be excluded because of investigations by electron microscopy.

4. Conclusions

It could be demonstrated that EXAFS spectroscopy represents a powerful tool to extract lattice parameters of nanocrystalline Ag particles in glasses with high accuracy. With that tensile and compressive stress states could be detected by changing the Ag-Ag bond lengths in the range of 0.0001 to 0.0020 nm. For ion-exchanged glasses and subsequent treatments in air or hydrogen atmosphere, the strength of interaction across the particle/matrix interface leads to lattice dilatation due to the thermal expansion mismatch of metal particle and glass matrix. The corresponding increase of Ag-Ag distances mainly in a surface near region of particles should be caused by Ag-O interactions across the particle/matrix interface. This effect does not exist for sol-gel samples. Here, the behaviour of particles is similar to isolated particles, i. e. the influence of Ag at the surface of particles dominates or there are no considerable interface effects,

respectively. The experiments on quenched Ag/glass composites demonstrated that even stresses of 93 MPa can be proved by EXAFS spectroscopy.

Abstract

Local structures of nanocomposite Co-C_{60} and Co-SiO_2 thin films have been studied by fluorescence XAFS. The results indicate that the bond length R and coordination number N of the first Co-Co shell of Co-SiO_2 thin film are 2.49 Å and 11.8, respectively. It indicates that the local structure around Co atoms in the nanocomposite Co-SiO_2 thin film is similar to that of the metallic Co thin film. However, the local structure and the XANES spectrum of the Co-C_{60} thin film are much different from those of the Co-SiO_2 thin film. There are two Co-C and Co-Co coordination shells in the first neighbor of Co atoms of the Co-C_{60} thin film. For the Co-C_{60} thin film, the R, N and σ of the first Co-C and Co-Co shells are 1.88 Å 1.6, 0.050 Å, and 2.47 Å, 7.8, 0.110 Å, respectively. The decrease (4.0) of the coordination number and the contraction (0.04 Å) of the average band length for the first Co-Co shell in the Co-C_{60} thin film show that there is a strong interaction between the Co nano-particles and the C_{60} matrix. The XANES results further confirm that there is an electron transferring from Co atoms to C_{60} molecules in the Co-C_{60} thin film.

1. Introduction

The fabrications from nano-structural materials based on fullerenes have attracted considerable attention since an easy way was discovered for the synthesis of C_{60} in macroscopic quantities [1]. This is largely due to the unique properties of C_{60} such as an atom-like spherical molecular with an outer shell diameter of 1 nm, closed-cage molecular morphology, chemical inertness, stability at the pressure up to 20 GPa [2], and so on. In particular, the C_{60} modified by element metals have shown some novel properties. For example, superconductivity in K (or Rb, Cs)-doped fullerite crystal [3], higher coercivity magnetic materials Ni-C_{60} [4] and fast magnetic switching as well as high out of plane remanence materials Fe (or Co, CoFe)-C_{60} [5].

Zheng *et al*. [5] and Hou *et al.* [6] have reported that there is a strong interaction between C_{60} and metallic nano-particles in the nano-composite Fe (Co, CoFe)-C_{60} and Cu-C_{60} thin films, which results in the fascinating properties significantly different from those of both bulk metals and fullerenes. Zhao *et al*. [4] had studied the structures of the Ni nano-particles embedded in an amorphous C_{60} matrix by XRD and Raman spectra. Their results have demonstrated that the lattice expansion exists in the Ni particles and charge transfer is from Ni atoms to C_{60}. Hunt *et al.* [7] had studied the charge state and C_{60} monolayers desposited on Au (110), polycrystalline Ag, and Ni (110) with electron-energy-loss spectroscopy and low-energy electron diffraction. They found that the charge was transferred from the metallic surface of Au (110), Ag and Ni (110) to the C_{60}. Obviously, the properties of metal-C_{60} nano-composite thin films mainly depend on the interfacial interaction between metal particles and the C_{60} matrix. However, it is not clear enough of the local structures around the metallic atoms and C_{60} in the metal-C_{60} thin film yet.

In this paper, fluorescence XAFS has been used to investigate the local structures around the Co atoms in the nanocomposite Co-C_{60} and Co-SiO_2 thin films. We focus on the interaction between the metallic Co and the C_{60}. By comparing with the local structures of metallic Co and Co-SiO_2 thin film, it is possible to obtain the local structures around the Co atoms and the interactive distance $R_{Co\text{-}C}$ in the Co-C_{60} thin film. This result is useful to understand the electronic structures of C_{60} in the nanocomposite Co-C_{60} thin film modified by Co smaller particles.

2. Experimental

Nanocomposite Co-C_{60}, Co-SiO_2 and metallic Co thin films were prepared by magnetron sputtering. The base pressure of the growth chamber was 2.0×10^{-5} Pa. For the Co-C_{60} thin film, the metallic Cobalt (99.99%) target was sputtered with dc sputtering at an Ar pressure of 3.0 Pa, and the deposition rate was 0.1 Å/s. Meanwhile, a thermal heating source was used to sublimate C_{60} powder (99.9%) at a deposition rate of 0.6 Å/s. During the co-deposition, the Co target and the C_{60} heating source were separated from each other. The thickness of the Co-C_{60} thin film was 70 nm. Similarly, the Co-SiO_2 and metallic Co thin films were prepared by means of co-sputtering and dc sputtering, respectively. The thickness of Co-SiO_2 thin film was 72 nm and thickness of Co thin film was 36 nm. All three samples were deposited on the Si substrate at room temperature.

The Co K-edge XAFS spectra of metallic Co, nanocomposite Co-SiO_2 and Co-C_{60} thin films were measured at the XAFS station of 4W1B beamline of Beijing Synchrotron Radiation Facility. The electron beam energy was 2.2 GeV and the maximum stored current was about 80 mA. The fixed-exit Si (111) flat double crystals were used as monochromator. The X-ray harmonics were minimized by detuning the two flat Si (111) crystal monochromator to about 70% of the maximum incident light intensity. Data were collected at room temperature with fluorescence mode, using Lytle ion chamber detector filled with Ar gas. The USTCXAFS3.0 software packaged [8] was used for XAFS data analysis.

3. Results and Discussions

The Co K-edge EXAFS functions $k^2\chi(k)$ and their Fourier transformations (FT) of metallic Co, Nanocomposite Co-SiO_2 and Co-C_{60} thin films are shown in Fig. 1 and Fig. 2, respectively. It can be observed that the oscillation shape and peak intensity of

*Correspondent: Shiqiang Wei, E-mail: sqwei@ustc.edu.cn

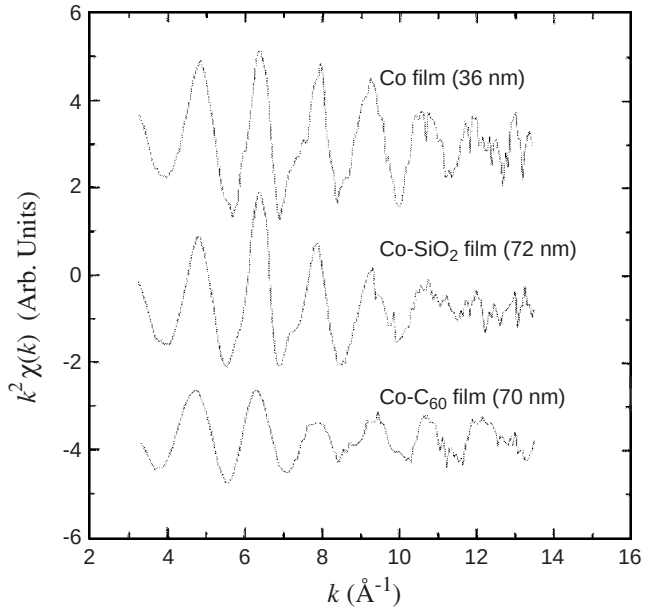

Fig. 1. Co K-edge EXAFS functions $k^2\chi(k)$ of metallic Co, nanocomposite Co-SiO_2 and Co-C_{60} thin films.

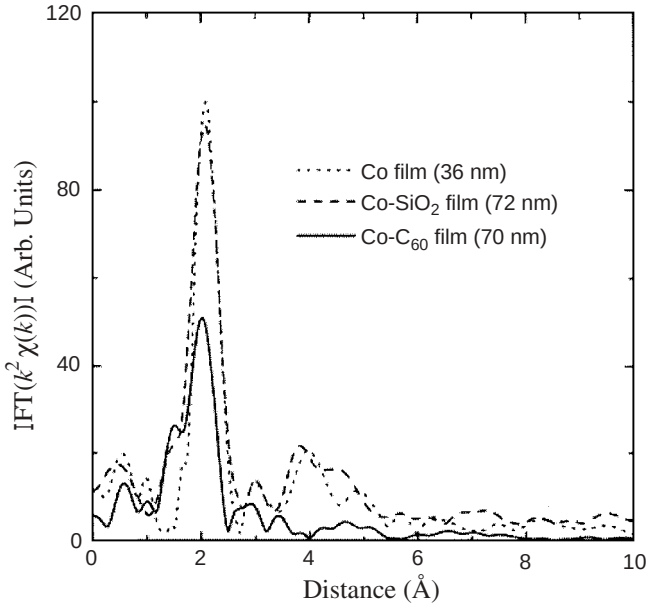

Fig. 2. The RSF functions of metallic Co, nanocomposite Co-SiO_2 and Co-C_{60} thin films.

$k^2\chi(k)$ curve of Co-SiO_2 thin film is similar to those of metallic Co thin film. However, the oscillation magnitude of Co-C_{60} thin film is about 50% weaker than those of the above two thin films. This result indicates that the local structure around Co atoms in the Co-C_{60} thin film is largely different from that in the Co-SiO_2 thin film. Furthermore, it can be clearly seen in Fig. 2 that the FT main peak of the metallic Co and Co-SiO_2 thin films appears at 2.09 Å, which corresponds to the first shell of the Co-Co coordination. However, the FT main peak shifts to 2.01 Å and its magnitude largely decreases for the Co-C_{60} thin film. In addition, a new small peak appears at 1.51 Å in the FT curve of the Co-C_{60} thin film, corresponding to the first shell of Co-C coordination. These results suggest that the local structure of Co atoms in the Co-C_{60} film has greatly modified by C_{60}.

Table I. *Structural parameters of the metallic Co, nanocomposite Co-SiO_2 and Co-C_{60} thin films.*

Sample		Bond type	R (Å)	σ (Å)	N	ΔE_0 (eV)
Co-C_{60}	(70 nm)	Co-C	1.88 ± 0.02	0.05	1.6 ± 0.6	-16.7
		Co-Co	2.46 ± 0.02	0.11	7.8 ± 0.8	-10.6
Co	(36 nm)	Co-Co	2.50 ± 0.01	0.090	12.0 ± 0.7	-2.84
Co-SiO_2	(72 nm)	Co-Co	2.49 ± 0.01	0.097	11.8 ± 1.0	-5.63

For obtaining the structural parameters of nanocomposite Co-C_{60} and Co-SiO_2 thin films, the least-squares curve fit is performed in the XAFS data analysis using the USTCXAFS3.0 code [8]. The theoretical amplitude and phase shifts functions are calculated by FEFF7.0 [9]. The curve fitting ranges of ΔR and Δk are from 1.1 to 2.5 Å and from 3.2 to 11.0 $Å^{-1}$, respectively. The structural parameters of the metallic Co, nanocomposite Co-SiO_2 and Co-C_{60} thin films are listed in the table I.

Seen from table I, the results indicate that the bond length R, coordination number N and Debye-Waller factor σ of the first Co-Co shell in the Co-SiO_2 thin film are 2.49 Å, 11.8 and 0.097 Å, respectively. It means that the local structure around Co atoms in the Co-SiO_2 thin film is similar to that of the Co thin film. Hence, the interaction between the Co nano-particles and SiO_2 matrix is very weak in the Co-SiO_2 thin film. This result is in good agreement with that reported by Murayama *et al*. [10] who have studied the interaction between the Co grains and the SiO_2 matrix in Co-SiO_2 thin film with Raman spectra. Furthermore, table I has shown that there are two coordination signals of Co-C and Co-Co shells around Co atoms in the Co-C_{60} thin film. The R, N and σ of the first Co-C sub-shell and the first Co-Co sub-shell are 1.88 Å, 1.6, 0.050 Å and 2.47 Å, 7.8, 0.110 Å for the Co-C_{60} thin film, respectively. It can be found that there is a large ratio (about 17%) of Co-C to Co-Co coordination number in the first shell of the Co-C_{60} thin film, and that the $N_{\text{Co-Co}} = 7.8$ and the $R_{\text{Co-Co}} = 2.46$ Å in the Co-C_{60} thin film is about 4.0 and 0.04 Å smaller than those of the metallic Co thin film, respectively. The

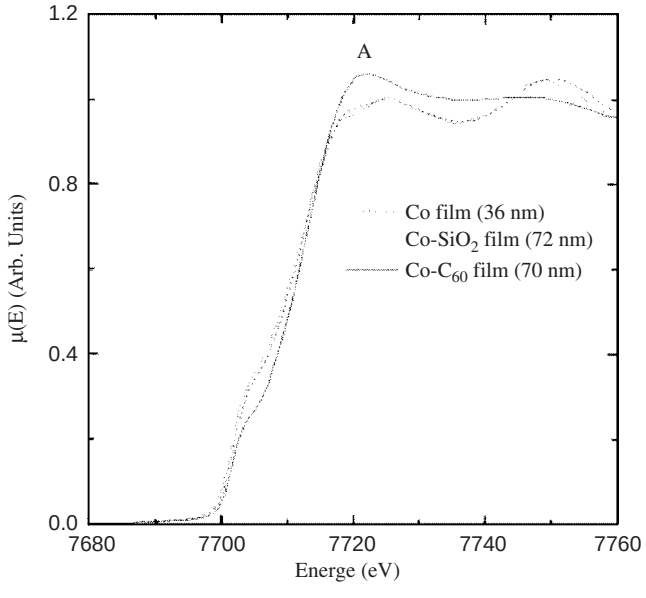

Fig. 3. XANES spectra of metallic Co, nanocomposite Co-SiO_2 and Co-C_{60} thin films.

decrease of the coordination number and the contraction of the bond length in the first Co-Co shell of the Co-C_{60} thin film indicate that there are a strong interaction between the Co nano-particles and the C_{60} matrix in the Co-C_{60} thin film. Kolobov *et al*. [11] have shown that the contraction of the average bond length of the first Co-Co shell in the Co nanocrystals embedded in carbon matrix. Their results are in good agreement with ours.

The X-ray absorption near-edge structure (XANES) spectra of the metallic Co, nanocomposite Co-SiO_2 and Co-C_{60} thin films are shown in Figure 3. The peaks A located at 7722 eV in the Co K-edge XANES spectrum of the Co-SiO_2 thin film is corresponding to the 1s $\rightarrow$ 4p electron transition of Co atoms. Moreover, the shape of XANES spectrum of the Co-SiO_2 thin film is similar to that of metallic Co thin film, in which the intensity of peak A is very lower. However, the XANES spectrum of the Co-C_{60} thin film is much different from that of the Co-SiO_2 thin film. The intensity of peak A in the Co-C_{60} thin film is stronger than those of the metallic Co and Co-SiO_2 thin films. Compared with the XANES spectra of CoO and Co_3O_4 studied by Modrow *et al*. [12] and Huffman *et al.* [13], the XANES spectrum of the Co-C_{60} thin film is close to those of CoO and Co_3O_4. Hence, we consider that there are electrons trasferring from Co atoms to C_{60} molecules in the Co-C_{60} thin film. Zhao *et al*. [4] have reported that there are $2 \sim 4$ electrons transferred to each C_{60} molecule Ni-C_{60} thin film from their results of Raman spectra. These indicate that the electronic structures of Co atoms are modified by C_{60} in the nanocomposite Co-C_{60} thin film.

Abstract

The forms of Fe(3+) ions stabilization on TiO_2, ZrO_2 oxide nanoparticles and their composition were studied by EXAFS spectroscopy. The structure of the iron local surrounding was investigated with respect to: preparation method, coverage, support crystal modification, acidity of oxide surface and way of iron introduction into oxide matrix. For all oxides, it was shown that Fe(3+) ions stabilized mainly on the nanoparticle surfaces as isolated ions at low coverage. The location of these ions on the oxide surface depends on the correlation between Fe-O bond length and *Me*-O (Me = Ti, Zr) interatomic distances of oxide carriers. The increase of surface coverage results in formation of two-dimension layer structures. For the ZrO_2-TiO_2 composition, it should be noted that the iron cations interact mainly with zirconia. A few structural models of different iron locations were discussed.

1. Introduction

Irradiation of semiconductor particles suspended in water to catalyse oxidative or reductive processes of substrates present in solution is a well-known process, specially useful for the transformation of toxic substances into less harmful products. Although TiO_2 is the most useful photocatalyst, attention has been paid in recent years to iron-doped titania samples (testing efficiency) to replace the bare TiO_2. Results have been controversial, depending on multiple factors such as iron-loading, preparation method, calcination temperature, etc. [1–3]. Generally, no direct correlation between UV-VIS spectroscopic features and photochemical activity could be found, and the preparation method seems to be one of the most important factor for the reactivity of the catalyst.

In paper [4], concerning the iron-doped Degussa P25, it was shown that although wet impregnation method does not seem to be a suitable procedure to obtain a uniform distribution of the dopant into the matrix, the use of $Fe(acac)_3$ instead of $Fe(NO_3)_3$ yields a more homogeneous distribution of iron at the surface.

Structural study of the iron location at the surface seems to be a crucial step for understanding the correlation between the iron content and the preparation method with the catalytic activity of samples. Similar studies have been recently carried out using Fe/ZrO_2. ZrO_2 is also a semiconductor oxide that provides a suitable band-gap energy that enables it for photocatalytic uses.

In paper [5], the effect of iron doping on ZrO_2 was characterised and Fe/ZrO_2 system was tested for several photocatalytic reactions. EXAFS structural studies [6, 7] reveal that, for the sol-gel prepared samples, iron seems to form a two-dimensional layer structure that becomes a segregated oxide at higher loading. This segregated iron oxide could be in principle responsible for the low photocatalytic activity of systems.

This our paper is devoted to a study by EXAFS spectroscopy of iron doped ZrO_2-TiO_2 systems obtained by two different ways, co-precipitation and impregnation techniques.

2. Experimental

2.1. *EXAFS method*

EXAFS spectra of the Ti-K, Zr-K, Fe-K edges for all the samples were obtained at the EXAFS Station of Siberian Synchrotron Radiation Center. The storage ring VEPP-3, with electron beam energy of 2 GeV and an average stored current of 80 mA, has been used as the source of radiation. The X-ray energy was monochromated with a channel cut Si(111) monochromator. The EXAFS spectra of the Ti-K, Zr-K edges were recorded under transmission mode, using two ionization chambers as detectors. The EXAFS spectra of the Fe-K edge were recorded under fluorescent mode. For the Ti-K edge measurements, a harmonics rejection was performed by using a gold mirror. For transmission EXAFS measurements, the samples were prepared as pellets with thickness varied to obtain a 0.5–1.0 jump at the Ti-K, Zr-K absorption edges. The EXAFS spectra were treated using the standard procedures [8]. The background was removed by extrapolating the pre-edge region onto the EXAFS region in the forms of Victoreen's and 4-th power polynomials for transmission and fluorescent modes, respectively. Three cubic splines were used to construct the smooth part of the absorption coefficient. The inflection point of the edge of the X-ray absorption spectrum was used as initial point ($k = 0$) of the EXAFS spectrum. The modulus of Fourier transform (|FT|) was calculated from the EXAFS spectra in $k^3\chi(k)$ at the wave number interval 4.0–12.0 $Å^{-1}$. Curve fitting procedure with EXCURV92 [9] code was employed to determine precisely the distances and coordination numbers in similar wave number intervals after preliminary Fourier filtering using the known XRD data for the bulk zirconium, titanium and iron oxides. Debye-Waller factors are fixed (all the values are equal to 0.005 $Å^2$).

2.2. *Preparation of samples*

The samples studied were prepared by means of two different sol-gel techniques. The ZrO_2-TiO_2 system was prepared by using $ZrOCl_2 \cdot 8H_2O$ and TiO_2 Degussa P25 as precursors. The ZrO_2 content was about ~3–10 wt%. Iron doped systems were obtained by two different ways, co-precipitation and impregnation techniques. In both cases, iron loading was ~0.5–1.5 wt%

*e-mail: kriven@inp.nsk.su

Fe_2O_3. In the coprecipitation method, $Fe(acac)_3$ was settled in suspension jointly with $ZrOCl_2 \cdot 6H_2O$, commercial TiO_2 and urea as a precipitating agent. This solution was heated under reflux at about 80 °C for several hours and a precipitated was obtained after filtration. On the other hand, by the impregnation method, ZrO_2-TiO_2 mixed oxide was previously obtained by precipitation of $ZrOCl_2 \cdot 8H_2O$ on a TiO_2 suspension in distilled water at pH 10, and using ammonia as precipitating agent. The gel obtained was filtered and repeatedly washed in order to eliminate Cl- anions, and finally dried in oven at 110 °C. Fe was then incorporated into the ZrO_2-TiO_2 fresh mixed oxide by pouring down the corresponding amount of $Fe(acac)_3$ in ethanol. Two sets of samples were finally dried at 110 °C and then calcined at 600 °C during 2 hours. Those sets of samples were named as impregnation and co-precipitation samples prepared with/without Fe. Additionally all samples were characterized by XRD method.

3. Results and Discussion

Firstly it should be noted that the |FT| (modulus of Fourier transform) curves describing titanium local arrangement of all samples studied, not presented in this paper, are similar to that of TiO_2 (Degussa P25). |FT| curves describing iron local arrangement of two iron doped samples prepared by impregnation and co-precipitation are shown in Fig. 1(a,b). |FT| curves describing zirconium local arrangement for all the samples studied are shown in Fig. 1(c,d,e,f). EXAFS data (the interatomic distances and coordination numbers) of the studied samples for the iron and zirconium local arrangements are presented in Table I and Table II respectively.

As seen from Table I, there are three structural models describing the iron local arrangement for the doped impregnation and three model for the doped co-precipitation samples, which assume different iron localisation. For the trigonal α-Fe_2O_3, the

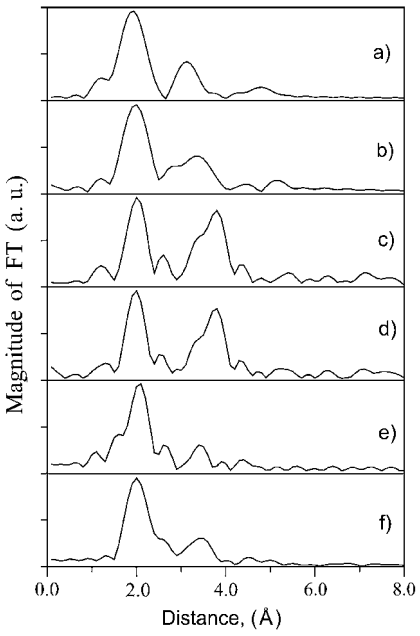

Fig. 1. |FT| curves describing iron local arrangement: a) Fe doped impregnation sample, b) Fe doped co-precipitation sample and zirconium local arrangement, c) impregnation sample, d) Fe doped impregnation sample, e) co-precipitation sample, f) Fe doped co-precipitation sample.

XRD data [10] show two Fe-O distances (1.941, 2.118 Å) and four Fe-Fe distances (2.895, 2.969, 3.361, 3.701 Å). All the models presented yield very similar results both for impregnation and co-precipitation samples: the first Fe-O distances of ∼1.97–2.00 Å and second Fe-Fe distances of ∼2.86–2.95 Å. The corresponding coordination numbers varied within ∼4.3–5.1 and ∼1.1–2.7, respectively. Analysis of the obtained set of distances evidenced for the presence of the Fe-O-Fe species seemingly as small iron oxide nanoclasters or layered structures located onto the

surface and pre-surface region of the modified titania, ZrO_2/TiO_2 interface or ZrO_2.

Although the shapes of the |FT| curves (Fig. 1a,b) differ for the impregnation and co-precipitation samples that probably indicate on a few positions or different proportion between the iron localisation sites, a detail analysis is difficult because the choice of a preferred structural model is controversial in both cases.

Nevertheless, the EXAFS data (Table I) allows possibility that additionally both the Fe-O-Ti and Fe-O-Zr species, located on the surface/pre-surface region, could be formed. It should be noted that, for impregnation sample, the best is Model 3 which corresponds to Fe adsorbed on ZrO_2, while for co-precipitation sample the best is Model 1 more corresponding to Fe adsorbed on modified titania framework.

By analysis of the zirconium local arrangement of the impregnation samples, obtained from the |FT| curves (Fig. 1c,d) and EXAFS data (Table II), one may assume the formation of mainly tetragonal ZrO_2 phase located on TiO_2 surface.

The presence only of Zr-O distances of about ∼2.10–2.31 Å and long Zr-Zr distances of about ∼3.55–3.66 Å, which are typical for tetragonal ZrO_2 structure, clearly proves this suggestion. In our paper [6], a detailed discussion is presented about monoclinic/tetragonal zirconia determination by EXAFS data. It seems that iron doping does not influence on the formed structures because the shapes of |FT| curves as well as fitting results are similar for both samples. This our conclusion about ZrO_2 structures formed on the TiO_2 surface is in good agreement with the abovementioned hypothesis about iron localisation mainly on ZrO_2 surface.

For the co-precipitation samples, as seen from Fig. 1(e,f), the |FT| curves differ greatly from those for impregnation samples and have some differences between each other. So, amplitudes of the second Zr-Zr and/or Zr-Ti peaks are greatly decreased and the corresponding distances are shorter, while the amplitudes of first peaks are slightly increased as compared with those for impregnation samples. Such phenomena may be explained by assumption that the solid solution of ZrO_2 in the TiO_2 matrix is formed in addition to small amorphous ZrO_2 particles, and perhaps that a distorted $ZrTiO_4$ phase on TiO_2 surface is formed. It should be noted that the method limitation of the number of independed parameters for fitting does not allow to combine all the possibilities to elucidate the situation completely.

There are two structural models present in Table II for these cases. The first model corresponds more to small amorphous ZrO_2 particles, which have the an unusual structure with very short Zr-Zr distances of about ∼3.24–3.39 Å. Earlier such short Zr-Zr distances were shown for Fex/ZrO_2 system [6] and were explained by retaining the initial structures by anion residual after calcination. However, the Zr-O distances for doped and undoped co-precipitation samples are differerent: 2.06; 2.19 Å and 2.12; 2.31 Å respectively, the first is unusually short for the ZrO_2 structure and may be a subject for discussion. The second model corresponds more to a distorted $ZrTiO_4$ phase formed on the TiO_2 surface. Indeed, the presence of suitable Zr-Zr and/or Zr-Ti distances clearly proves this assumption but it should be noted that although the values of the Zr-Me distance are similar to those laying within ∼3.3–3.6 Å for the $ZrTiO_4$ structure, it seems that the bulk $ZrTiO_4$ phase is not formed, whereas the Zr-O distances of about 2.09–2.20 Å for the undoped co-precipitation sample and of about 2.07–2.2 Å for the doped co-precipitation sample, resulted from fitting (Table II), are longer than those corresponding to the $ZrTiO_4$ structure (1.937 Å; 1.948 Å; 2.228 Å). Because the both presented models may be realised in reality, the choice of the best variant is very complicated.

4. Conclusions

The local zirconium and iron arrangements of the iron doped ZrO_2-TiO_2, prepared by sol-gel method, were studied by EXAFS spectroscopy. Only a tetragonal ZrO_2 structure is located on TiO_2

surface for impregnation samples. It seems that the distorted $ZrTiO_4$ structure or small amorphous ZrO_2 particles are formed on the TiO_2 surface for the co-precipitation samples. The presence of the Fe-O-Fe species as well as the Fe-O-Ti and Fe-O-Zr species located on the surface/pre-surface region are shown. The small iron oxide nanoclasters or layered structures are located on the surface and pre-surface region of the modified titania, ZrO_2/TiO_2 interface or ZrO_2.

Abstract

The local structure of the Fe, Co and Nb surroundings of niobium doped $Sr(Co/Fe)O_{3-x}$ perovskites was studied by EXAFS spectroscopy. The samples were prepared by ceramic method at $T = 1250\,^{\circ}C$. In order to vary the oxygen content, the samples were (*i*) slowly cooled in the furnace, (*ii*) quenched in liquid N_2 and electrochemically oxidised. According to EXAFS data, the Nb and Fe cations occupy octahedral positions even at low oxygen content. At the same time, the Co cations seemingly occupy highly distorted octahedral positions. It should be noted that the mean Co-O distance (∼1.84 Å) is much shorter than the mean Fe-O (∼1.92 Å) distance in this case. It was assumed that oxygen vacancies are mainly located near cobalt cation positions.

1. Introduction

Nonstoichiometric oxides $Sr(Co/Fe)O_{3-x}$ exhibiting the mixed electron/oxygen conductivity, are intensively studied as candidate oxygen membranes for catalytic partial methane oxidation and syn.gas production reactors [1–3].

Distribution and location of oxygen vacancies in a nonstoichiometric oxide are important for understanding the mechanism of oxygen transportation (the main functional property of an oxide) and structural transformations in the membrane material regarding the oxygen concentration.

Doping or introduction of different cations into the nonstoichiometric oxide crystal structure is a promising way to improve permeability, chemical and mechanical stability of oxygen membranes.

XRD is usually used to obtain information on the structure of doped oxides. Unfortunately, this method has a number of drawbacks. First, nonstoichiometric oxides can possess a number of point defects as oxygen vacancies, providing a distortion of the cation local surrounding. Since these vacancies are likely disordered, the standard diffraction methods can not be used for their analysis.

The second problem arises when oxides are doped by cations of elements with close scattering abilities. Sometimes these cations are located in several non-equivalent crystallographic positions and one should establish how different chemical element cations are distributed among these positions.

To distinguish them, one should apply some special techniques such as anomalous diffraction (using synchrotron radiation) along with the standard methods.

The above problems can be solved by EXAFS, which is both the local and selective method. This method permits one to study local structure of every chemical element surroundings regardless of the sample crystallization degree.

In this work EXAFS spectroscopy was used to study the $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ perovskites with different oxygen concentrations.

2. Experimental

The $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples were synthesized from stoichiometric amounts of $SrCO_3$, Fe_2O_3, Co_3O_4, and Nb_2O_5, which were thoroughly mixed in an AGO-2 planetary ball mill. Prior to this, ethanol was added to the reagents to prepare a paste-like mixture which was then treated in a mill for 30 seconds. After drying and calcination at 950 °C for 8 h, the mixture was retreated in a mill for 30 s. The pellets prepared from the oxide mixture were placed into a furnace at 1250 °C and held there for 12 h. To prepare $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ with low oxygen concentration $(3 - x) \sim 2.5$, the samples were quenched in liquid nitrogen, if the samples were slowly cooled in the furnace oxygen content increased to $(3 - x) \sim 2.7$. The samples electrochemically oxidized in 1 M KOH [4] possessed the highest value $(3 - x) \sim 2.9$. According to XRD the samples with different oxygen content were monophasic and all X-ray reflections were indexed in perovskite cubic cell. The increase of oxygen concentration in $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples is accompanied by the slight decrease of perovskite cubic parameter. XRD study was carried out on DRON-3M diffractometer with graphite monochromator using CuK_α radiation. Samples $SrCoO_{2.5}$, $SrFeO_{2.5}$ (brownmillerite type) and $SrCoO_3$, $SrFeO_3$ (perovskite type) were used as reference samples.

EXAFS spectra of the Nb-K, Co-K, Fe-K edges for all the samples were obtained at the EXAFS Station of Siberian Synchrotron Radiation Center (SSRC). The storage ring VEPP-3, with electron beam energy of 2 GeV and an average stored current of 80 mA, has been used as the source of radiation. The X-ray energy was monitored with a channel cut Si(111) monochromator. The all EXAFS spectra of the Nb-K, Co-K, Fe-K edges were recorded under transmission mode, using two ionization chambers as detectors. The samples were prepared as pellets with thickness varied to obtain a 0.5–1.0 jump at the Nb-K, Co-K, Fe-K absorption edges. The EXAFS spectra were treated using the standard procedures [5]. The radial distribution function of atoms (RDF) was calculated from the EXAFS spectra in $k^3\chi(k)$ as the modulus of Fourier transform at the wave number interval 3.8–12.0 $Å^{-1}$. Curve fitting procedure with EXCURV92 [6] code was employed to determine precisely the distances and coordination numbers in similar wave number intervals after preliminary Fourier filtering using the known XRD data for the $SrCoO_{2.5}$, $SrFeO_{2.5}$ (brownmillerite type) and $SrCoO_3$, $SrFeO_3$ (perovskite type) bulk compounds. Debye-Waller factors are fixed (all the values are equal to 0.005 $Å^2$).

EXAFS spectra of the cobalt, iron and niobium local surrounding were used to calculate effective coordination

numbers and distances Me-O and Me-Me in three coordination spheres (Tables I–IV). This way was chosen to analyze coordination numbers, because both doping and a change in the oxygen stoichiometry result in changes in average coordination numbers and distortion degrees of the coordination polyhedron. All nearby Me-O distances merge into one peak due to insufficient spatial resolution of the method. In this case, effective coordination number becomes the only available value providing the information on a true change in the coordination number due to oxygen vacancies and differences between interatomic Me-O distances.

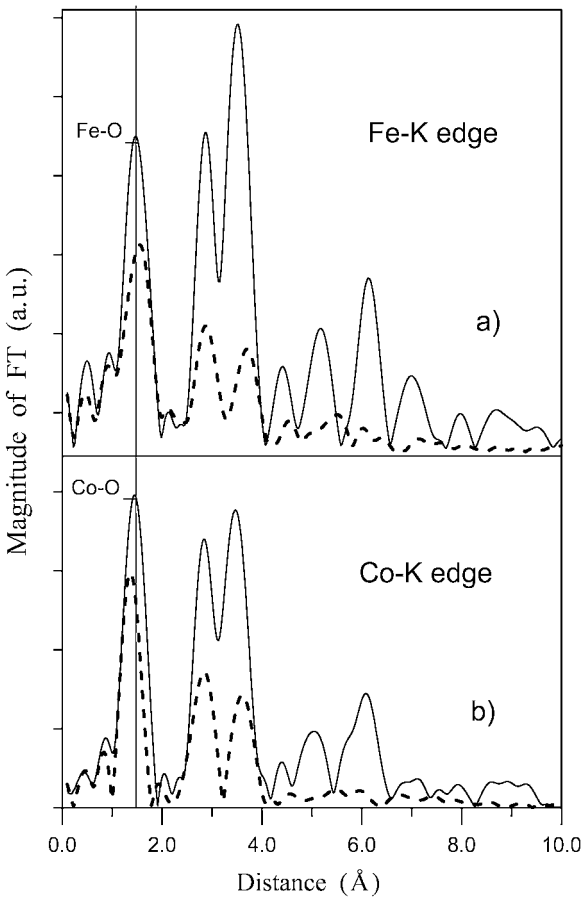

Fig. 1. Radial distribution function (RDF) curves describing a) Fe and b) Co local surrounding of reference samples: (solid line) – $SrFeO_3$, $SrCoO_3$; (dashed line) – $SrFeO_{2.5}$, $SrCoO_{2.5}$.

3. Results and Discussion

RDF curves, describing Fe and Co local surroundings, of reference samples are shown in Fig. 1. RDF curves, describing Co, Fe, Nb local surroundings of $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples are presented in Fig. 2–4. EXAFS data (*R* – distances (Å); *N* – effective coordination numbers) for $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ and reference samples are shown in Tables I–IV. XRD data, for reference and $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples, are presented in Table V.

Structural data on cubic perovsikte AB_3 (A = Sr, B = Co, Fe, Nb) suggest that 6 oxygen atoms are observed in the cation first coordination sphere in position B. The second and third coordination spheres contain 8 strontium atoms and 6 metal atoms, respectively. The latter sphere can involve all metals, excepting strontium. A particular composition of the third coordination sphere depends on distribution of three metal cations through the compound bulk.

Reference samples: Diffraction data on samples $SrMeO_{3-x}$ (Me = Co, Fe; x = 0.5, 0.0) (Table V) comply with the literature evidence [7–10]. The oxides whose composition approximates the ideal perovskite $SrMeO_3$ have a cubic structure, but their effective coordination numbers (Fig. 1, Table I) for first spheres (Me-O) are low for both iron and cobalt containing perovskites. This indicates that random microdistortions exist in the structure as the long-range ordering (manifesting itself in diffraction) preserves. Note that the distortion degrees are close in both compounds.

Samples $SrMeO_{2.5}$ are crystallized in the brownmillerite type. It is of interest that for the cobalt sample, the unit cell parameter

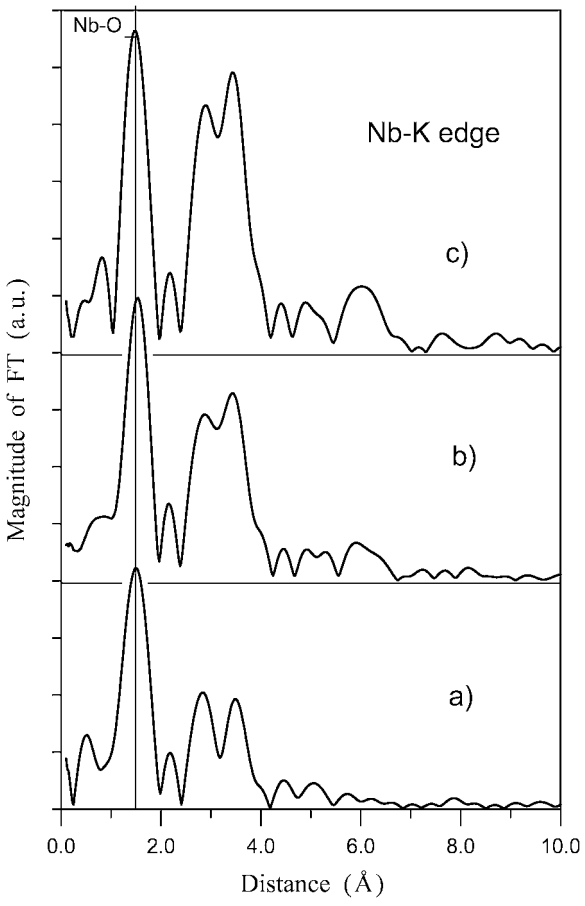

Fig. 2. Radial distribution function (RDF) curves describing Nb local surrounding of $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples: a) $x \sim 0.5$; b) $x \sim 0.3$; c) $x \sim 0.1$.

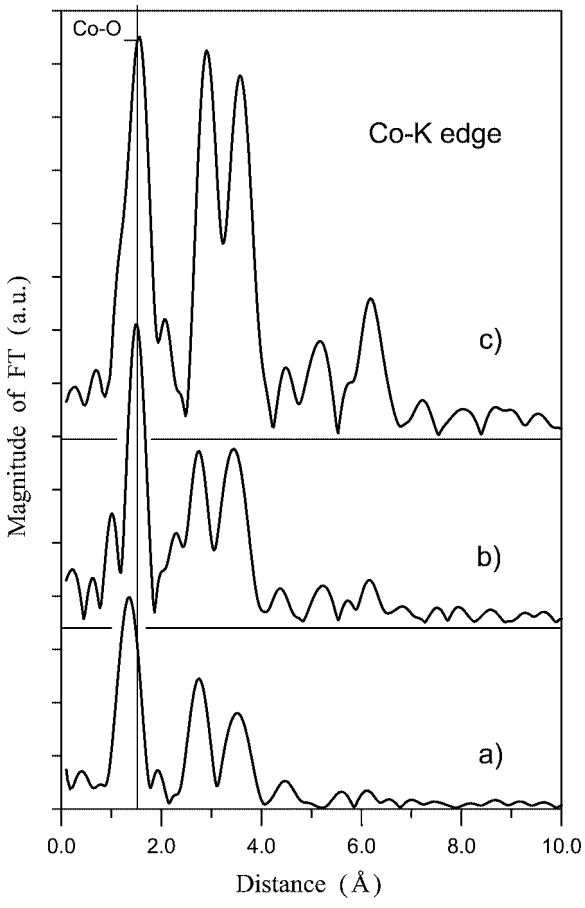

Fig. 3. Radial distribution function (RDF) curves describing Co local surrounding of $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples: a) $x \sim 0.5$; b) $x \sim 0.3$; c) $x \sim 0.1$.

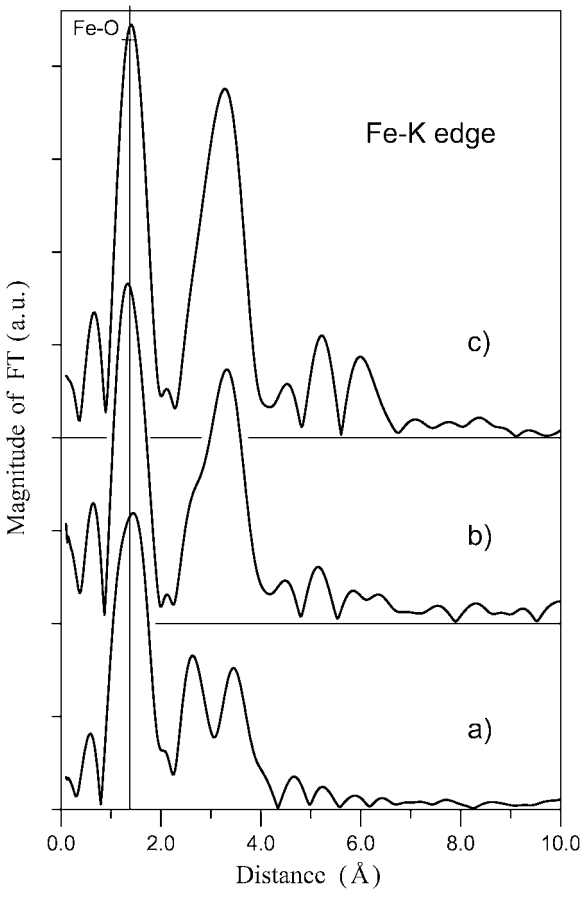

Fig. 4. Radial distribution function (RDF) curves describing Fe local surrounding of $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples: a) $x \sim 0.5$; b) $x \sim 0.3$; c) $x \sim 0.1$.

along axis *a* significantly differs from that of the iron oxide. In EXAFS data (Fig. 1, Table I), this difference manifests itself as a decrease in the average interatomic distance Co-O by ∼0.1 Å. Whereas for the iron oxide, a transition to a brownmillerite structure does not affect average interactomic distances. For the cobalt sample, a great decrease in the effective coordination number of Co-O exceeds the probable decay value associated with a stoichiometry distortion and indicates large distortions in the cobalt environment with decreasing oxygen amount as compared to iron. Analysis of the changes in the interatomic distances and coordination numbers observed for the third coordination sphere permit one to arrive at the same conclusion. Therefore, though the iron and cobalt containing brownmillerite structures are similar in appearance, their local structures differ.

Additionally it should be noted that the sub-lattice of Co and Fe cations exhibits high symmetry. Some distortions are observed only in the oxygen sub-lattice and in the Me-Sr distances.

$SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples: XRD (Table V) suggests that all the synthesized samples (regardless of oxygen concentration) belong to the perovskite type and are crystallized into a cubic syngony. As oxygen concentration decreases, lattice parameters increase.

As noted above, all coordination numbers have relative values, which primarily evidence the degree of distortion of the local surrounding for given chemical element. According to the obtained data (Fig. 2, Table II), the niobium surrounding is highly symmetric and does not depend on the oxide stoichiometry. It is likely that the oxidation degree of niobium in all complexes is +5, the ion radius being small.

Table V. *XRD data for references and $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ samples.*

	Reference samples								$SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$

	Exper.	Lit. [7]	Exper.	Lit. [8]	Exper.	Lit. [9]	Exper.	Lit. [10]	Exper.		
a	5.477	5.456	5.664	5.671	3.824	3.840	3.855	3.855	3.926	3.886	3.856
b	15.746	15.664	15.553	15.590							
c	5.575	5.556	5.528	5.528							

The local surrounding of iron and cobalt radically differs (Fig. 3, 4; Tables III, IV). Thus, an increase in the oxygen concentration results in the increase in the iron coordination number only. For cobalt, changes in the effective coordination number are more complex. Since a change in the average coordination number is accompanied by an increase in the average interatomic distance Co-O. Within the limits of experimental error, distances Co-Co, Fe are constant. But the lattice parameter grows with oxygen removal. On studying the local distortions in cubic $KNbO_3$ [11–13], this observation was interpreted as a partial irregular shift of cations from their crystallographic positions and a turn of octahedrons being relative to each other, which is associated with a symmetry breakdown due to removal of some oxygen. Based on the above, one can assume that similar distortions are primarily associated with cobalt surrounding. Analysis of the EXAFS data suggest that local distortions accumulate with decreasing oxygen concentration on retention of macrosymmetry (long-range ordering). Thus, the introduced cations are not equivalent and the larger part of distortions is associated with cobalt. Indeed (Tables II–IV) a decrease in the oxygen concentration in the structure $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ perovskites most strongly affects cobalt.

It is likely that iron and niobium are in the non-distorted octahedral at $(3 - x) = 2.5 - 3.0$, whereas cobalt can also occupy strongly distorted octahedral positions if oxygen is in deficiency. The cobalt local surrounding becomes more symmetric (more regular octahedral positions) with further decreasing oxygen deficiency.

It should be noted that the average distance Co-O for the modified perovskite in oxygen deficiency corresponds to that in $SrCoO_{2.5}$ having a brownmillerite structure.

On oxygen saturation the structure of all studied samples becomes more ordered, which manifests itself as appearance of new peaks in the region of large distances and a considerable rise in coordination numbers for the existing distances.

4. Conclusions

Using the EXAFS method to study modified perovskite-like $SrCo_{0.7}Fe_{0.2}Nb_{0.1}O_{3-x}$ system, it was shown that oxygen vacancies are mainly located near cobalt cation positions.

Abstract

It has long been understood that EXAFS is sensitive to crystallite size, since the average coordination number for a given scattering path is suppressed by a factor that depends upon the distance between the absorbing and scattering atoms. Careful analyses by other researchers have demonstrated the feasibility of determining crystallite size and even morphology in this way, but have in general been limited to well-characterized monodispersed samples. Here, we compare various techniques for estimating mean particle size in a polydispersed sample, using both EXAFS and conventional techniques. It is found that for polydispersed samples with an unknown size distribution, an analysis utilizing a simple spherical model performs nearly as well as more sophisticated models using realistic morphologies. Using simulations as well as experimental data, we demonstrate that EXAFS selects a "mean" size considerably smaller than that found by Scherrer analysis of XRD data; the two in combination can thus be used to give a crude estimate of polydispersion even in samples in which the form of the size distribution is unknown. Finally, we show that the sensitivity of EXAFS to the smallest crystallites present in the sample make it a useful adjunct to TEM in some cases.

1. Introduction

Since the extended X-ray absorption fine structure (EXAFS) of an element within a material is related to the radial distribution function about that element, it is necessarily true that even if a nanocrystalline material[1] adopts a structure identical to its bulk counterpart, the EXAFS will differ due to the reduced coordination numbers associated with atoms near the surface of the crystallites (here called the *termination effect*). In addition, the termination effect will be greater for longer direct scattering paths than for shorter ones, since the suppression is related to the number of atoms within half the path length of the crystallite boundary. Thus it is in theory possible to obtain information on the size and even the morphology of crystallites from analysis of the EXAFS data. Understanding of the termination effect is important for at least two reasons: it may be used to extract information regarding the size and morphology of a nanocrystalline sample; and, even if the sizes and morphologies of the particles in the sample are known, it is necessary to account for the termination effect to accurately analyze the EXAFS of the sample.

Several rigorous studies of the termination effect have been performed over the past several decades. Greegor and Lytle [1], for example, calculated the termination effect for particles in the shapes of spheres, cubes, and monolayer discs; they considered these shapes to be representative of more general classes of polyhedra. Using various metals supported on silica or alumina, they showed good agreement between the EXAFS results and size estimates based on chemisorption measurements. More recently, Frenkel *et al.* [2] and Arcon *et al.* [3] have both applied realistic geometries to the case of supported metal catalysts.

The aforementioned models assume that all of the crystallites in the sample are identical. For supported catalysts this is often a reasonable approximation. Almost all methods of synthesizing free nanoparticles, however, produce a distribution of particles of at least moderately different size, often approximating a log normal distribution [4]:

$$N(r) \propto \frac{1}{r \ln \sigma} \exp\left[\frac{-\left(\ln \frac{r}{r_0}\right)^2}{2(\ln \sigma)^2}\right] \Delta r. \quad (1)$$

In this equation, N is the number of particles with radii $r \pm \Delta r$; r_0 is the *geometric mean* and σ is the *geometric standard deviation* of the distribution.

Although it is possible in principle to extend the methods described above to polydispersed samples, in most cases where the distribution is not known by other means it is doubtful that an EXAFS spectrum contains sufficient information to unambiguously extract a complete size distribution. For the most part, therefore, the question of the termination effect in polydispersed samples has not been previously treated in the literature.

2. Comparison to Scherrer Analysis of X-Ray Diffractograms

An analogous situation holds in the field of X-ray (or, for that matter, electron) diffraction. It is well known that the Bragg peaks of samples comprising small crystallites are broadened due to the limited number of diffraction planes. In 1920, Scherrer computed the relationship between peak width and crystallite size for cubic crystallites [5]. This relationship is still frequently used to estimate the mean size of crystallites in a sample, despite the obvious drawbacks:

- The formula was derived for crystallites of equal size
- Other effects, such as strain, can contribute to the broadening of peaks in diffractograms
- In the case of powder samples, the formula assumes a cubic morphology
- The formula does not yield a measure of polydispersion; the Scherrer standard deviations sometimes reported in the literature measure the reproducibility of the technique when applied to different peaks in the diffractogram, and are unrelated to the width of the size distribution.

Considerable effort has gone into addressing these drawbacks (*e.g.* Bertaut tackled the issue of polydispersion [6]) or into using more sophisticated approaches such as the Fourier peak profile [7]. Nevertheless, the Scherrer formula continues to be the most widely applied method for determining mean size from X-ray diffractograms.

*e-mail: SCalvin@mailaps.org

[1] A sample consisting of single-crystal nanoparticles is, of course, itself a nanocrystalline material; the discussion in this paper is applicable to both freestanding nanoparticles and nanocrystals incorporated into a larger-scale matrix.

If "improved" techniques exist, why does the Scherrer formula continue to be used? In our opinion, the primary reason is its ease of use, combined with the poorly characterized nature of the samples to which it is often applied. A chemist or materials scientist attempting to synthesize nanoparticles, for example, frequently desires a rough estimate of the particle size. At an early stage, many new syntheses produce particles with irregular morphologies or size distributions (*e.g.* they may be contaminated with a few bulk-scale particles); in these cases, so little is known about the distribution that a sophisticated analysis is a waste of resources and the Scherrer analysis will produce a number which is nearly as accurate for much less effort.

In this paper, we discuss using EXAFS in a similar manner. Rather than computing the termination effect for precise morphologies, sizes, and size distributions, we utilize a simple spherical model. The remainder of this paper evaluates the properties and limitations of this model, and compares sizes determined in this way by those determined by Scherrer analysis and transmission electron microscopy (TEM).

3. Termination Effect for Homogenous Spheres

In this model, the crystallite is considered a homogeneous sphere of radius R. An atom a distance ρ from the center has an associated scattering sphere of radius r for each path. The fractional weight of this path relative to a bulk crystal is then equivalent to the fraction of the surface area of the smaller sphere that is contained with in the larger one. This fraction is equal to:

$$\frac{R^2 - (\rho - r)^2}{4\rho r}. \tag{2}$$

By integrating through the entire sphere and dividing by the volume, the formula for the average fraction of the surface area of a small sphere centered at a point in a larger one that is contained within the larger sphere (*i. e.* the fractional suppression of coordination number for direct scattering paths) is derived [8]:

$$1 - \frac{3}{4}\left(\frac{r}{R}\right) + \frac{1}{16}\left(\frac{r}{R}\right)^3. \tag{3}$$

Note that in the homogenous spherical model, atoms are not treated as residing on discrete lattice points, and no use is made of the crystal structure. For multiple-scattering paths, it is important to note that r in equation (3) is the distance from the absorbing atom to the most distant scattering atom, rather than half of the total path length.

4. Mean Size Determinations in Polydisperse Samples

Mean size is not a uniquely defined quantity for polydisperse samples, since it depends on the weighting scheme utilized. Number weighting, for example, counts each crystallite equally, and is therefore the natural scheme for determining size from microscopy images. Volume weighting, on the other hand, counts each atom equally (neglecting differences in density). X-ray absorption spectroscopy is, strictly speaking, volume-weighted. Eq. (3), however, deviates strongly from unity only as R becomes small, and does so in a nonlinear fashion. Thus the difference between the EXAFS spectrum of a sample containing small crystallites from a bulk sample of the same substance will be disproportionately influenced by crystallites toward the small end of the size distribution. Mean sizes determined in this way, therefore, will be somewhat smaller than the volume-weighted mean.

XRD amplitudes, on the other hand, are weighted by the square of the crystallite volume [9]. Because Scherrer analysis utilizes the full width of a diffraction peak at half its maximum value, the size as determined by Scherrer analysis is not identical to the mean weighted by the square of the volume, but it will generally be larger than that found by volume weighting, and thus larger than that found by EXAFS.

To examine the differences between the sizes determined by the two techniques, we constructed a numerical simulation of both EXAFS and Scherrer size determinations. In both cases, log normal distributions were used with specified geometric means and standard deviations. For the EXAFS simulation, simulated particles from 0.1 to 200.0 nm in diameter were included, with the sizes spaced by 0.01 nm (*i.e.* 0.01, 0.02, 0.03 . . . nm). Due to the need to construct a peak profile for each size simulated, the Scherrer simulation used fewer particle sizes, including particles from 0.75 to 19.5 nm in diameter spaced by 1.25 nm (*i.e.* 0.75, 2.00, 3.25 . . . nm).

The results for three log normal distributions are shown in Fig. 1, along with the volume and number weighted mean diameters. It is evident that all mean diameters are similar when the geometric standard deviation is 1.1 or below, while at 1.35 the Scherrer-determined mean is about 15% larger than that found by EXAFS.

More remarkable behavior is expected for samples with geometric standard deviations above a critical value of $e^{\sqrt{6}/6} \approx 1.50$ In these cases, it is straightforward to show that the mean of the distribution given in Eq. (1) diverges. A survey of the literature shows polydispersity of this degree is not uncommon [4, 10–12]. What, then, does this mean?

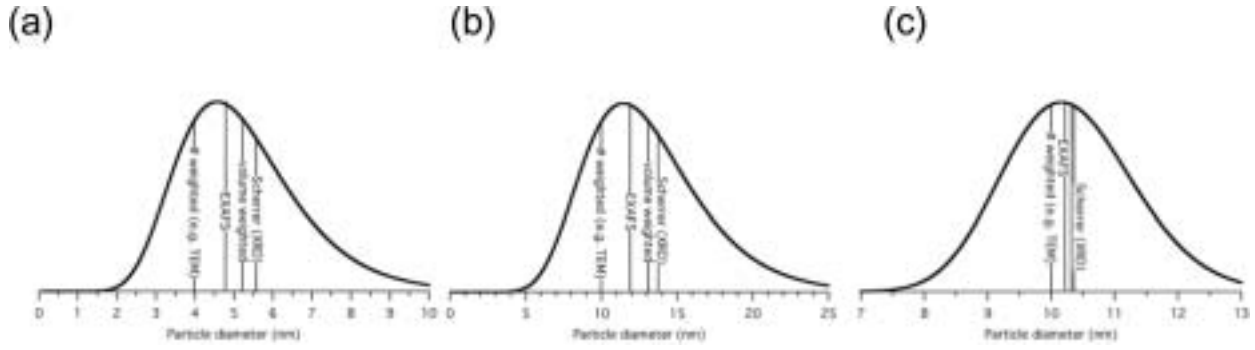

Fig. 1. Volume-weighted log normal size distributions for nanoparticles. The mean diameters as found using various weightings are also shown. Note the different scales on the x-axes. (a) $r_0 = 1.91$ nm, $\sigma = 1.35$; (b) $r_0 = 4.78$ nm, $\sigma = 1.35$; (c) $r_0 = 4.98$ nm, $\sigma = 1.11$. In (c), there is insufficient space to label the volume-weighted mean diameter; it is identified by the unlabeled line between the Scherrer and EXAFS sizes.

The answer lies in the log normal distribution, which includes particles of *all* sizes. In reality, of course, there must be a cut-off size at the high end, if for no other reason than that the sample itself is finite. (The low end also has a cut-off size – one atom!) When a particle distribution is reported as log normal, it is of course meant that the log normal distribution provides a good fit to the actual particle distribution over the size range of interest. The divergence of the theoretical Scherrer size for large polydispersion, then, suggests that Scherrer analysis of such samples is sensitive primarily to the details of the high end cut-off rather than the number or volume-weighted mean size. It is our assertion, therefore, that Scherrer analysis of a sample with a geometric standard deviation of more than 1.5 is not a meaningful measure of the mean particle size.

EXAFS, on the other hand, remains convergence until the volume-weighted mean itself diverges, *i.e.* until the geometric standard deviation exceeds $e^{\sqrt{3}/3} \approx 1.78$. Thus EXAFS size determinations are applicable over a wider range of polydispersity than Scherrer analysis.

5. Experimental Comparison to Atomic Models

In order to investigate these effects in a real system, nanoparticles of the element palladium were synthesized according to the method of Teranishi and Miyake [13] using polyvinylpyrrolidone (PVP) of molecular weight 29,000 Daltons in pure ethanol. Five samples were synthesized, using 75, 100, 255, 500, and 750 mg of PVP in 15 mL of ethanol. The greater the amount of PVP used in this synthesis, the smaller the expected particle size.

Samples were prepared by grinding the powders in a mortar and pestle, and then spreading thin layers of finely ground powder on multiple layers of Kapton tape. The number of layers of tape was chosen so that the total absorption was approximately one absorption length. Uniformity was confirmed at the beamline by measuring transmission as a function of beam position.

The prepared samples were taken to the National Synchrotron Light Source at the Brookhaven National Laboratory in Long Island, New York where X-ray absorption spectra were taken at beamline X-11A. Background subtraction was performed using the method described in Ref. [14], with the background region considered to extend up to 1.0 Å^{-1} in the Fourier transform. The k^2-weighted data is shown in Fig. 2, with the Fourier transform shown in Fig. 3. The typical decrease in amplitude with decreasing particle size is clearly evident.

The technique of curve-fitting to a FEFF8 theoretical standard was used to extract sizes from the data. First, a preliminary fit was performed on a bulk foil to determine $S_0{}^2$ (0.59 ± 0.01), ΔE_0 (-4.7 ± 0.3 eV), the lattice parameter (3.87 ± 0.01 Å), the mean square radial disorder (MSRD) for the nearest-neighbor path ($0.0033 \pm 0.002\ \text{Å}^2$), the MSRD for all other direct-scatterer paths ($0.0079 \pm 0.0014\ \text{Å}^2$), and the third cumulant for the nearest-neighbor path. Direct scattering paths out to the sixth co-ordination shell were included, as well as the fourteen most significant multiple-scattering paths. Multiple-scattering paths were constrained according to the method discussed in Ref. [15]. Because of a strong correlation between the value found for $S_0{}^2$ and the MSRD for the nearest-neighbor, $S_0{}^2$ was refined in a preliminary process that takes advantage of the different dependence on k of the two variables; see Ref. [16] for a complete description of this procedure. Likewise, the third cumulant for the nearest-neighbor was strongly correlated with the lattice parameter; applying the k-dependence procedure yielded a value of nearly zero for the nearest-neighbor third cumulant (the latter was therefore constrained to zero for the final fit). The R factor for this fit was 0.009.

Two models were then used to account for the termination effect: an "atomic" model in which the sample was assumed to be composed of perfect cuboctahedra, and the spherical homogenous model described in Section 3. In the atomic model, the possible mean size was made continuous by allowing for cuboctahedra of two sizes (*e.g.* 3-shell and 4-shell) to be present. All parameters were constrained to the values found for the foil except for the particle size and the lattice parameter; the lattice parameter was constrained to be the same for all nanoparticulate samples. For comparison, a fit that does not account for the termination effect was also performed. As can be seen from Fig. 3, both the atomic and spherical homogenous models yield very good fits, while the bulk (*i.e.* non-terminated) fit is poor. In the case of the sample

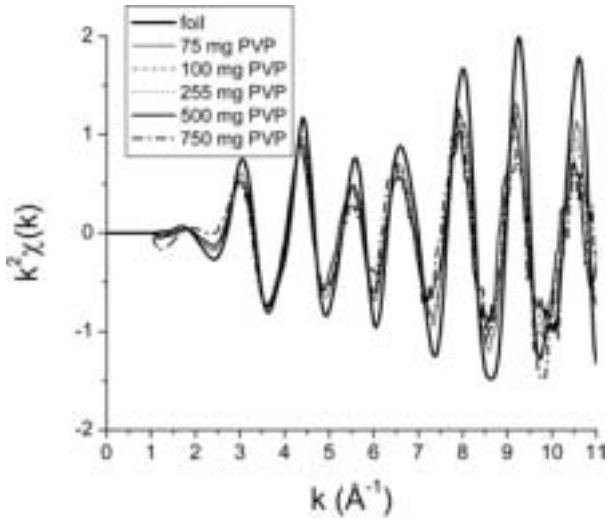

Fig. 2. $\chi(k)$ for palladium nanoparticle data, weighted by k^2.

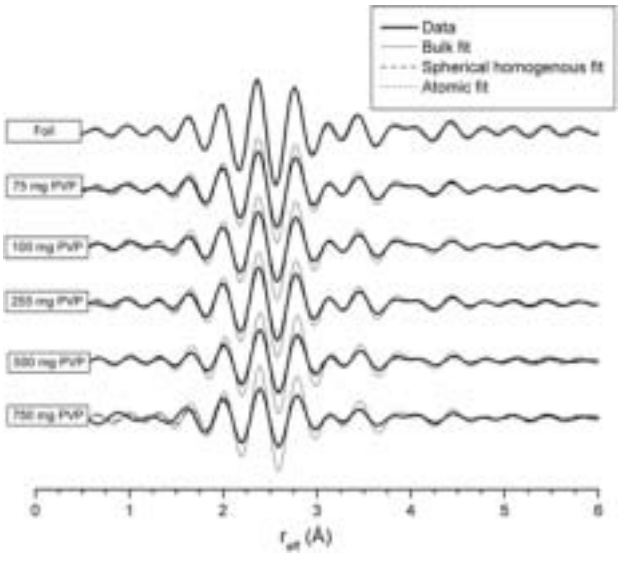

Fig. 3. Real part of Fourier transforms of data and fitted models. Atomic and spherical homogenous fits are essentially indistinguishable in these plots. Above r_{eff} of 2 Å atomic and spherical homogenous fits are essentially indistinguishable from the data as well. Only a bulk fit is shown for the foil, since the other two models would not be meaningful.

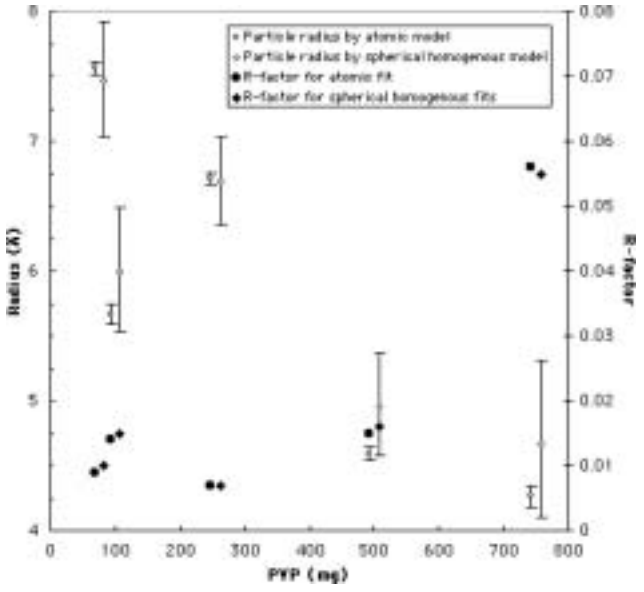

Fig. 4. Particle radius and *R* factor for atomic and spherical homogenous model fits. Results for the two models have been displaced horizontally from each other for visibility.

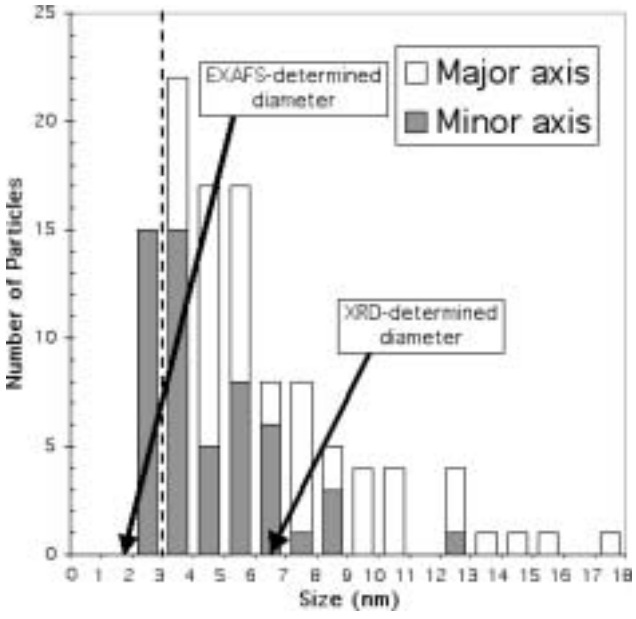

Fig. 5. Figure adapted from Ref. [17]. Histogram of nickel crystallite dimensions from TEM of a nanocrystalline sample. Crystallites with a major axis smaller than about three nanometers did not have sufficient diffracted intensity to be resolved by TEM; this limit is indicated by the dashed line. Note that the EXAFS indicated size is below this limit, and that the EXAFS and XRD determinations establish an interval that includes the majority of the crystallites found by TEM.

with the greatest amount of PVP there is a noticeable mismatch at low r; this may be due to residual PVP bound to the surface of the crystallite.

The results of the terminated fits are shown in Fig. 4 (the lattice parameter was found to be 3.88 Å in both cases). Both fits yield similar values for the radii of the particles, although the uncertainties in the atomic fits are considerably smaller. As expected, particle size is found to generally decrease with increasing PVP. Interestingly, both methods show an exception to this tend: the size of the sample prepared with 100 mg of PVP is found to be smaller than that prepared with 255 mg of PVP. This result was confirmed by TEM. Since TEM also showed the samples to be significantly polydispersed, the spherical homogenous model appears to be appropriate for obtaining a crude estimate of mean crystallite size.

6. Experimental Comparison to Scherrer Analysis

Fig. 5 is taken from a study published elsewhere [17] that compares the results of the spherical homogenous model, Scherrer analysis, and TEM for the same nanocrystalline sample. In that study, the method of using EXAFS to determine the mean size was especially crude, but also especially simple. Fourier transforms of the EXAFS spectra of both the sample and a bulk standard were taken, and the amplitude of the sample's Fourier transform was suppressed by the function given in Eq. (3), with r found by a single-variable fit. Note that this method requires no theoretical standard or multivariable fits. On the other hand, this method does not treat multiple-scattering paths correctly, care must be taken in accounting for the phase shift between EXAFS Fourier transforms and the true radial distribution function as well as artifacts introduced by the Fourier transform, and no allowance is made for relaxation of the nanocrystallites relative to the bulk sample. Nevertheless, the fits were quite good, yielding a mean EXAFS diameter of 1.8 nm. The Scherrer-determined diameter, in contrast, was 6.4 nm; in light of the discussion in Section 4, the difference between the two values suggests considerable polydispersion. TEM images confirmed polydispersion and increasing numbers of crystallites as the diameter dropped below 4 nm. Unfortunately, contrast was not sufficient to image crystallites smaller than 3 nm, and thus direct comparison to the EXAFS result could not be made. Nevertheless, Fig. 5 is qualitatively similar to Fig. 1, providing some confirmation for the ideas discussed above. Further studies are underway to provide additional experimental verification of the relation between mean size, polydispersion, and Scherrer, EXAFS, and TEM sizes.

7. Conclusions

In summary, we believe that EXAFS analyses using a simple homogenous spherical termination model show promise as a method of estimating crystallite sizes in polydispersed samples. Although the method does not provide the accuracy of atomic models, this is not a crucial drawback for samples with poorly characterized size distributions. In many cases, the ease with which this model can be applied may argue for its use over the more sophisticated techniques.

We also wish to emphasize that in samples with high polydispersion, Scherrer analysis is not sensitive to the mean crystallite size, making EXAFS an important alternative. In samples with more moderate polydispersion, the EXAFS determined size will generally be smaller than that determined by Scherrer analysis, with the difference between the two providing an indication of the degree of polydispersion that is present. Thus, the two techniques in combination can provide a first estimate of both size and polydispersion in cases where microscopy is difficult or unavailable.

Abstract

Alumina-supported PdO is largely accepted as an effective catalyst for the methane combustion reaction. In this study, we investigated the influence of the addition of CeO_2 to the PdO catalysts supported on χ-Al_2O_3 on their microstructures by XAFS spectroscopy and X-ray diffraction technique (XRD).

We obtained the radial structure functions (RSF) from Fourier transform of Pd K-edge EXAFS spectra of both fresh and as-tested catalysts for the PdO and PdO-CeO_2 system on alumina, respectively. A single peak, which is assigned to the nearest neighbor Pd-Pd bonds in Pd metal, was seen after the catalytic activity test at 573 K under a methane-oxygen stream. This is consistent with the fact that PdO in both the catalysts are reduced to metallic Pd at 573 K. In the fresh PdO-CeO_2 catalyst, the second- and third-neighbor peak intensities in the RSF were reduced to about one-half, compared with those in the fresh CeO_2-free catalyst, while these catalysts showed the same peak intensities for the nearest neighbor RSF. These results suggest that CeO_2 induces disordering of the outer shells of Pd scattering atoms in the PdO catalyst. It can be presumed that CeO_2 improves the dispersiveness of PdO particles over the support and depresses the aggregation among the particles.

1. Introduction

Combustion catalysts exert effects on the suppression of the evolution of dioxins, because the reaction is initiated at low temperature. As the combustion of iron oxides starts at 573 K, they are typical and widely used as combustion catalysts [1, 2]. Recently, PdO catalysts, which are supported on alumina, are used as combustion ones [3], and garbage bags or resin bags for daily procurement into which PdO catalysts are impregnated are in production. This is because PdO catalysts are colorless and transparent. In addition they burn at temperatures as low as 523 K. The effect of PdO catalysts on the depression of the evolution of dioxins is expected to be larger than that of iron oxides. Generally, γ-Al_2O_3, which is made by thermal treatment of boehmite (AlOOH), is used as a support. However, in a recent study we showed that the PdO catalyst supported on χ-Al_2O_3, whose precursor is gibbsite ($Al(OH)_3$), has a higher oxidation activity than that supported on γ-Al_2O_3 [4].

The most striking characteristic is that PdO has a high catalytic activity already at low concentration. As a matter of fact, the concentration of the PdO catalyst, which has been in practical use is less than 0.1 mol%. XRD is one of the conventional methods to determine the structure of catalysts. However it is less effective for highly dispersed and/or low concentration systems. X-ray absorption fine structure (XAFS) is applicable in such dilute systems to determine the local structure around X-ray absorbing atoms.

In this study, the X-ray absorption spectra near the Pd K-edge of catalysts of both fresh and as-tested PdO/Al_2O_3 and PdO-CeO_2/Al_2O_3, in which cerium oxides were added as promoters, were measured. In addition, XRD measurements were performed for synthesized high concentration catalysts. We discuss the role of CeO_2 promoters and the relationship between the catalytic activities of PdO catalysts and crystal structure of the catalysts as well as the local structure.

2. Experimental

2.1. *Catalyst preparation*

Weighed portions of $Al(OH)_3$ (gibbsite) and $Ce(NO_3)_3 \cdot 6H_2O$ were admixed together with deionized water with stirring for 0.5 h. An aqueous solution of $Pd(NO_3)_2$ (Pd content is 4.5 or 11.4 mass%) was added to the mixture of metal salts in atomic ratios from Ce/Pd = 0 to 5 while keeping the mass ratio of Al_2O_3/PdO = 9, resulting in a suspension. The suspension was calcined for 1 h at 773 K after stirring and drying for 1 h and 15 h, respectively. Samples for measurements were obtained after crushing the calcined solids and sieving into #10–#24 (1.68 mm–0.71 mm) mesh components.

2.2. *Catalytic reaction*

The catalytic experiments were performed in a fixed-bed continuous-flow quartz reactor operated at atmospheric pressure. Details of the reactor design have been described elsewhere [5]. A half-gram of the catalyst was loaded. The gas used was diluted with helium so that the pressure of methane and oxygen would be kept at 3.4 and 20.3 kPa, respectively. The reactants and products were analyzed with an on-stream gas chromatograph (Shimadzu GC-8APT) equipped with a TC detector and integrator (Shimadzu C-R6A).

2.3. *XRD measurements*

Powder X-ray diffraction data were collected using a high-performance diffractometer (Rigaku RINT2500VHF) with monochromatized CuKα radiation with a source power of 30 kV–100 mA for phase identification of the specimens.

2.4. *XAFS measurements and analysis*

Pd K-edge XAFS spectra for PdO/Al_2O_3 and PdO-CeO_2/Al_2O_3 were measured after the tests in a gas flow (CH_4: 2 ml/min, O_2: 2 ml/min) except for the fresh catalyst, in transmission mode at BL-10B of the Photon Factory, Tsukuba. The synchrotron radiation was monochromatized by a Si(311) channel-cut monochromator. The positron storage ring current and energy were approximately 300 mA and 2.5 GeV, respectively. Ionization chambers were applied as incident and transmission beam intensity detectors. Argon gas and krypton gas in the ionization chambers were employed for the incident and transmission monitors, respectively, to achieve optimum signal-to-noise ratio. The appropriate amounts of fine-powder sample and boron nitride powder were mixed and pressed into pellets of 1 mm thickness and

†e-mail: murai@chem.tokushima-u.ac.jp

10.0 mm diameter. All samples had edge-jumps of 1 ($\Delta\mu d$), where μ is the linear absorption coefficient and d is the thickness.

The EXAFS interference function, $\chi(k)$, was extracted from the measured absorption spectra using standard procedures [6], where k denotes the wave number of a photoelectron: $k = [2m(E - E_0)/\hbar^2]^{1/2}$. $\chi(k)$ was normalized using MacMaster coefficients according to the EXAFS workshop report [7]. The programs *XAFS93* and *MBF93* [6] were employed for the data analysis to determine local structure parameters. The EXAFS formula based on single-scattering theory is expressed by the cumulant expansion [8]:

$$\chi(k) = \sum_j \frac{N_j}{kR_j^2} \left|f_j(k,\pi)\right| \exp(-2\sigma_j^{(2)}k^2 + \tfrac{2}{3}\sigma_j^{(4)}k^4) \exp\left(-\frac{2R_j}{\lambda_j}\right) \times \sin\left[2kR_j - \frac{2k}{R_j}\left(1 + \frac{2R_j}{\lambda_j}\right)\sigma_j^{(2)} - \tfrac{4}{3}\sigma_j^{(3)}k^3 + \Psi_j(k)\right], \quad (1)$$

where N_j is the coordination number in the jth shell at distance R_j from the absorbing atom, $\left|f_j(k,\pi)\right|$ is the back-scattering amplitude of the photoelectron, and $\Psi_j(k)$ is the total phase shift function [9]. The quantities $\sigma_j^{(n)}$ are the nth cumulants. The mean free path λ_j of the photoelectron was taken to depend on the wave number k with the relationship $\lambda_j = k/\eta_j$. In this study, because we take a harmonic vibration model, the quantities $\sigma_j^{(3)}$ and $\sigma_j^{(4)}$ are zero. A Fourier-filtered EXAFS function of the peak in real space was compared with a theoretical EXAFS function. In the parameter fitting, the theoretical EXAFS function was filtered in the same way as the observed one in order to eliminate truncation effects in the Fourier transformation procedure.

3. Results and Discussion

Figure 1 shows the conversion of methane (C_M) on the catalysts. C_M was calculated by the following formula [2],

$$C_M(\%) = \frac{CO_2(P)}{CH_4(P) + CO_2(P)} \times 100 \quad (2)$$

where $CH_4(P)$ and $CO_2(P)$ represent the mole numbers of methane and carbon dioxide in the product stream. It was found that no methane oxidation occurred even at 873 K in the absence of the catalyst. The reaction started at temperatures as low as 473 K on the PdO catalysts. The conversions of both PdO and PdO-CeO_2 catalysts increased with increasing reaction temperature. Although the temperature at which C_M went up to 100% on PdO-CeO_2 catalysts was somewhat higher than that on Ce-free catalysts, the activity of PdO-CeO_2 catalysts was higher than that of Ce-free catalysts below 553 K. This result suggests that PdO-CeO_2 catalysts have higher catalytic activities than Ce-free catalysts.

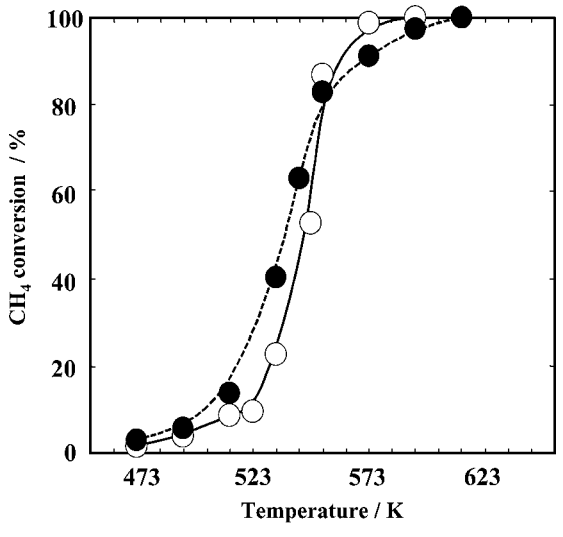

Fig. 1. Activity of methane oxidation of PdO and PdO-CeO_2 catalysts supported on χ-Al_2O_3. ○: PdO catalyst, ●: PdO-CeO_2 catalyst.

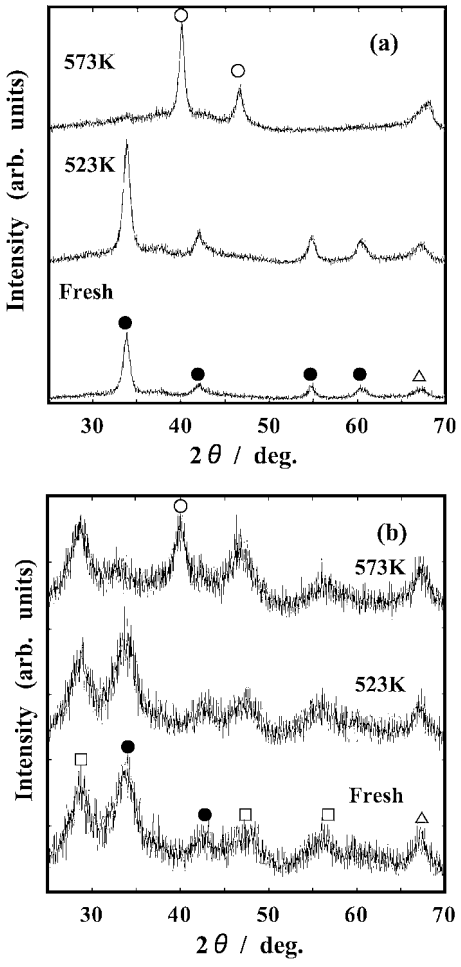

Fig. 2. XRD patterns for (a) the PdO and (b) the PdO-CeO_2 catalysts after tested in gases flow of CH_4 (2 ml/min) and O_2 (2 ml/min) at various temperatures. ○: Pd, ●: PdO, ⊡CeO_2, △: Al_2O_3.

Figure 2 shows XRD patterns for the PdO and PdO-CeO_2 fresh catalysts and those after tested in gas flow of CH_4 (2 ml/min) and O_2 (2 ml/min) at two different temperatures. All diffraction peaks for CeO_2-free catalysts could be assigned to PdO. The peaks were broadened after tested at 523 K. The diffraction profile at 573 K showed that PdO had been reduced to Pd metal. Equally, in the diffraction profile for PdO-CeO_2 catalysts at 573 K, no peaks for PdO were observed but those for Pd metal. In addition, the peaks for CeO_2 were still observed for PdO-CeO_2 catalysts. This suggests that the active species of the reaction is not CeO_2 but PdO. The diffraction profile for PdO-CeO_2 catalysts at each temperature was broader than that for PdO catalysts. It is obvious that PdO is remarkably affected by CeO_2. The results of XRD measurements indicate that the addition of CeO_2 prevents PdO from crystallization and PdO stays finely dispersed. Figure 3 shows a three dimensional structure of PdO and its projection down to the c-axis. The structure of PdO belongs to the tetragonal

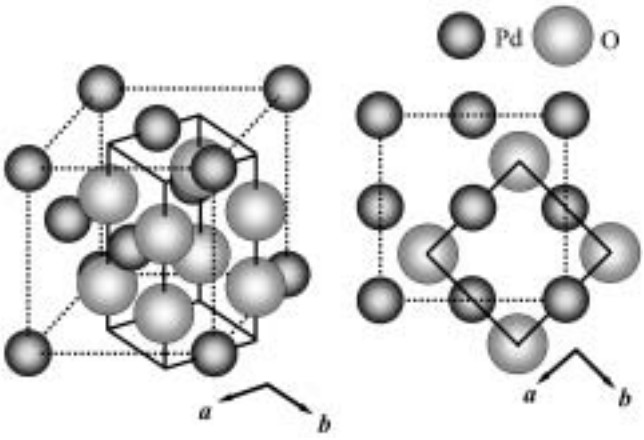

Fig. 3. A three dimensional structure of PdO and its projection down to the *c*-axis.

system. It is presumed that face-centered cubic lattices of Pd are formed just by removing oxygen atoms when PdO is reduced to Pd metal. In the EXAFS analyses, the distances between an absorbing Pd atom and its second-nearest neighbor are equal to the lengths of the *a*- or *b*-axes of the tetragonal PdO unit cell: they correspond to Pd-Pd bonds in Pd metal as shown in Figure 3.

Figure 4(a) shows normalized Pd K-edge XANES spectra of Pd foil (standard sample), fresh and as-tested PdO/Al_2O_3 catalysts at 523 K and 573 K. The XANES spectrum of as-tested catalyst at 523 K was nearly identical with that of fresh catalyst. On the other hand, the XANES spectrum of as-tested at 573 K was distinctly different from the above two spectra. The spectrum of as-tested at 573 K catalyst is characterized by a shift in the edge to lower energy and two peaks above the absorption edge. The normalized Pd K-edge XANES spectra of Pd foil, fresh and as-tested $PdO\text{-}CeO_2/Al_2O_3$ catalysts at 523 K and 573 K, as shown in Figure 4(b), have the same tendency as those of CeO_2-free catalysts. The shift of the absorption edge to lower energy corresponds to the reduction of the absorbing Pd atoms. These results are in agreement with the results of the XRD method. The spectral shapes above the absorption edge are roughly similar to that of Pd foil. These results indicate that PdO was reduced and is present in its metallic state on alumina. In a detailed comparison of the XANES spectra, the difference in the ratio of two peak intensities above the absorption edge was observed between catalysts for PdO and PdO-CeO_2 system on alumina after the catalytic activity test at 573 K. That is to say, the intensity ratio of the second peak around 24.37 keV to the first peak around 24.34 keV of $PdO\text{-}CeO_2/Al_2O_3$ catalyst after the test at 573 K is smaller than that of CeO_2-free catalyst after the test at 573 K. This characteristic of the spectral shape has been observed on a catalyst, which has high dispersiveness and activities [10]. This suggests that the addition of CeO_2 improves the dispersiveness of PdO on supports.

Fourier transformations were performed on Pd K-edge EXAFS spectra in the 3.0–16 $Å^{-1}$ region in *k*-space. The Fourier transforms of the Pd K-edge EXAFS spectra, which are the radial structure functions (RSF), are presented in Figure 5. No phase shift corrections are made. In Figure 5(a), the first-peak at 1.7 Å corresponds to the nearest Pd-O bonds and the second- (2.7 Å) and the third-one (3.1 Å) correspond to the second and the third Pd-Pd shells, respectively. Similarly, in Figure 5(b) the three peaks assigned to the nearest bonds (Pd-O), second-nearest neighbor (Pd-Pd) and the third-nearest neighbor (Pd-Pd) were observed at 1.7 Å, 2.7 Å and 3.1 Å, respectively. The three main peaks of

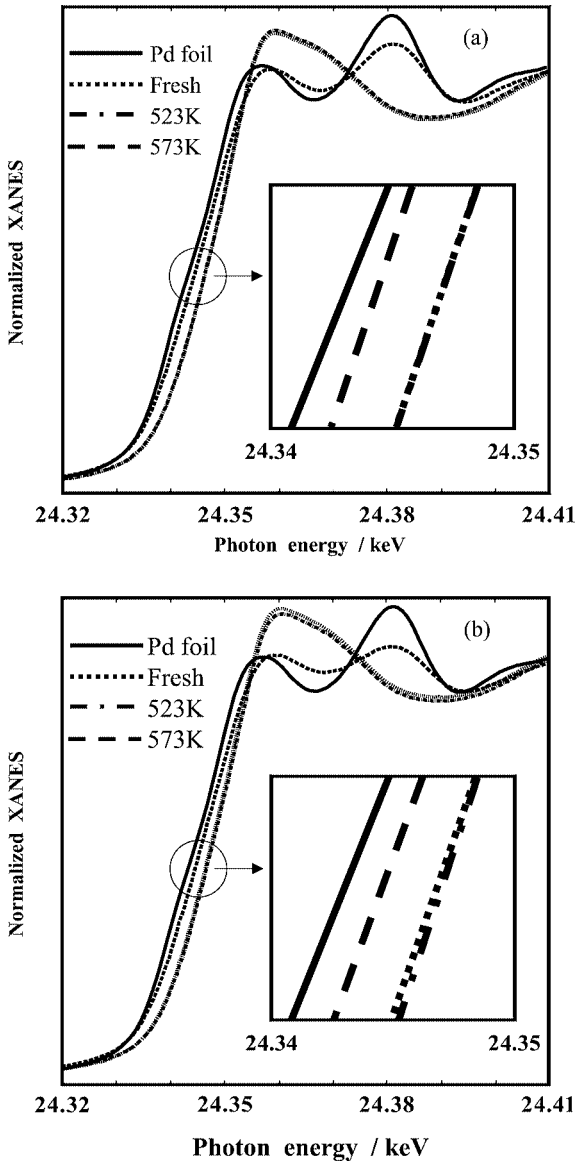

Fig. 4. Normalized XANES spectra for (a) the PdO and (b) the PdO-CeO_2 catalysts after tested in gases flow of CH_4 (2 ml/min) and O_2 (2 ml/min) at various temperatures with those for Pd metals.

PdO/Al_2O_3 are located almost at the same positions as those of $PdO\text{-}CeO_2/Al_2O_3$ catalyst in both results of the fresh catalyst and the catalyst tested at 523 K. However, in each result the two RSFs differ in terms of the amplitude. The amplitudes of the second and third peaks of $PdO\text{-}CeO_2/Al_2O_3$ catalyst were much weaker than those of the CeO_2-free catalyst in spite that the first peaks have the same amplitudes. This kind of phenomenon has been reported by Nakabayashi *et al*., 1995 [11], on Raney nickel catalyst. Such results indicate that there is crystal distortion in the $PdO\text{-}CeO_2/Al_2O_3$ catalysts, as supported by the broad peaks in the XRD patterns shown in Figure 2. CeO_2 induces disordering of the outer shell of Pd scattering atoms in the PdO catalysts. Figure 5(c) shows the FTs of the Pd K-edge EXAFS spectra for the sample after tested at 573 K and for Pd foil as a standard sample. All FTs for catalysts of PdO/Al_2O_3, $PdO\text{-}CeO_2/Al_2O_3$ and the Pd foil show the peaks corresponding to that for Pd-Pd in metal (Pd foil) at 2.4 Å. However, the intensity of the peak corresponding to the metallic Pd-Pd bond decreases in the order, Pd foil > PdO/Al_2O_3 > $PdO\text{-}CeO_2/Al_2O_3$, indicating that the Pd particle size decreases with support on Al_2O_3 and the addition

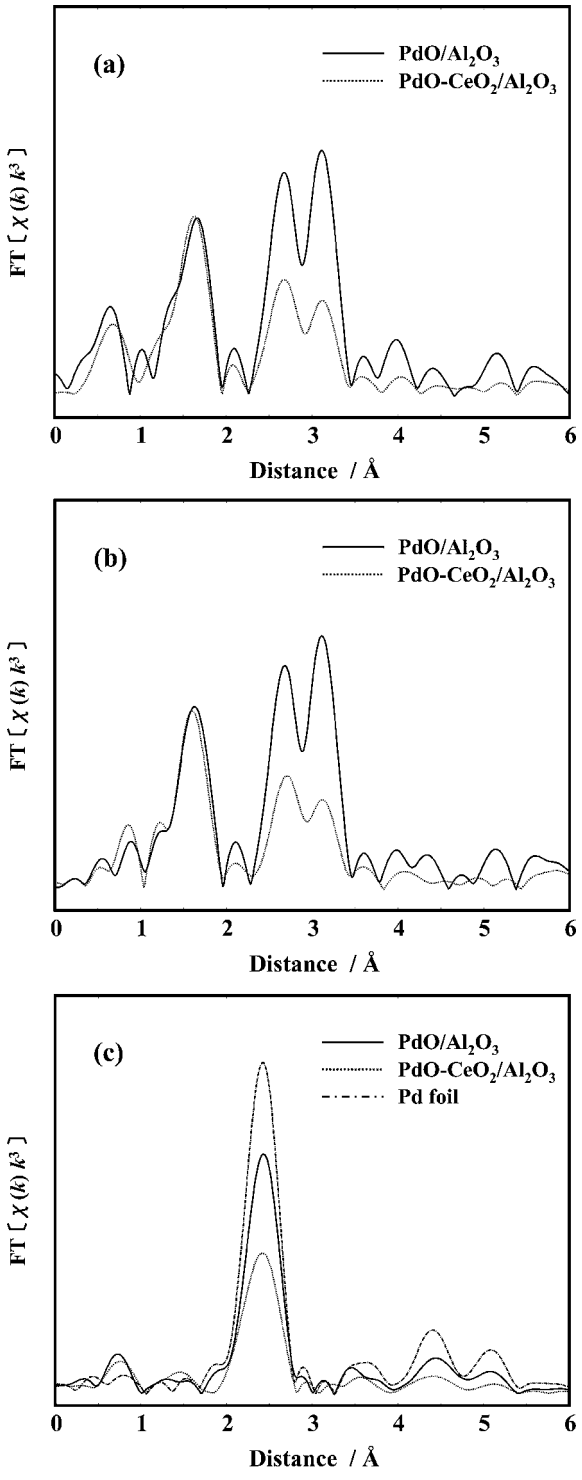

Fig. 5. The Fourier transforms of $\chi(k)k^3$ for (a) fresh, (b) tested at 523 K and (c) 573 K.

of CeO_2. This result shows that the addition of CeO_2 prevents PdO catalysts from being easily reduced to Pd metal and has an effect on the retention of catalytic activities. The results of local structure parameters fitting are shown in Table I. The reliability of fit parameters,

$$R = \sum_s \left| k_s^3 \chi(k_s)_{\exp} - k_s^3 \chi(k_s)_{calc} \right| \Big/ \left| k_s^3 \chi(k_s)_{\exp} \right|, \qquad (3)$$

Abstract

Iron-modified aluminophosphate with a triclinic form of the chabazite topology FeAPO-34, synthesized hydrothermally from a fluoride medium, is analyzed by Fe K-edge XANES and EXAFS. XANES analysis reveals that the as-synthesized sample contains approximately equal amounts of Fe(II) and Fe(III) cations, while the oxidation state of iron in the template-free sample is Fe(III). EXAFS analysis confirms the incorporation of iron into different framework sites of the as-synthesized FeAPO-34 with triclinic symmetry. In the template-free FeAPO-34 with rhombohedral symmetry, iron cations are located on tetrahedral sites, forming catalytically active acid and redox centers.

1. Introduction

The isomorphous substitution of aluminum sites in the framework of microporous aluminophosphates ($AlPO_4$-n, n denotes structure type) by small amounts of transition metal ions generates catalytically active acid and redox centers. In this way heterogeneous catalysts can be produced. The degree of incorporation of the metal atoms depends on the particular structure of the aluminophosphate.

In the triclinic form of aluminophosphate with chabazite topology ($AlPO_4$-34) successful substitutions of aluminum with Co, Mn, Ni and Zn cations were reported, producing CoAPO-34, MnAPO-34, NiAPO-34 and ZnAPO-34 aluminophosphates [1–3]. The aluminophosphate with triclinic form of chabazite topology ($AlPO_4$-34) can be synthesized from fluoride medium using morpholine or piperidine as structure-directing agents [4, 5]. There are three inequivalent aluminum sites in the framework of $AlPO_4$-34. Two aluminum sites are tetrahedrally coordinated while the aluminum at the third site is octahedrally coordinated with two fluoride atoms in addition to four oxygens. The fluoride ions bridge two Al atoms in a 4-ring connecting double-6-rings of the structure and thus break the rhombohedral symmetry of chabazite [4]. After the thermal treatment the template- and fluoride-free material adopts the rhombohedral symmetry of chabazite topology in which all aluminum atoms are tetrahedrally coordinated [5]. The framework structure of this phase reforms the triclinic symmetry of chabazite in the presence of water [6].

In this paper we examine the incorporation of iron into the framework of triclinic $AlPO_4$-34. We synthesized hydrothermally the FeAPO-34 aluminophosphate. XRD analysis confirmed that the as-synthesized sample had triclinic symmetry, while the framework of the template-free sample adopted the rhombohedral symmetry. The elemental analysis of the as-synthesized sample indicated isomorphous substitution of the framework aluminum by iron. Detailed information on the Fe cation location, however, was difficult to obtain by XRD, since Fe concentration was very low and Fe cations were randomly distributed in the structure. Therefore we used Fe K-edge XANES and EXAFS analysis to probe directly the valence state and the local environment of Fe cations in the as-synthesized and template-free FeAPO-34 samples.

2. Experimental

We synthesized hydrothermally triclinic FeAPO-34 from a fluoride medium using piperidine as a structure-directing agent [3]. A template-free sample was obtained by calcination in oxygen flow at 500 °C for 3 hours.

X-ray absorption spectra were measured in the transmission mode at E4 beamline of HASYLAB synchrotron facility at DESY in Hamburg. The E4 station provided a focused beam from an Au-coated torroidal mirror and a Si(111) double crystal monochromator with about 1 eV resolution at the Fe K-edge. Harmonics were effectively eliminated by a plane Au-coated mirror, and by a slight detuning of the monochromator crystals, keeping the intensity at 60% of the rocking curve with the beam stabilization feedback control. Powder samples of the as-synthesized and template-free FeAPO-34 materials and reference samples were prepared on multiple layers of adhesive tape and mounted on a sample holder in a vacuum chamber of the beamline, so that during measurements the samples were kept in high vacuum. The standard stepping progression within [−250 eV ... 1000 eV] region of the Fe K-edge was adopted with an integration time of 2s/step. The exact energy calibration was established with the simultaneous absorption measurements on the Fe metal foil.

3. Results and discussion

The Fe XANES spectra of the FeAPO-34 samples and reference compounds $Fe(III)PO_4$, $Fe(II)SO_4$, Fe(0) with known oxidation numbers are extracted by a standard procedure (Fig. 1) [7]. The zero energy is taken at the first inflection point in the Fe metal spectrum (7112 eV), i.e., at the 1s ionization threshold in the Fe metal. The shape of the K-edge and the pre-edge resonances is characteristic of the local symmetry of the investigated atom and can be used as a fingerprint in identification of its local environment [7, 8]. Tetrahedrally coordinated atoms are recognized by a single pre-edge peak, which can be assigned to the $1s \rightarrow 3d$ transition, as for example in the $FePO_4$ reference sample. The characteristic tetrahedral resonance is present in the template-free FeAPO-34 demonstrating that iron cations are incorporated into the tetrahedral sites. In the case of the as-synthesized sample

*E-mail: iztok.arcon@p-ng.si

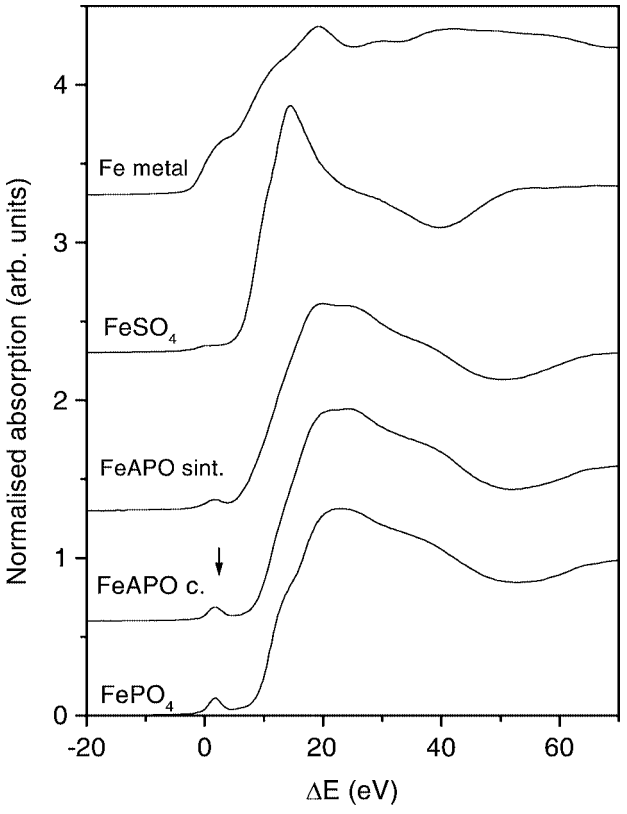

Fig. 1. Normalized Fe K-edge XANES spectra of the as-synthesized and template-free FeAPO-34 and reference samples: $FePO_4$, $FeSO_4$ and Fe metal. The zero energy is taken at the 1s ionization threshold in the Fe metal (7112 eV). The pre-edge resonance characteristic for tetrahedrally coordinated atoms is marked by the arrow.

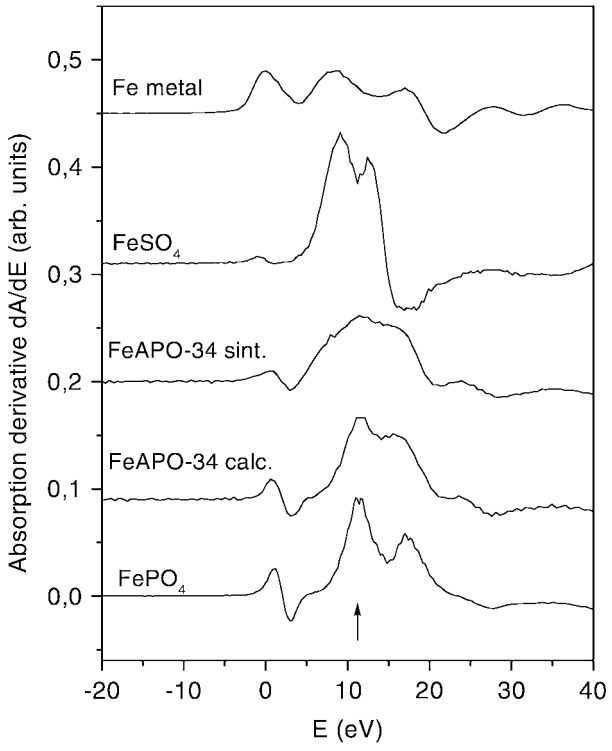

Fig. 2. Absorption derivative of the Fe K-edge profile of the as-synthesized and template-free FeAPO-34 and reference samples from Fig. 1. Vertical arrow is plotted at the energy position of Fe K-edge in $FePO_4$ sample.

the pre-edge peak is weaker, which indicates that only a fraction of iron cations in the sample occupy tetrahedral sites.

A change in the valence state of metal cations during calcination can be deduced from the energy shift of the Fe absorption edge. The precise energy position of the edge is taken at the edge inflection point, which can best be determined in the derivative spectrum (Fig. 2). A linear relation between the edge shift and the valence state has been established for the atoms with the same type of ligands [7–9]. From the spectra of the reference samples ($FeSO_4$ and $FePO_4$) with known iron oxidation states, we derive a Fe K-edge shift of about 3.0 eV per valence state. The Fe XANES spectra of the FeAPO-34 samples clearly indicate oxidation of iron cations during the calcination: the Fe K-edge in the template-free sample is shifted for 1.5 eV when compared to that in the as-synthesized sample. We obtained an average iron valence of about +2.5 in the as-synthesized and +3 in the template-free sample. The as-synthesized FeAPO-34 thus contains about the same amount of Fe(II) and Fe(III) cations, while during calcination all Fe(II) cations in the sample oxidize to Fe(III).

The Fe K-edge EXAFS spectra were quantitatively analyzed for the coordination number, distance, and Debye-Waller factor of the nearest coordination shells of neighbor atoms. The analysis was performed with the University of Washington UWXAFS package [10] using FEFF6 code [11] for ab initio calculation of scattering paths. The k^3 weighted Fourier transform magnitudes of Fe EXAFS spectra calculated in the k-range from 4.5 to 11.5 $Å^{-1}$ are shown in Fig. 3, together with the best fit EXAFS models.

In the case of the as-synthesized FeAPO-34 sample the fit of the first coordination shell shows that iron is coordinated on average

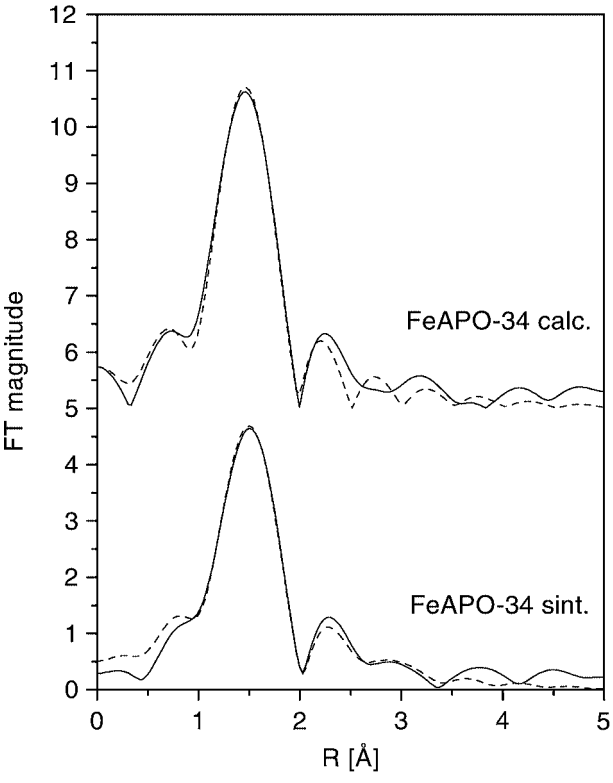

Fig. 3. Fourier transforms of k^3-weighted EXAFS spectra of the as-synthesized and template-free FeAPO-34 (experiment – solid line, EXAFS model – dotted line).

to five oxygen neighbors at 1.92 Å. This average Fe-O distance is consistent with Fe-O distances (1.91 Å) reported earlier for FeAPO-18 sample [12]. In addition, about 0.3 fluorine atoms on average are found at 2.18 Å. A presence of phosphorous atoms is

Table I. *Structural parameters of nearest coordination shells around iron in the as-synthesized and template-free FeAPO-34: neighbour atom, number of atoms (N), distance (R), and Debye-Waller factor (σ^2). Uncertainities of the last digit are given in the parentheses.*

Neighbour atom	N	R (Å)	σ^2 (Å^2)
as-synthesized (triclinic)			
O	4.9(5)	1.92(1)	0.007(2)
F	0.3(2)	2.18(1)	0.002(1)
P	0.6(4)	3.13(1)	0.002(1)
template-free (rhombohedral)			
O	3.8(5)	1.86(1)	0.004(1)

indicated in the second coordination shell at about 3.1 Å. Best fit parameters are listed in Table I.

This result supports isomorphous substitution of framework aluminum by iron in the as synthesized sample, as suggested by elemental analysis. Iron cations replace aluminum at all three inequivalent aluminum sites (tetrahedral and octahedral) in the framework of the triclinic $AlPO_4$-34 framework. In view of the limited sensitivity of the EXAFS signal it should be noted that fluorine neighbor atoms, expected on octahedral sites, cannot be reliably distinguished from oxygen atoms.

In the template-free sample we found four oxygen neighbors at a shorter distance of 1.86 Å in agreement with previously reported values for tetrahedrally coordinated Fe(III) cations [13]. This is in agreement with the rhombohedral symmetry of the template-free sample after the evacuation, when water molecules are removed from the pores. Taking into account also the XANES results we can conclude that in the template-free sample iron is incorporated into the tetrahedral framework sites in the form of Fe(III). The results are additionally supported by the IR spectroscopic analysis of adsorbed CO at 100 K, which gives clear evidence that the acidic Brønsted and redox centers are present in the template-free FeAPO-34 sample [3].

Abstract

Alumina supported gold catalyst prepared by spray reaction method (spr) provides gold particles with about 20 nm diameter. The gold particle size is larger than for conventional gold catalysts. However, the spr catalyst shows catalytic activity for NO-CO reaction. In the present paper, we discuss the local structures of spr-Au/Al_2O_3 catalyst by using Au L_3-edge XANES spectra. In order to investigate the local structures of Au-sites, multiple scattering approach to XANES analysis was applied. Calculated Au L_3-edge XANES spectrum for fcc-Au and Au_2O_3 were in good agreement with the observed spectra. XANES spectra for spr-Au/Al_2O_3 were characterized by 4 types of Au sites (bulk, interface, surface and peripheral). In this case, almost all gold sites (>90%) are bulk sites. Less than 10% of the gold particles are in interface sites. However, the experimental result for spr-Au/Al_2O_3 requires about 30% of gold oxide or hydroxide. Bulk of Al_2O_3 contains a certain number of gold nano-particles, which was incorporated in the Al_2O_3 support. In the interface area, gold oxide forms a few layers. This result was also supported by DV-Xα electronic structure calculations.

1. Introduction

Gold was known as inert material, before nanoscale gold particles dispersed on metal oxide supports were found to exhibit a remarkable catalytic activity and have become widely recognized for many reactions [1–4]. Catalytic properties of supported gold depend on the particle size of gold and the nature of the metal oxide supports. The various efforts have been focused on the preparation of gold catalysts by conventional methods (impregnation, co-precipitation, sol-gel, deposition-precipitation, etc.).

Using the advantage of spray technique [5–8], we have developed a new preparation method for multi-component composite systems and investigated various applications. We have applied the spray reaction method to supported metal catalysts (Ni/ZrO_2, Ru/Al_2O_3 and Ru/TiO_2) [5, 6]. We found high catalytic activities in multi-component nano-composite systems including Au. The spray reaction method (spr) provides Au nano-particles with diameters of 10–30 nm and catalytic activities. The Au particle size is larger than conventional Au catalysts (2–3 nm) which was expected as inert material in empirical assumptions.

In previous work, two kinds of supported Au catalysts, Au/TiO_2 and Au/Al_2O_3, were prepared by the spr method and we investigated their catalytic properties for CO oxidation over Au/TiO_2 and for NO-CO reaction over spr-Au/Al_2O_3, respectively [7, 8]. The synergy interactions between Au particles and supports will cause such catalytic activity. In this paper, we discuss the nano-structure based on Au L_3-edge XANES analysis of spr-Au/Al_2O_3 catalysts.

2. Theory

Multiple scattering approach to L_3-edge XANES formula [9] can be written as

$$\sigma = -\frac{2}{\pi}\mathrm{Im}\left[\frac{\rho_{3/2}(2)^2 e^{2i\delta_2^A}}{15\pi}(3\tau_{21,21} + 2\tau_{20,20}) + \frac{\rho_{3/2}(0)^2 e^{2i\delta_2^A}}{6\pi}\tau_{00,00} - \frac{2\sqrt{5}}{15\pi}\rho_{3/2}(2)\rho_{3/2}(0)e^{i(\delta_2^A+\delta_0^A)}\tau_{20,00}\right], \quad (1)$$

where A means absorption atom site and ρ means radial dipole integral. j_c is total angular momentum of initial core state,

$$\rho_{j_c}(l) = \int R_l(kr) r R_{j_c}(r) r^2 \, \mathrm{d}r. \quad (2)$$

In eq. (1), τ is a renormalized infinite order multiple scattering term and defined by

$$\tau_{L,L'} = [t^{-1}(1 - tG)^{-1}]^{\alpha\beta}_{L,L'}, \quad (3)$$

where t, G are angular momentum representation of t-matrix and Green's function. This matrix element describes a physical process where a photoelectron propagates from site β with angular momentum L' to site α and is scattered with angular momentum L. The t-matrix reflects the electronic structure, whereas G reflects the geometric structure. XANES analysis can give us useful information on electronic and geometric structures around the excited atom.

3. Experimental

The alumina-supported Au catalysts, Au/Al_2O_3 were prepared by a spray reaction (spr) and a conventional impregnation method (imp) [7, 8]. The catalytic activity was tested for NO-CO reaction with a 1 : 1 mixture gas after pre-treatment with O_2 and/or H_2. The O_2 pretreated catalyst showed remarkable activity (Fig. 1). We can expect the gold oxide and hydroxide to play important roles in this reaction.

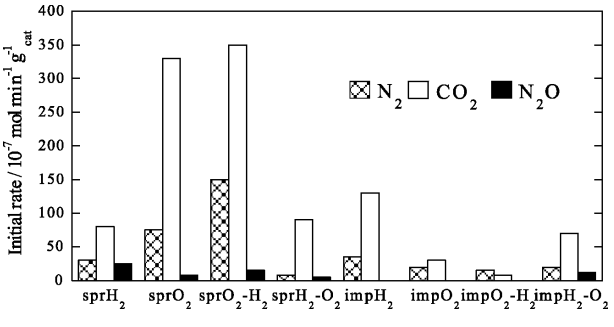

Fig. 1. Initial ratio of NO-CO reaction on Au/Al_2O_3 catalysts.

*e-mail: nagamatsu@restaff.chiba-u.jp
**e-mail: uematsu@faculty.chiba-u.jp

The properties of these catalysts were characterized by BET, XRD, XPS, EXAFS, XANES and other methods. BET surface areas were $22\,m^2/g_{cat}$ for spr catalyst and $97\,m^2/g_{cat}$ for imp catalyst, respectively. The crystallite sizes of Au (111) obtained by XRD analysis were 22 nm and 28 nm for spr catalyst and imp catalyst, respectively. The surface compositions of Au particles were obtained by XPS analysis of Au 4f spectra. The dispersion of Au was (0.29%) and (0.08%) for sprH$_2$ and impH$_2$, respectively. After H_2 pretreatment, Au particles were grown and surface areas decreased. However, sprH$_2$ kept large Au surface compositions.

There may be two interpretations; (1) The spr catalyst has a strong metal support interaction and hence sprH$_2$ keeps small particles during H_2 pretreatment, or (2) Au nano-particles are incorporated into the alumina support.

Figure 2.1 shows Au L_3-edge XANES spectra were measured at BL-10B of the Photon Factory (KEK) with a Si(311) channel cut monochromator (Proposal No. 2001G321). The supported Au particle catalysts are compose of bulk gold and gold oxide. Figure 2.2 shows linear combinations of observed Au foil and Au_2O_3 spectra. Comparison of white line intensity and peak structure at 11950 eV shows that there are 30% of Au_2O_3 in Au nano-particles on spr-Au/Al_2O_3.

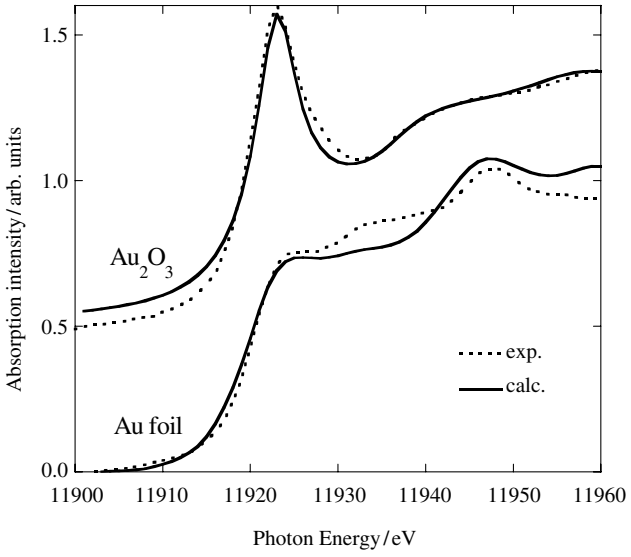

Fig. 3. Comparison of calculated Au L_3-edge XANES spectra for Au foil and Au_2O_3 and observed ones.

4. Result and discussion

First, we tried to calculate Au L_3-edge XANES spectra for fcc Au systems. The lattice constant is 0.408 nm, the nearest neighbor distance is 0.288 nm (12 atoms). The cluster includes 87 atoms and the radius is 0.7 nm. The electronic structure was obtained by FEFF8 [10] calculation [$(5d)^{9.6}$ $(6s)^{0.75}$ $(6p)^{0.65}$]. These values are close to relativistic tight-binding results [$(5d)^{9.6}$ $(6s)^{0.89}$ $(6p)^{0.51}$] [11]. In the case of Au_2O_3, the crystal structure is orthorhombic and Fdd2 [12]. There are two nonequivalent oxygen sites. The electronic structure was obtained by using FEFF8 code [10]. The results are Au [$(5d)^{9.29}$ $(6s)^{0.70}$ $(6p)^{0.61}$], O1 [$(2s)^{1.86}$ $(2p)^{4.40}$] and O2 [$(2s)^{1.87}$ $(2p)^{4.43}$]. The 5d-hole number is larger than that of bulk fcc gold, and two oxygen sites show similar electron occupation numbers. Figure 3 shows a comparison of experimental results and calculated Au L_3-edge for Au foil and Au_2O_3. Calculated results reproduced the observed one, except for the shoulder like structure around 11935 eV of Au foil.

The crystallite size of Au was calculated by Scherrer's equation from the half-width of Au (111). The XRD results show that the diameters of Au particles were 20–30 nm. The multiple scattering calculation uses atomic clusters with 0.5–1.0 nm diameter, and the catalyst particle size is large enough. Since less than 10% of the Au nano-particles are surface atoms, we can expect that the bulk like character is dominant. Furthermore, the metal-support interaction modifies the electronic structures of interface sites. We considered that 4 types of absorption sites (surface, bulk, peripheral, interface). The photoelectron mean free path is about 0.5–1.0 nm and thus these 4 sites are well independent. Observed XANES spectra were characterized by the linear combination of them.

A model structure was constructed with fcc Au and γ-alumina. The slight increase of statical disorder together with the general features of the XANES spectra allowed us to exclude structural changes from the fcc bulk metal structure to the icosahedral structure, even for clusters of 50 atoms [13]. The alumina support has γ-alumina structure, under these conditions.

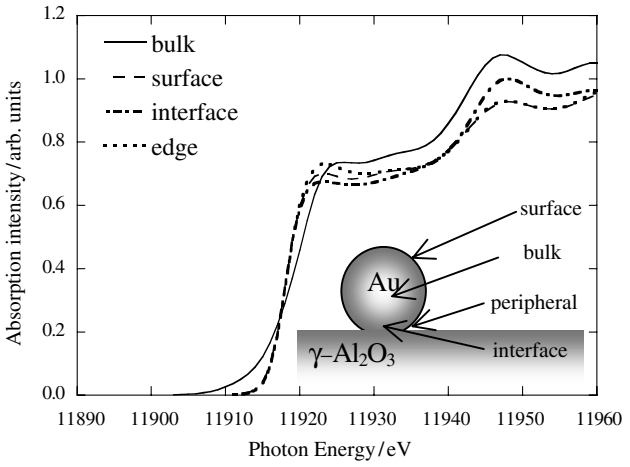

Fig. 4. Comparison of calculated Au L_3-edge XANES spectra for each atomic site.

4.1. *Au L_3-edge XANES spectra*

Figure 4 shows the calculated Au L_3-edge XANES spectra of each atomic site. For surface and peripheral sites, the peak height at 11950 eV is smaller than those for the bulk and the interface sites. These small coordination number sites show small peak heights at 11950 eV structure. On the other hand, the peak heights for Au L_3-edge XANES spectra of Au nano-particles were smaller than for bulk state [13] due to surface effect. There are two possibilities; Au nano-particles for spr-Au/Al_2O_3 are smaller than for other samples or gold oxide or hydroxide phase is rich.

4.2. *DV-Xα*

In order to estimate the effects of interface and surface depth, the local density of state for the different sites are calculated by DV-Xα method [14]. The atomic cluster models are very simple. They are flat surface and interface (fcc-Au (111) and O-terminated γ-alumina (111)). Figure 5 shows these results. For the surface and the interface site, these 5d local density of states (LDOS) were shifted to the high energy side. Interface effects modified the electronic structures a few layers from the interface. The peak shifts were larger than that for the surface.

5. Conclusion

Au/Al_2O_3 catalyst was prepared by spray reaction and impregnation method. We found that spr-Au/Al_2O_3 is more active than imp-Au/Al_2O_3 for NO-CO reaction. The activities depended on the pretreatment.

We tried to characterize the Au nano-particle on spr-Au/Al_2O_3 by using XANES spectra. 4 types of atomic sites characterize XANES spectra and multiple scattering theory allowed us to investigate this in more detail. In this case, bulk site is dominant. The other sites give similar spectra except for a peak structure at 11945 eV and white line structures. This result supports that simple analysis by the superposition of observed Au foil and Au_2O_3 (or $Au(OH)_3$). The spr-Au/Al_2O_3 contains 30–40% of gold oxide or hydroxide. They are distributed in the interface and the peripheral area. However, the surface area is less than 10% and the interface and the peripheral area are much smaller than the surface. It is too large to take the spr-Au/Al_2O_3 model

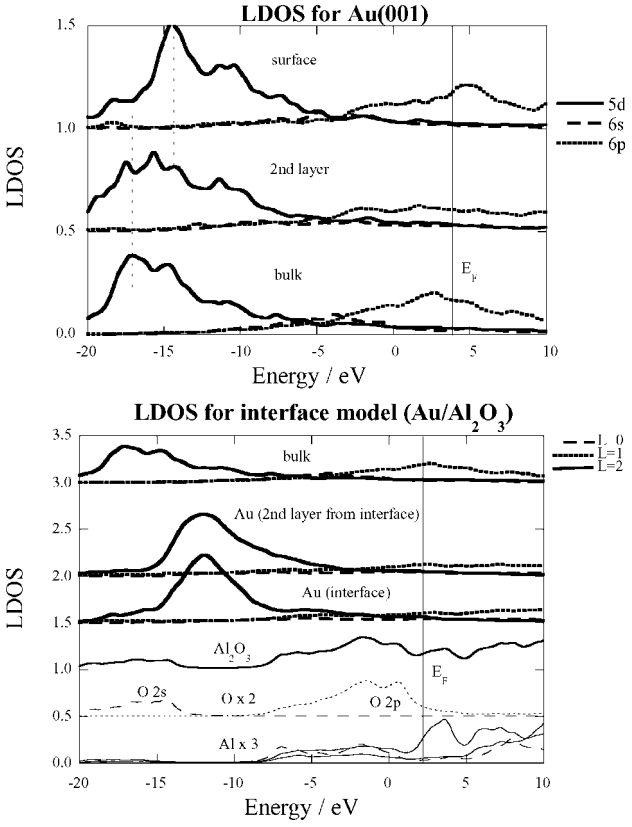

Fig. 5. Local density of states (LDOS) of surface and interface sites.

as 'gold particles on metal oxide'. There are Au nano-particles in the bulk of alumina support and a Au/Al_2O_3-interface are formed. However, Au particles with 20 nm diameter will supply only 10% of gold oxide. In order to investigate the effects of interface depth, we calculated LDOS for gold surface and gold/alumina interface. The LDOS structure of Au 5d is shifted by interface or surface effects. We found such peak shifts in 3–4 atomic layers from the interface. Therefore, it is a plausible model for spr-Au/Al_2O_3 that a part of Au nano-particles are distributed into the alumina.

Abstract

The structure of different carbon nanotubes grown without catalyst has been investigated and compared with graphite using XANES (X-ray Absorption Near Edge Structure) spectroscopy at the carbon K edge using surface-sensitive total electron yield technique. The surface and bonding properties (π^* and σ^* bands of sp^2 coordinate) are identified looking at the pre-edge features, while the structural characteristics of these materials have been identified looking at the structures in the multiple-scattering region of their XANES spectra.

1. Introduction

Since the discovery of carbon nanotubes [1], these hollow cylindrical molecules have been attracting great interest over the past decade, due to the fundamental scientific interest and their potential applications. Their one dimensional, hollow geometric structure and large surface area have made them manifest unique electronic [2] and mechanical [3] properties. Theoretical [4] and experimental [5, 6] studies have shown that single walled carbon nanotubes (SWNTs) can be metal, semiconductor or semimetal, depending on their chiral angle and diameter, which can be determined by Scanning Tunneling Spectroscopy (STM) [5–7] and other techniques [8]. Because of these properties, they can be used as electron field emission sources [9], scanning probes [10, 11], nanoelectronic devices [12], actuators [13], as well as selective molecular filter [14, 15], Li storage [16, 17], gas absorber [18–20], and so on. Experimental studies confirm that the electronic properties of SWNTs are very sensitive to the chemical environment and that a semiconducting tube can be converted to a metallic one through the exposure to air or oxygen [21]. Theoretical work [22] has also been carried out for the electronic properties of the oxidized carbon nanotubes and confirmed this sensitivity. However, recent high resolution photoemission spectroscopy study [23] of the interaction of molecular oxygen with single walled carbon nanotubes suggested that during the interaction, the surfactant contaminant caused by the extensive use of metal catalysts in the growth process and chemicals during tube purification and dispersion also play a major role, and these contamination traces are usually difficult to detect with conventional diagnostics, which limits the utilization of the intrinsic properties of the tubes. Therefore, a well-established technique [24, 25] to obtain carbon nanotubes without using metal catalysts is worth further investigation.

In this paper, we investigate the structure of carbon nanotubes grown without metal catalysts compared with graphite using XANES (X-ray Absorption Near Edge Structure) spectroscopy at the carbon K edge, and give a simple method for further treatment of the samples.

2. Experimental Details

Carbon nanotube samples were prepared [24, 25] by flowing amorphous carbon nano-sized (diameter 50 ± 20 nm) particles generated by laser-induced chemical vapor deposition [26] over a Joule-heated Si(100) substrate. The process was carried out in a controlled atmosphere reactor, with a residual base pressure of 10^{-6} atm. An inert gas carrier (Ar) was used to drive the nanoparticles from the reservoir in the deposition chamber with a controlled delivery rate. The nanoparticle flow accelerates through an expansion nozzle and then impacts on the substrate surface, placed along the expansion path. As the carrier gas flows by the substrate, the inertia of the particles causes them to travel across flow streamlines and collide with the surface. The high temperature of the substrate surface leads to self-assembled growth of the carbon nanotubes. The deposition parameters were Ar carrier flow = 300 sccm, $p = 0.04$ atm, substrate temperature is 950 °C, deposition time is 30 and 60 minutes for samples A and B, respectively.

As observed from SEM images, the carbon nanotubes grow directly from the particle surface, the mean tube diameter is 30–60 nm, very close to the particle size. A tube length of about 2–3 μm can be estimated. From Raman spectroscopy it can be deduced that the tubes consist mainly of bundles of several hundreds of SWNTs, and it can be estimated that a SWNT has a diameter ranging from 0.85 to 1.33 nm, with a mean of 1.1 nm.

The C K-edge near edge absorption spectroscopy measurements were performed at the Photoelectron Spectroscopy station of Beijing Synchrotron Radiation Facility of the Institute of High Energy Physics, Chinese Academy of Sciences. Samples were loaded in an ultrahigh vacuum chamber and maintained in a background pressure of $\sim 8 \times 10^{-10}$ Torr, reaching a pressure up to $\sim 1 \times 10^{-9}$ Torr during the data acquisition. The spectra were recorded using the total electron yield (TEY) mode, a surface-sensitive detection method with a typical probing depth of a few nm. The photon energies used to record the C K-edge absorption spectrum ranged from 275 to 320 eV, and the experimental resolution at these photon energies is about 0.3 eV.

3. Results and Discussions

In Fig. 1 we compare the C K-edge XANES spectra of carbon nanotube (sample A, prepared at the substrate temperature of 950 °C with deposition time for 30 minutes), graphite, pristine carbon nanopartical (CNP) and highly oriented polycrystalline graphite (HOPG). As labeled in the figure, we assign the common

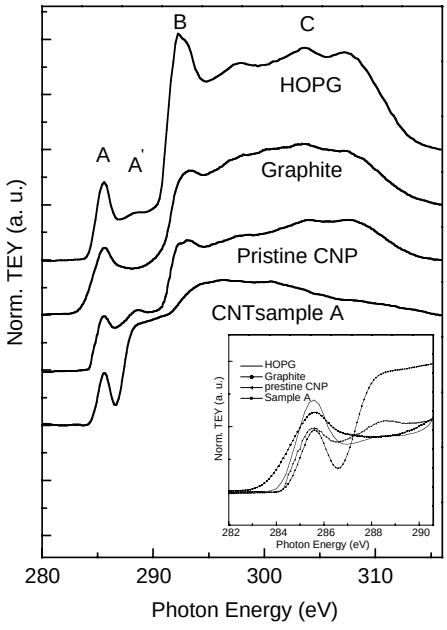

Fig. 1. C 1s x-ray absorption spectra in total electron yield of carbon nanotube sample A (with deposition time for 30 minutes), graphite, pristine carbon nanopartical (CNP) and highly oriented polycrystalline graphite (HOPG). Inset is the superposition of the four spectra in the energy range 282–290 eV.

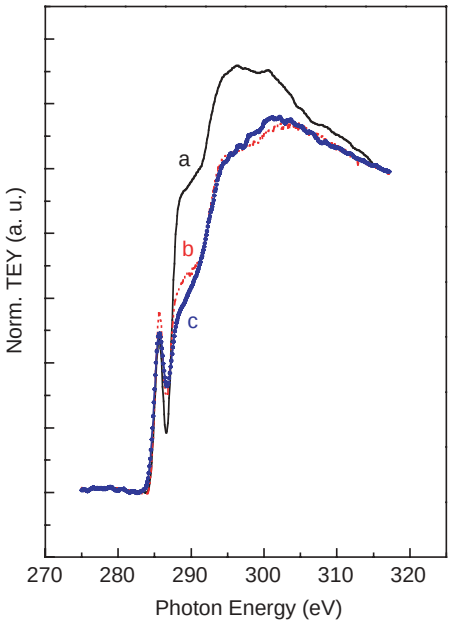

Fig. 2. Comparison of the C K-edge XANES spectra of sample A measured after different treating processes: (a) XANES of sample A as it was (solid line), (b) after annealing at 350 °C for 4 h (dashed line) and (c) a further Ar bombardment at 150 V and 20 mA for 1 h followed by an additional annealing of 1 h (dash-dotted line).

feature A at about 285.6 eV to the transition of C 1s to π^* unoccupied states, the feature B at about 292.5 eV to the 1s to π^* unoccupied states, and the quite broad and rich feature C to multiple scattering resonances. It can be observed that feature A, caused by C-C interaction (sp^2 bonding) of these four kinds of materials are similar in shape, despite a little broadening for the graphite. The intensity (all the spectra were normalized) of feature A of the nanotube sample, which is proportional to the DOS of the π^* bands, is almost the same as that of pristine carbon nanoparticle, but smaller than that of the graphite and HOPG, indicating that the nearest neighbor structure between the pristine carbon nanoparticles and the carbon nanotubes is nearly the same. However, significant differences can be noted for the feature between π^* and σ^* bands, labeled as A' in the figure. For HOPG, it was attributed to the free electron like interlayer states [27, 28], and it disappears for the amorphous graphite, confirming this argumentation. The more pronounced feature A' exhibites in the spectrum of amorphous pristine CNP, which has no free like electron states. Therefore this feature can be attributed to C-H σ^* like states, resulting from the hydrogenation of the pristine carbon nanoparticles [29]. The intensity of the feature is even more prominent for the nanotube sample, implying that more hydrogen atoms came out from the bulk of the pristine nanoparticles during the nanotube formation process to bond with the carbon atoms on the sidewall of the tubes. Since they are mostly on the surface, we can introduce a simple surface treating method to get pure nanotubes free from hydrogen atoms.

Fig. 2 shows C K-edge XANES spectra of sample A with and without surface treatment. (a) is the spectrum of the sample as it was, (b) is the one after annealing at 350 °C for 4 hrs in ultrahigh vacuum and (c) is the one after further modest Ar bombardment at 150 V and 20 mA for 1 h followed by annealing at 350 °C for 1 h. It can be noticed that feature A has no change after the treatment, implying that the short range structure is not affected during the treatment process, while the intensity of feature A′ decreases going from (a) to (c). This behavior immediately indicates that the surface is gradually cleaned from the hydrogen.

The C K-edge XANES spectrum of sample B (prepared at the substrate temperature of 950 °C with deposition time of 60 minutes after modest Ar ion bombardment for 1.2 h at 150 V and 20 mA beam current and further 1.5 h of annealing in ultrahigh vacuum chamber at 350 °C) is shown in Fig. 3 and compared with the spectrum of graphite. There is no evidence of bonding C-H σ^* structure in the spectrum of B, suggesting that the longer time of deposition during the formation of nanotubes is useful

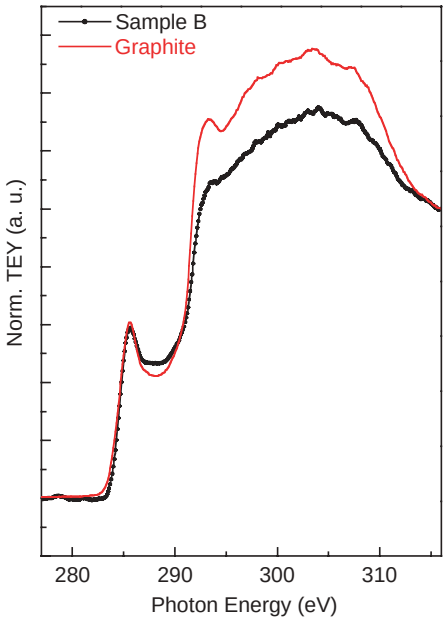

Fig. 3. C 1s XANES spectra in total electron yield of sample B (with deposition time for 60 minutes) and graphite. The XANES spectrum of sample B was measured following Ar ion bombardment for 1.2 h at 150 V and 20 mA beam current after 1.5 h of annealing in ultrahigh vacuum chamber at 350 °C.

for surface treatment of cleaning the tubes from hydrogen. It is worth noticing that XANES of sample B does not exhibit a complex pre-edge structure, which addresses also a reasonable ordering of the carbon matrix. However, a difference between the spectra of sample B and graphite can be recognized looking at the 289–320 eV region: the transition from 1s to σ^* like states is less intense and fairly broadened in the carbon nanotube of sample B. This behavior implies that the "long- or medium-range" atomic order deviates from the graphite one (e.g. disorder and/or distortion effects). Actually, in a nanotube more C atoms are surface ones, experiencing an anisotropic geometry, where a C atom is bonded to inner and outer atoms simultaneously. The anisotropic environment of the surface C atoms can certainly be one of the causes of the distortion of the original trigonal structure. This mechanism, in turn, increases the number of distinct photoelectron scattering paths in a nanotube, yielding a broadening of the XANES spectrum: B feature disappears and C broadens. These effects may be due to a random phase decoherence among each set of closely similar multiple scattering paths and the variation in the threshold E_0 in the absorption coefficient [30]. However, also the compositional disorder, i.e. the presence of residual amorphous carbon, leads to the smearing of near-edge features.

4. Conclusions

In summary, we investigated the carbon 1s XANES spectra of carbon nanotubes grown without catalyst, which are prepared by spraying the amorphous nanoparticals onto a silicon substrate at high temperature for different deposition time. The high temperature causes the transformation of amorphous hydrogenated nanoparticles into nanotubes and leaves some pristine particles (sample A). The data at the C K edge in both graphite and nanotubes show that structural and bonding configurations can be recognized looking at the characteristic pre-edge features but also the large differences in the multiple-scattering region can be investigated to better understand topology and degree of order of these materials. The achieved results are also consistent with the expected chemical environment of a carbon nanotube. It was found that a longer deposition time is preferable for obtaining pure tubes free from hydrogen with further surface treatment (sample B).

Abstract

Iron-containing mesoporous molecular sieves (Fe-MCM-41) synthesized by both direct hydrothermal (DHT) and template-ion exchange (TIE) methods have been used as catalysts for the liquid phase oxidation of bulky organic compounds, *i.e.*, anthracene and *trans*-stilbene, with diluted hydrogen peroxide. In the case of Fe-MCM-41-DHT, analysis of Fe K-edge XAFS revealed that isolated and tetrahedrally coordinated Fe species exist in the framework of MCM-41. On the other hand, the Fe-MCM-41-TIE mainly contains small iron oxide clusters, which have octahedrally coordinated Fe species. The tetrahedrally coordinated Fe species in Fe-MCM-41-DHT showed both high activity and efficiency of hydrogen peroxide in the liquid phase oxidations, whereas the iron oxide clusters in the Fe-MCM-41-TIE showed low activity. Moreover, the iron cations incorporated inside the framework of MCM-41 do not leach during the reaction, whereas the small iron oxide clusters leach out into the liquid phase and do not contribute to the catalytic reaction.

1. Introduction

Metal ion-containing mesoporous silicates such as MCM-41 and MCM-48, which possess uniform nano-order mesopores and high concentration of isolated active sites, has attracted much attention as a new type of oxidation catalyst, especially for liquid phase oxidations of bulky organic compounds since a facile diffusion of relatively large molecules can be expected. Many studies have been done for synthesizing and characterizing metal ion-containing MCM-41. Some of these materials, *e.g.*, Ti-MCM-41 and V-MCM-41 showed unique catalytic properties for the reactions of a wide variety of organic substrates such as phenols, alkenes, naphthalenes, alcohols, and thioethers, etc. [1–5].

In order to introduce active metal centers to MCM-41, several kinds of methods have been proposed. The most popular method is the direct hydrothermal (DHT) method. The conventional impregnation, grafting [6] and the template ion exchange (TIE) methods [5] have been also reported. It can be expected that the metal cations with different environments in mesoporous material would result in various catalytic properties. Indeed, Ti-MCM-41 prepared by surface grafting method is more active than that prepared by the DHT method for the epoxidation of cyclohexene with TBHP (*tert*-butyl hydro peroxide) [7]. Vanadium species in V-MCM-41 prepared by the TIE method are dispersed on the surface of channel, preferring the oxidative dehydrogenation of propane, whereas vanadium sites prepared by the DHT method are incorporated in the framework of MCM-41, capable of oxidizing propane to acrolein with moderate selectivity [8]. On the other hand, iron functions as catalytic center in monooxygenase enzymes such as cytochrome P-450 and many selective oxidation systems containing iron, *i.e.*, Gif system and Fenton's reagent have also been developed. Iron is also the active center in many heterogeneous catalysts such as iron-containing microporous amorphous silica synthesized by a sol-gel method, Fe-ZSM-5, Fe-containing Y zeolite with Pd and $FePO_4$, for the selective oxidation of benzene and alkanes.

In the present work, we investigated the structure of iron species in Fe-MCM-41 prepared by two methods, *i.e.*, direct hydrothermal (DHT) and template-ion exchange (TIE) methods by means of Fe K-edge XANES/EXAFS. Iron cations were added into the synthesis gel before hydrothermal synthesis in the former method, while Fe^{3+} ions in the ethanol solution were exchanged with the template cations contained in the as-synthesized MCM-41 in the latter method. The catalytic performances of Fe-MCM-41 thus prepared were tested in the oxidation of both anthracene and stilbenes with H_2O_2, and the effects of the coordination environments of iron species on the catalytic performance are discussed.

2. Experimental

Fe-MCM-41 catalysts were prepared by both hydrothermal synthesis (DHT) and template ion exchanging (TIE) methods according to the previous report [5]. Sodium silicate, iron nitrate and hexadecyltrimethylammonium bromide were used as the sources of Si, Fe and template, respectively. The samples were finally calcined at 823 K for 6 h in a flow of dry air. The mesoporous structure of Fe-MCM-41 was confirmed by XRD and N_2 adsorption. FeO_x/Cab-O-Sil catalyst was also prepared by impregnation method as a reference. Cab-O-Sil is SiO_2, which has no pore structure.

The Fe K-edge XAFS spectra of samples were measured in a fluorescence mode at room temperature at BL7C of KEK-PF with a Si(111) channel cut monochrometor. Normalization of XANES and data reduction on EXAFS were carried out as described elsewhere [9]. Data treatments were carried out with the FACOM M1800 computer system of the DATA Processing Center of Kyoto University.

The liquid phase oxidations were performed using a batch type reactor. Products were identified by GC-MS and quantified by GC.

3. Results and discussion

The XRD patterns showed that all the Fe-MCM-41 with different iron contents had hexagonal regularity of mesopore and their pore diameters determined by N_2 adsorption were around 2.5–3.0 nm.

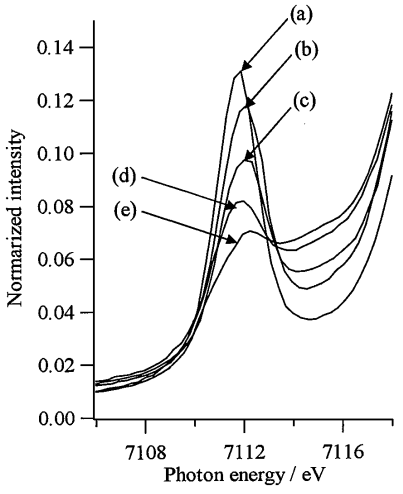

Fig. 2. Pre-edge region of Fe K-edge XANES spectra of Fe-MCM-41 and reference compounds. (a) Ferrisilicate (Si/Fe = 48), (b) Fe-MCM-41-DHT (Si/Fe = 105), (c) Fe-MCM-41-TIE (Si/Fe = 75), (d) FeOx/Cab-O-Sil (Si/Fe = 96), (e) α-Fe_2O_3. The numbers in parentheses are the Si/Fe atomic ratios.

Figure 1 shows the Fe K-edge XANES spectra of Fe-MCM-41 prepared by both DHT and TIE methods together with the reference compounds, ferrisilicate with MFI structure and α-Fe_2O_3. Iron atoms in ferrisilicate are mainly in tetrahedral coordination, and those in α-Fe_2O_3 are in octahedral coordination. A characteristic feature of these XANES spectra can be seen in the pre-edge peak at ca. 7112 eV, attributed to the 1s-3p dipolar forbidden transition. The 1s-3d pre-edge peak of Fe K-edge XANES spectra is sensitive to the electronic and geometric structure of the iron site. Principally, this forbidden transition gains additional intensity when the iron is in a noncentral symmetric environment or through mixing of 3d and 4p orbitals caused by the breakdown of inversion symmetry due to the structure distortion. Since the local symmetry around the iron is lowered from octahedral to tetrahedral coordination, the intensity of this peak tends to increase, *i.e.*, $I_{\text{tetrahedral}} > I_{\text{square pyramidal}} > I_{\text{octahedral}}$ [10] (Figure 2). Ferrisilicate which possessed regular tetrahedral coordination structure showed the largest intensity, whereas α-Fe_2O_3 with distorted octahedral coordination structure

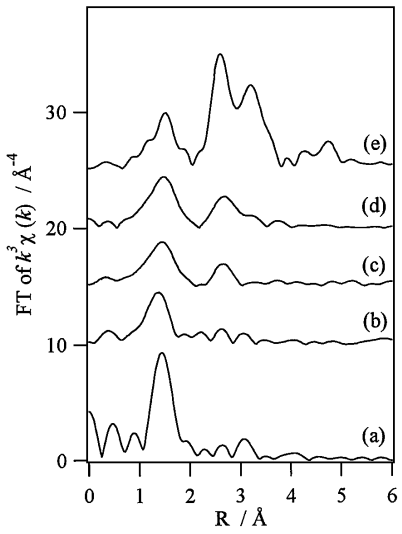

Fig. 3. Fourier transforms of k^3-weighted Fe K-edge EXAFS of Fe-MCM-41 and reference compounds. (a) Ferrisilicate (Si/Fe = 48), (b) Fe-MCM-41-DHT (Si/Fe = 105), (c) Fe-MCM-41-TIE (Si/Fe = 75), (d) FeOx/Cab-O-Sil (Si/Fe = 96), (e) α-Fe_2O_3. The numbers in parentheses are the Si/Fe atomic ratios.

showed very weak and broad absorption. The pre-peak intensity of the Fe-MCM-41-DHT was slightly lower than that of ferrisilicate. In the case of Fe-MCM-41-DHT, the oscillation by XANES which appears at high energy region (above ca. 15 eV from the absorption edge) is almost similar to that of ferrisilicate. These results indicate that the iron species in Fe-MCM-41-DHT exist in a tetrahedrally coordinated environment. The lower intensity of pre-edge peak may due to the difference in the framework structure of MCM-41 and that of the silicates zeolite. The wall of MCM-41 is essentially amorphous, while silicate zeolite is crystalline. Thus, the Si-O-Fe bonds in the amorphous framework of Fe-MCM-41-DHT may be connected with more relaxing angles than those in ferrisilicate. The pre-edge peak intensity of the Fe-MCM-41-TIE was lower than that of Fe-MCM-41-DHT, whereas higher than that of FeO_x/Cab-O-Sil.

Figure 3 shows the Fourier transforms (FTs) of k^3-weighted EXAFS spectra of Fe-MCM-41 FeOx/Cab-O-Sil, ferrisilicate and α-Fe_2O_3 (Phase shift was not corrected). The peak at 1.5 Å can be assigned to the contribution of the Fe-O shell. It should be noted that no considerable Fe-Fe shell, which is detected in the FTs for Fe-MCM-41-TIE, FeOx/Cab-O-Sil and α-Fe_2O_3 at around 2.8 Å, was observed for the Fe-MCM-41-DHT and ferrisilicate, suggesting that iron species dispersed as a monomer in the Fe-MCM-41-DHT and ferrisilicate. The curve-fitting analysis

of Fe K-edge EXAFS are summarized in Table I. As for the Fe-MCM-41-DHT, the incorporation of the majority of Fe^{3+} into the framework of MCM-41 with a tetrahedral coordination structure is inferred, since both the Fe-O distance (1.85 Å) and the coordination number (4.2) of Fe-MCM-41 were similar to those of the ferrisilicate with MFI structure. On the other hand, two kinds of Fe-O shells with the lengths of 1.85 and 1.99 Å and the coordination numbers of 3.2 and 3.2, respectively, were obtained in Fe-MCM-41-TIE. The iron in α-Fe_2O_3 possessed two kinds of Fe-O shells with the lengths of 1.91 and 2.04 Å and the coordination numbers of 3.0 and 2.9, respectively. The coordination number of Fe-Fe shell in Fe-MCM-41-TIE (2.1) was much smaller than that in α-Fe_2O_3 (7.9) [11]. These results suggest that small size iron oxide clusters exist in the channel of MCM-41.

The Fe-MCM-41 catalyzed efficiently the liquid phase oxidation of bulky organic compounds such as anthracene and *trans*-stilbene with H_2O_2. The activities of Fe-MCM-41 for the oxidations of anthracene and *trans*-stilbene were higher than those of FeO_x/Cab-O-Sil, which was prepared by a conventional impregnation, and ferrisilicate zeolite with MFI structure. Table II shows the results obtained with several catalysts in the epoxidation of *trans*-stilbene. *trans*-Stilbene oxide and benzaldehyde were formed in the oxidation of *trans*-stilbene. The Fe-MCM-41-DHT showed much higher conversion of *trans*-stilbene and slightly better selectivity to *trans*-stilbene oxide than the Fe-MCM-41-TIE at the same loading amount of iron. FeO_x/Cab-O-Sil showed not only lower conversion of *trans*-stilbene but also worse selectivity to *trans*-stilbene oxide. The low activity of ferrisilicate can be ascribed to its small pore size (0.51 nm × 0.54 nm) and narrow three-dimensional pore structure. The Fe-MCM-41-TIE showed slightly higher activity than FeO_x/Cab-O-Sil, while the surface area of the Fe-MCM-41-TIE is much higher than that of FeO_x/Cab-O-Sil. This indicates that the surface area of the catalyst is not important factor for the catalytic activity.

From these results mentioned above, we suggest that the isolated and tetrahedrally coordinated iron sites in the framework of MCM-41 over the Fe-MCM-41-DHT are responsible for the oxidations of both anthracene and *trans*-stilbene, whereas the small iron oxide clusters formed over the Fe-MCM-41-TIE are not effective. The Fe-MCM-41-DHT showed no leaching of iron species during the reaction. On the contrary, a large amount of iron cation in Fe-MCM-41-TIE leached out into the liquid phase and do not contribute to the catalytic reaction. Thus, the iron cations tetrahedrally coordinated and incorporated inside the framework of MCM-41 is stable towards leaching, whereas the small iron oxide clusters, which have octahedrally coordinated iron species, leach out.

Acknowledgment

The X-ray absorption measurements were performed under the approval of the Photon Factory (KEK-PF) Program Advisory Committee (Proposal No. 2002G097). The authors thank Dr. H. Yoshida (Nagoya University, Japan) for kind help in the measurements of the X-ray absorption spectra.

Abstract

In-situ Ag K-edge XAFS measurements have been carried out for fully Ag^+-exchanged zeolite 4A (Ag-4A) during continuous dehydration under vacuum in the temperature range between room temperature (r.t.) and 300 °C. The structural parameters (distance r, coordination number N and root mean square displacement σ) were derived by a three-shell (short and long Ag-O contacts and Ag-Ag contact) by curve-fitting analysis. The systematic dehydration effect on the structural change in the Ag clusters is studied by *in-situ* XAFS experiments. Ag^+ ions are reduced by removal of water molecules due to evacuation for 20 minutes at r.t. The formation of Ag clusters is suggested by full evacuation at r.t. With increasing dehydration temperature, N of Ag around a central Ag increases. For the Ag cluster formed at 300 °C the Ag-Ag contact distance is evaluated to be 2.79 ± 0.02 Å and N of Ag around a central Ag is 4.1 ± 0.3. The cluster formation is supported by XANES spectra which show that the Ag^+ ions in the fully hydrated Ag-4A change to Ag atoms in the dehydrated Ag-4A at 300 °C under vacuum.

1. Introduction

In the fully Ag^+-exchanged 4A (Ag-4A) the $12Ag^+$ ions are present inside zeolite cages, as needed to balance the anionic charge of the zeolite framework. The white color of the hydrated Ag-4A changes through yellow to brown by heating up to 400 °C under vacuum [1]. These changes in color by heating under vacuum are related to the formation of silver clusters due to the interaction of the silver atoms produced by reduction of Ag^+ ions during dehydration with the other silver atoms or Ag^+ ions [2]. X-ray diffraction experiments of the zeolite single crystal [3, 4] and EXAFS measurements on powder [5, 6] suggest the presence of the silver cluster in the zeolite cage. Recently it was found that the color of the white Ag-4A changes into pale yellow by full dehydration under vacuum at 27 °C for 7 hours [7]. It is interesting to study the changes in the local structure of the silver cluster for the same Ag-4A zeolite by heating at different temperatures under continuous evacuation. For this purpose an *in-situ* XAFS measurement was carried out using a special chamber [8] where the evacuation and heating are operated simultaneously. In this paper, we report results of *in-situ* EXAFS measurements on the Ag K-edge for the fully Ag^+-exchanged Ag-4A powder sample by continuous evacuation at room temperature (r.t.) and heating under vacuum, respectively.

2. Experimental and data analyses

Fully Ag^+-exchanged 4A (Ag-4A) powder samples were prepared by immersing Na-4A ($Na_{12}[(AlO_2)_{12}(SiO_2)_{12}]27.5H_2O$) zeolite in an aqueous $AgNO_3$ solution at 25 °C. The details of the sample preparation are described elsewhere [4, 6]. The white Ag-4A powder (fully hydrated) sample was packed in the cell. The cell was mounted in the *in-situ* XAFS measurement chamber. By holding the sample in the chamber XAFS measurements were carried out (1) under continuous evacuation at r.t. and (2) heating up to 300 °C under vacuum ($\sim 10^{-3}$ Pa) [8]. Ag K-edge X-ray absorption spectra were obtained at beamline BL-10B of the Photon Factory in KEK. A Si(311) channel-cut monochrometer was used, and energy and current of the storage ring were 3.0 GeV and 250∼400 mA, respectively. EXAFS spectra were recorded in transmission mode using ionization chamber detectors. The EXAFS interference function extracted from the absorption spectra was Fourier transformed by XANADU code [9]. In order to obtain the structural parameters, the EXAFS function was fitted by a non-linear least-squares method. The non-linear least square fitting method was applied to the experimental data as described below:

$$\chi(k) = \sum_j \frac{S_0^2 N_j}{k r_j^2} f_j(k, r_j) \exp(-2\sigma_j^2 k^2) \times \exp(-2r_j/\lambda(k)) \sin[2kr_j + \varphi_j(k)]$$

where r, N and σ are interatomic distance, coordination number and root mean square displacement, respectively, for each atomic pair. Phase shift $\varphi(k)$, backscattering amplitude $f(k, r)$ and electron mean free path $\lambda(k)$ are obtained from FEFF6.01 calculation [10]. The k-range for the curve-fitting method was $3.0 \sim 11.5$ Å^{-1}. Ag foil and $AgNO_3$ were used as standard samples for energy correction. In the present analyses, the multiple-scattering effect was neglected.

3. Results

Figure 1(a) shows the changes of $k\chi(k)$ EXAFS spectra obtained for Ag-4A during continuous evacuation from 0 to 20 minutes at r.t. In these experiments the sample was evacuated from 0.1 MPa to $\sim 10^{-3}$ Pa and the EXAFS spectra were recorded continuously for 2 minutes per one scan. It is found that at the evacuation for 20 minutes a few water molecules are removed from the unit zeolite cage [7]. The EXAFS spectra at the evacuation for 20 minutes were the same as those at the fully dehydrated condition after 7 hours. As seen in Fig. 1(a) $k\chi(k)$ profiles change clearly with increasing evacuation time. Especially the structure around $1 \sim 4$ Å^{-1} is changing as indicated by arrows in Fig. 1(a).

The corresponding change of Fourier transforms, |FT(r)|, is shown in Fig. 1(b). With increasing evacuation time, the intensity of the first peak (around 2 Å) decreases, while the intensity of the second peak (around 3 Å) increases considerably. The first peak corresponds to short Ag-O contact and the second peak to long Ag-O contact and Ag-Ag contact, respectively [5, 6]. As the evacuation proceeds, the positions of the first peak and the second peak shift to smaller r, which indicates that the contact

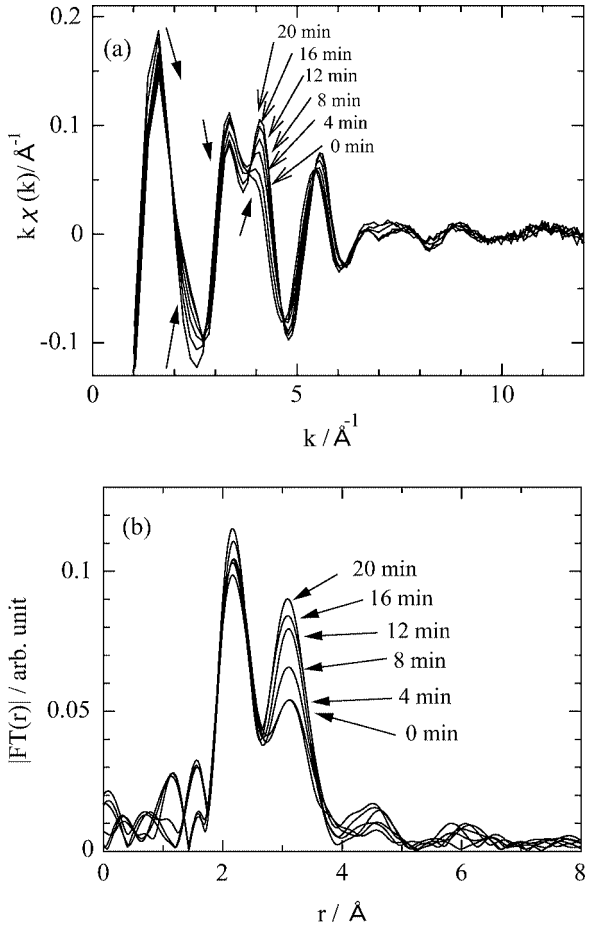

Fig. 1. Change of EXAFS $k\chi(k)$ spectra (a) and corresponding Fourier transform (b) for Ag-4A during evacuation as room temperature. The thick arrows indicate the change of evacuating time. The time interval for each spectrum is 4 minutes.

distances become short with increasing dehydration at r.t. It is interesting to point out that these changes in the contact distances for evacuation at r.t. are in qualitative agreement with those obtained for evacuation at high temperatures [6]. However, further analyses were not tried for the results obtained by 2 minutes per scan, because the quality of data was not high enough.

Figure 2(a) shows the changes of $k\chi(k)$ EXAFS spectra of the same Ag-4A sample obtained by scanning for more than 20 minutes. All spectra were measured at room temperature. The quality of data is good for further analyses. The curve represented by "A. 0.1 MPa" corresponds to the condition at 0.1 MPa and r.t. (Before evacuation and fully hydrated), "B. full evac." to full evacuation at r.t., "C. after 100 °C" to heating up to 100 °C under vacuum, "D. after 200 °C" to heating up to 200 °C under vacuum and "E. after 300 °C" to heating up to 300 °C under vacuum. In the $k\chi(k)$ curve for the fully hydrated Ag-4A (sample A) there appear a peak around 3.2 Å^{-1} and a shoulder around 4 Å^{-1}. After full evacuation at r.t. (sample B) the shoulder disappears and two peaks appear around 3 and 4 Å^{-1}. By further heating under vacuum up to 300 °C (samples C, D and E) the dip between two peaks becomes deeper.

Figure 2(b) shows the corresponding changes of $|\mathrm{FT}(r)|$. Two peaks appear around 2 Å and 3 Å. From A to E the intensities of the second peak (around 3 Å) increase, then the ratio of the intensity of the second peak to that of the first peak becomes large. The positions of the first and second peaks shift to smaller r from A to E.

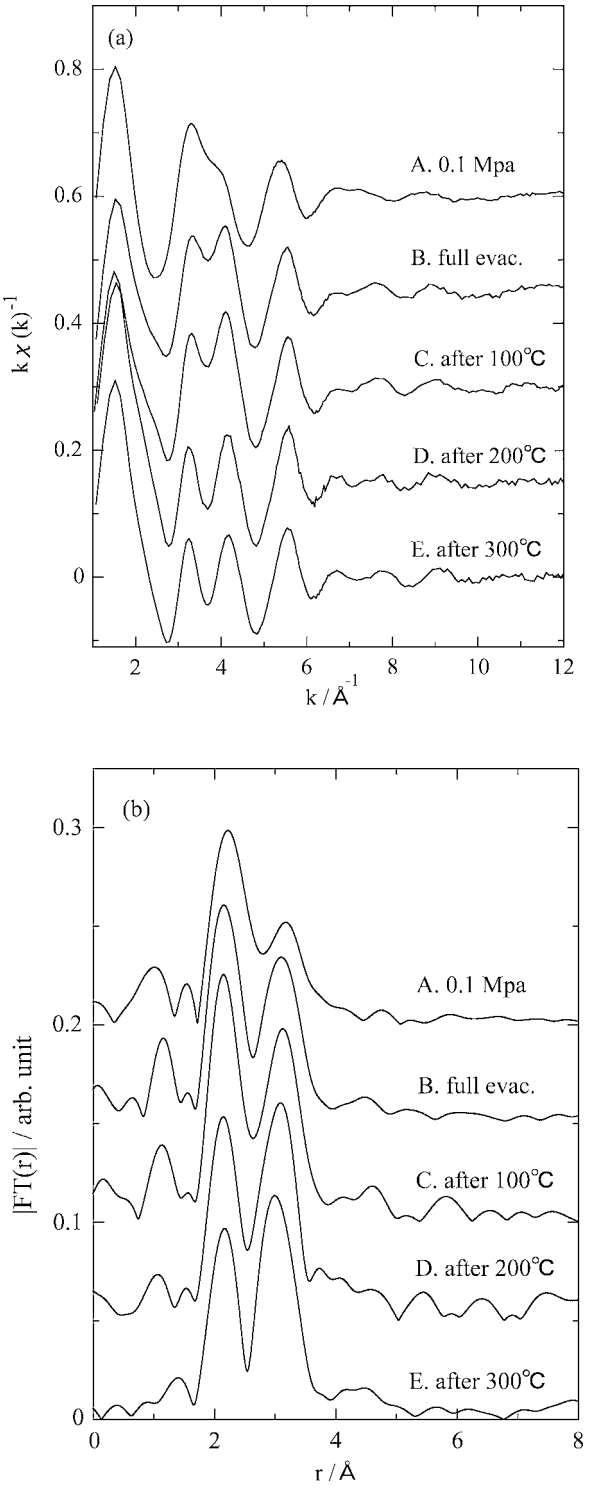

Fig. 2. Ag K-edge EXAFS $k\chi(k)$ spectra (a) and corresponding Fourier transform (b) for Ag-4A measured at r.t. A. measured at r.t. 0.1 MPa, B. measured at r.t. full evacuated, C. measured at r.t. after heating to 100 °C in vacuum, D. heating to 200 °C and E. heating to 300 °C.

4. Discussion

In order to derive the structural parameters, three-shell curve fitting analyses were carried out in the same way as in the previous work [6]: The three-shell model consists of two Ag-O contacts (short and long contact distances) and one Ag-Ag contact. An example of the fitting quality is shown in Fig. 3 for sample E. The fitting is fairly good. When the fitting was made by using the Ag-Si distance instead of the long Ag-O distance, the fitting quality was quite bad. The structural parameters obtained from the present

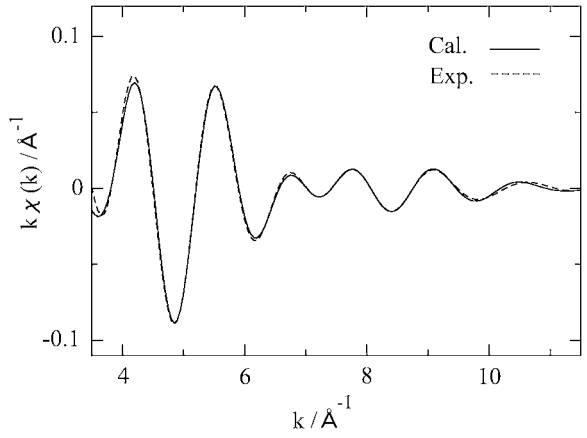

Fig. 3. Comparison for the Ag-K-edge EXAFS $k\chi(k)$ between experimental curve and calculated curve obtained by curve-fitting for the sample B.

Table I. *Structural parameters (r: contact distance, N: coordination number and σ: root mean square displacement) for Ag-4A.*

	Short Ag-O			Long Ag-O			Ag-Ag		
	r/Å	*N*	*σ*/Å	*r*/Å	*N*	*σ*/Å	*r*/Å	*N*	*σ*/Å
A	2.38	5.7	0.15	2.86	2.0	0.13	2.88	2.7	0.14
B	2.28	3.2	0.12	2.88	2.5	0.13	2.83	3.4	0.14
C	2.27	2.8	0.11	2.88	3.0	0.13	2.83	3.5	0.14
D	2.27	1.8	0.09	2.90	4.0	0.13	2.81	3.6	0.14
E	2.27	1.6	0.08	2.93	3.7	0.13	2.79	4.1	0.14

EXAFS spectra are summarized in Table I. Figure 4 shows the contribution from each shell in *r*-space (Fourier transform) as an example for sample E.

There are Ag^+ ions in the fully hydrated Ag-4A at 0.1 MPa and r.t. The short Ag-O distance decreases from 2.38 ± 0.02 Å (sample A) to 2.28 ± 0.02 Å (sample B) due to evacuation at r.t. The coordination number (*N*) of O around a central Ag^+ decreases from 5.7 ± 0.5 (sample A) to 3.2 ± 0.5 (sample B). In the fully hydrated Ag-4A there are water molecules in the vicinity of the Ag^+ ions. In common state, Ag^+ complex has tetrahedrally coordinated structure, for example, $Ag(H_2O)_4{}^+$ in aqueous solution [11], and the interatomic distance is reported to about 2.35–42 Å. On the other hand, in the distorted state, 5 or 6 coordinated complexes are reported [12] and the Ag^+ complex is expected to be distorted in the zeolite cavity. The large root mean square displacement *σ* of 0.15 shows the existence of distortion around the central Ag^+ ion and the coordination number of 5.7 includes the contributions from Ag-(OH_2) and Ag-O (zeolite cage). Therefore the interatomic distance of 2.38 Å is an average value for the widely distributed Ag-O pairs. By evacuation the water molecules are removed, then *N* of O around a central Ag^+ decreases. Since the Ag^+ ions in sample A have contact with oxygens in the zeolite framework and of water molecules, the interaction between the Ag^+ ion and the framework oxygen becomes strong by removal of water molecules, which results in a reduction of the short Ag-O contact distance. For the Ag-Ag contact the contact distance decreases from 2.88 ± 0.02 Å (sample A) to 2.83 ± 0.02 Å (sample B) and *N* of Ag^+ around a central Ag^+ increases from 2.7 ± 0.2 (sample A) to 3.4 ± 0.2 (sample B). The slight reduction of the distance and slight increment of *N* for the Ag-Ag contact by dehydration suggest that the Ag^+ ions are partly reduced to Ag atom by the removal of water molecules, since the Coulomb repulsion becomes weak when one of the Ag^+ ions is reduced to Ag atom between Ag^+ ions. For the long Ag-O contact the contact distance increases from 2.86 ± 0.02 Å (sample A) to 2.88 ± 0.02 Å (sample B) and *N* of O around a central Ag^+ increases from 2.0 ± 0.2 (sample A) to 2.5 ± 0.2 (sample B). It is noted that the appearance of Ag atoms produced by removal of water molecules makes the long Ag-O contact distance slightly longer due to an increase of the repulsive interaction. It is interesting to note that the partial reduction of the Ag^+ ions occur due to the removal of water molecules from the zeolite cages by full dehydration under vacuum at r.t., which results in the coloration of white Ag-4A at 27 °C [7] and the complete removal of water molecules has been confirmed by IR study of Ag-4A [8].

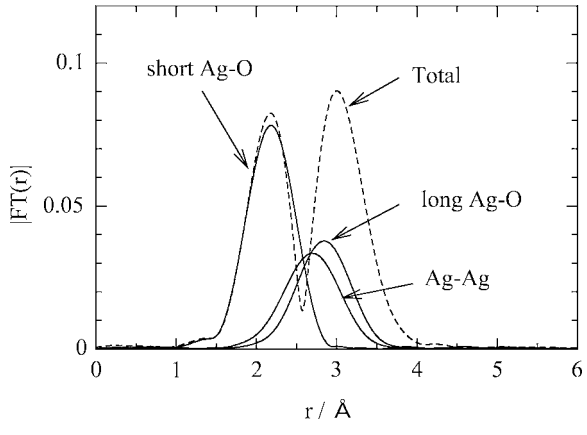

Fig. 4. Contributions from each shell (short Ag-O, long Ag-O, Ag-Ag, solid lines) in *r*-space (FT) for sample E. Dashed line is the FT from the total contribution.

For sample C to E the effect of the dehydration on the Ag-4A sample at high temperatures between 100 and 300 °C under vacuum is discussed. The short Ag-O contact distance remains at 2.27 ± 0.02 Å independent of temperature, while the *N* of O around a central Ag decreases from 2.8 ± 0.3 at 100 °C to 1.6 ± 0.3 at 300 °C, which arises from the increase of dehydration with increasing temperature under vacuum. This suggests that the reduction of the Ag^+ ion in the short Ag-O contact does not proceed at higher temperature. It is noted that, the distance of 2.27 Å for Ag-O is close to the value for linear or two-fold complex. The Ag-Ag contact distance decreases from 2.83 ± 0.02 Å at 100 °C to 2.79 ± 0.02 Å at 300 °C and the *N* of Ag around a central Ag increases from 3.5 ± 0.3 at 100 °C to 4.1 ± 0.3 at 300 °C. With increasing temperature the reduction of the Ag^+ ions proceed and the diffusion of the Ag atoms or Ag^+ ions is accelerated, which results in a decrease in the bond distance due to weaker repulsive interaction between Ag^+ ions and Ag atoms and the increase in the coordination number. For the long Ag-O contact the distance increases from 2.88 ± 0.02 Å at 100 °C to 2.93 ± 0.02 Å at 300 °C and the *N* of O around a central Ag increases from 3.0 ± 0.3 at 100 °C to 3.7 ± 0.3 at 300 °C. As the reduction of Ag^+ ion proceeds, the repulsion between Ag and the frame oxygen increases. This results in an increase of the long Ag-O distance. It is suggested that the contribution of the Ag atoms become dominant for the Ag-Ag and the long Ag-O contacts at high temperature [6].

The root mean square displacement *σ* for the short Ag-O contact decreases with increasing dehydration, while for the long Ag-O and Ag-Ag contacts *σ* remains unchanged.

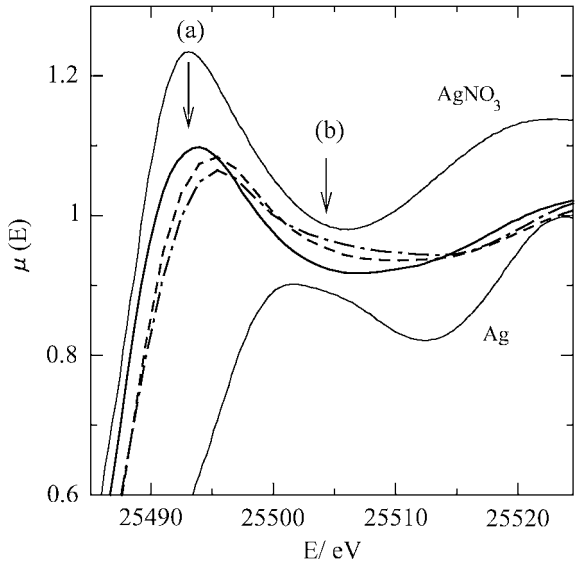

Fig. 5. XANES spectra of the Ag K-edge for Ag-4A: Solid line presents the result of sample A, dashed line does that of sample B, dot-dashed line does sample E. For comparison XANES's of $AgNO_3$ ($\mu(E)$ is shifted to $+0.1$) and Ag ($\mu(E)$ is shifted to -0.1) are also presented by thin solid line.

The fact that the coordination number N of Ag around a central Ag increases from 3.4 ± 0.3 for the Ag-4A fully evacuated at r.t. through 3.6 ± 0.3 at 200 °C to 4.1 ± 0.3 at 300 °C and the Ag-Ag contact distance decreases from 2.83 ± 0.02 Å for the evacuated sample at r.t. through 2.81 ± 0.02 Å at 200 °C to 2.79 ± 0.02 Å at 300 °C indicates that the formation of Ag clusters [3–7] in the zeolites cages sets on by dehydration under vacuum at r.t. and is accelerated by heating. The present systematic results for distance, coordination number and root mean square displacement are obtained for the first time by carrying out *in-situ* EXAFS experiments.

Figure 5 shows the changes of X-ray absorption near edge structure (XANES) for samples A, B and E. For comparison, XANES spectra of $AgNO_3$ and Ag foil are shown together. The XANES spectrum for sample A fully hydrated Ag-4A at r.t. is similar to that of $AgNO_3$ which is typical for the compounds with Ag^+-O pair. The peak (a) of the XANES spectra for samples B fully evacuated at r.t. and sample E heated to 300 °C under vacuum shift to higher energy and the intensity of the peak decreases with increasing dehydration. On the other hand, the intensity around the minimum (b) of XANES spectra for samples B and E increases with increasing temperature, which suggests the reduction of the valence state of the X-ray absorber from Ag^+ ions to Ag atom as indicated by XANES spectra of Ag foil. This behavior of the XANES spectra indicates that the Ag^+ ions in the hydrated Ag-4A is reduced to Ag atoms in the Ag-4A heated at 300 °C, which supports the formation of the Ag clusters with increasing dehydration temperature as we discussed on the EXAFS results.

5. Conclusion

The *in-situ* Ag K-edge EXAFS measurements have been carried out for fully Ag^+-exchanged zeolite 4A (Ag-4A) during continuous dehydration under vacuum in the temperature range between r.t. and 300 °C. The structural parameters (distance r, coordination number N and root mean square displacement) were derived by a three-shell (short and long Ag-O contacts and Ag-Ag contact) by curve-fitting analysis. The systematic dehydration effect on the structural change in the Ag clusters is discussed for the first time by carrying out the *in-situ* EXAFS experiments. It is found that the Ag^+ ions are reduced by removal of water molecules due to evacuation for 20 minutes. The formation of Ag clusters is suggested by full evacuation at r.t. With increasing dehydration temperature N of Ag around a central Ag increases. For the Ag cluster formed at 300 °C the Ag-Ag contact distance is evaluated to be 2.79 ± 0.02 Å and N of Ag around a central Ag of 4.1 ± 0.3. The cluster formation is supported by the XANES spectra which show that the Ag^+ ion in the fully hydrated Ag-4A change to Ag atoms in the dehydrated Ag-4A at 300 °C under vacuum.

Finally we should mention the limitation for the present analysis: our analysis is based on the three-shells model of short Ag-O, long Ag-O and Ag-Ag and the multiple scattering path was not taken into account. In our result the Ag coordination is indeed novel from the coordination chemistry point of view and a more sophisticated analysis using a later version of the theoretical EXAFS function (including the multiple scattering effect) will be needed to confirm the present results.

Abstract

Ex situ and *in situ* XAFS studies have been performed at the new ANKA-XAS beamline on zirconia-silica mixed oxides for oxidation reactions, silver-gold based catalysts for CO oxidation and Cu/ZnO catalysts for methanol synthesis. Spectra were recorded both in the transmission geometry and in the fluorescence mode. The studies give insight into the structure of newly prepared catalysts and present first examples from the area of heterogeneous catalysis studied at this beamline, which is a new alternative in the network of European synchrotron radiation beamlines.

1. Introduction

The demand of synchrotron radiation in the field of X-ray absorption fine structure (XAFS) spectroscopy is increasing. To meet this demand, a new XAFS beamline at the synchrotron radiation source ANKA (Ångströmquelle Karlsruhe) of the Forschungszentrum Karlsruhe for the energy region 2.4 to 25 keV has recently been built and commissioned. This "ANKA-XAS" beamline focuses on applications in materials science, solid state chemistry, geo- and environmental sciences and the field of catalyst research. Already during the commissioning period the first test experiments on solid catalysts were performed and some results are presented herein.

Preparation of novel materials and their proper characterization are important for the design and discovery of new heterogeneous catalysts. XAFS plays a crucial role because it allows characterization of both amorphous and crystalline phases in heterogeneous catalysts [1, 2]. Moreover, it can be used not only *ex situ* but also under *in situ* conditions [2–4]. We present three examples demonstrating the possibilities and limitations of the new ANKA-XAS beamline. The first two examples emerge from the field of "new materials". Two interesting routes for the preparation of new materials are flame synthesis [5] and the synthesis of aerogels [6]. In both cases, materials with high surface area but different crystallinity, hydrophilicity and pore structure can be produced. Here, we investigate gold-silver based catalysts for CO-oxidation prepared by flame synthesis. ZrO_2-SiO_2 aerogels and their corresponding flame-synthesized material, used for cyclohexene oxidation, are also investigated. XAFS results of the well-known Cu/ZnO system [2, 7, 8], used as catalyst for methanol synthesis, methanol oxidation or steam reforming are reported as a representative example for an *in situ* and time-resolved study. The reduction behaviour of this catalyst is strongly dependent on the preparation method. These studies let us also discuss some of the limitations of the beamline during time-resolved studies.

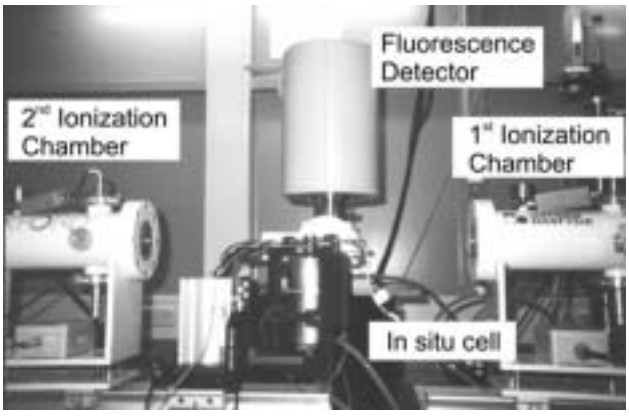

Fig. 1. Set-up of the XAFS experiment in transmission (ionization chambers) and fluorescence mode (detector at the back) at the ANKA-XAS beamline. Between the first and second ionization chamber there is an *in situ* EXAFS cell with furnace installed.

2. Experimental

2.1. *The ANKA-XAS beamline*

ANKA-XAS at the synchrotron radiation source ANKA, a storage ring operating at 2.5 GeV and a typical ring current of 85–180 mA, offers beamtime for scientific users and industrial customers. The beamline is equipped with a double crystal monochromator (DCM) with parallel mounted Si(111) and Si(311) crystal pairs for fast crystal changes. Studies in the energy range from 2.4 to 25 keV are possible [9], covering the S K-edge, L-edges of U up to the Pd K-edge. The optics includes a Zerodur mirror, deflecting downwards, which can be moved into the beam path behind the DCM to act as a low pass filter, suppressing higher harmonic reflections [10]. Three 300 mm ionization chambers are provided, which can be filled with counting gas at variable pressures (see Fig. 1). For our studies in fluorescence mode, a 5-element solid state detector (Canberra LeG 5-element) is used. A closed-loop He-cryostat allows measurements from about 15 K up to 310 K. User's own sample environment cells can be well adapted and thus easily set-up on the 200 × 100 cm optical table in the experimental hutch. Fig. 1 shows the set-up of our *in situ* fluorescence XAFS setup at ANKA-XAS. A chemical laboratory, located within the ANKA experimental hall, is now available for sample preparation during measurements. Thus the ANKA infrastructure is well-suited, e.g., for the characterization of new materials by XAFS also under *in situ* conditions.

2.2. *Preparation of the catalysts*

The gold and gold-silver catalysts (0.1–1 wt%Au, 1 wt%Ag) were synthesized in a methane/oxygen flame using a mixed solution of

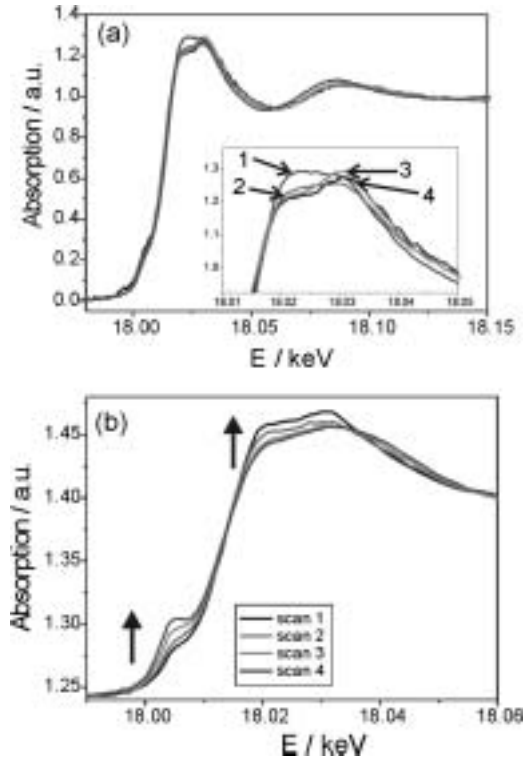

Fig. 2. Zr K-edge XANES for: (a) *ex situ* investigated samples: (1) 20%ZrO_2/SiO_2 (aerogel); (2) 5%ZrO_2/SiO_2 (flame-synthesis); (3) 5%ZrO_2/SiO_2 (aerogel); (4) 5%ZrO_2/-SiO_2 (aerogel, silylated); (b) 5%ZrO_2/SiO_2 (aerogel) during dehydration (scan 1: 50 °C, scan 2: 120 °C, scan 3: 180 °C, scan 4: 250 °C).

silver benzoate, dimethyl-acetylacetonato gold(III) and $Ti(O^iPr)_4$ precursors in an organic volatile solution. The catalysts were investigated as prepared and *in situ* reduction of the catalysts was performed in 5%H_2/He. ZrO_2/SiO_2 catalysts were prepared by aerogel synthesis using tetramethoxy silane and zirconium acetylacetonate as precursors, solvent extraction by supercritical CO_2 and subsequent calcination at 400 °C. The corresponding flame made precursors were prepared from the same precursors, similar as described in [11]. *In situ* dehydration was performed in a stream of He at a ramp rate of 5 °C/min. The 70%Cu/ZnO catalyst was prepared at pH = 8.5 and calcined at 330 °C (similar to as reported in [12]). The sample was reduced in 5%H_2/He at a heating rate of 1 °C/min.

3. Results

3.1. *ZrO_2/SiO_2 catalyst prepared by the aerogel and flame synthesis method*

Pre-investigations on the samples prepared by aerogel synthesis showed the samples are completely X-ray amorphous with high surface area (>200 m^2/g). Both XANES and EXAFS data on 5%ZrO_2/SiO_2 aerogels (without and with silylation) reveal zirconium to be mainly octahedrally coordinated. Fig. 2a displays the Zr K-edge XANES transmission mode data of several ZrO_2/SiO_2 samples. The absence of pre-edge features indicates octahedral coordination, as a pre-edge feature is expected for non-centrosymmetric Zr sites [13]. The XANES changes when 20 %ZrO_2 instead of 5%ZrO_2 is incorporated into the silica matrix. The change in the "fingerprint" at 18.02 keV is probably due to the formation of Zr-O-Zr species [13]. In contrast, the 5%ZrO_2/SiO_2 catalyst mainly contains Zr-O-Si species. Interestingly, the XANES fingerprint at the main absorption feature for the 5%ZrO_2/SiO_2 catalyst prepared by flame synthesis is intermediate to that of the 20%ZrO_2/SiO_2 catalyst and the corresponding sample prepared by the aerogel method. This indicates that during the flame synthesis more Zr-O-Zr species form than in the aerogel method. Probably, Zr-clusters originate from aggregation during the preparation process in the flame. The 5%ZrO_2/SiO_2 aerogel samples having a higher number of isolated Zr atoms showed a better catalytic performance in cyclohexene oxidation.

During dehydration of these samples (Fig. 2b) the pre-edge feature significantly increases, indicating an increase in tetrahedral coordinated Zr. A similar behavior is observed for TiO_2-SiO_2 aerogels [14], where Ti sites are mainly present as isolated species on the surface. Air moisture is sufficient to hydrate the Zr sites in the 5%ZrO_2-SiO_2 aerogel sample as also observed for Ti sites in TiO_2-SiO_2 aerogels and thereby change the coordination around the transition metal centres.

3.2. *Fluorescence EXAFS studies on 1%Au-1%Ag/TiO_2 and 0.1%Au-1%Ag/TiO_2*

Noble metal based heterogeneous catalysts have only rarely been prepared by flame pyrolysis. Recently, the technique was for the first time applied to bimetallic catalysts [15]. TEM investigations show that in order to achieve high noble metal dispersion during the preparation process, the noble metal loading has to be kept at a low level (<1 wt%). Fluorescence instead of transmission EXAFS studies are preferred at the Au L_3-edge in Au/TiO_2, since the TiO_2 support absorbs to a significant extent the X-rays and the gold concentration is low. Therefore the Au L_3 edge study is made in the fluorescence mode using a similar setup as described in ref. [16] and depicted in Fig. 1.

Fig. 3 shows the Au L_3 XANES of Au-Ag/TiO_2 samples used for CO-oxidation, indicating that most of the gold is in reduced state. This is supported by the fact that only slight spectral changes occur after *in situ* reduction of the catalyst. Based on simulations using the FEFF8.2 code [17], we found that only small variations in the near edge region are expected if gold is alloyed with silver. Therefore, we cannot exclude the possibility of alloy formation from the XANES. Analysis of the EXAFS (also shown in Fig. 3), however, point to the formation of alloyed Au-Ag particles, as can be e.g. seen by the altered Fourier transformed EXAFS spectra (cf. in [18]).

3.3. *In situ reaction combined with gas analysis: reduction of a CuO/ZnO catalyst*

The reduction of CuO/ZnO is a well-known example for *in situ* and time-resolved studies [2, 7, 8] greatly influenced by the preparation parameters. In a recent project, high throughput synthesis/testing has been combined with investigations by EXAFS [12]. Fig. 4 depicts typical XANES transmission spectra obtained during a scan of 7 min at the ANKA-XAS beamline. The simultaneously recorded mass changes in the mass spectrometer are also shown for comparison. The reduction of Cu^{2+} is clearly seen by the decrease in the white line and the formation of metallic copper by the increase of the pre-edge feature, starting at about 170 °C. The reduction is also reflected by hydrogen consumption ($m/e = 2$) and the formation of water ($m/e = 18$), observed in the mass spectrometer. The reduction covers a temperature span of 50 °C and thus about 7 spectra could be taken during the reduction of the catalyst. Modeling of the XANES through linear

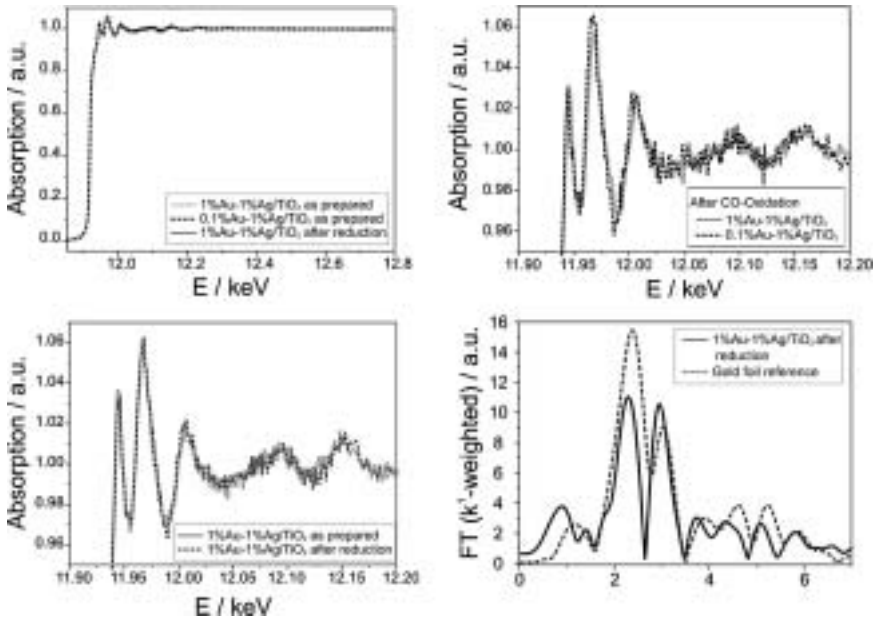

Fig. 3. Au L_3-edge fluorescence EXAFS data for Ag-Au/TiO_2 samples.

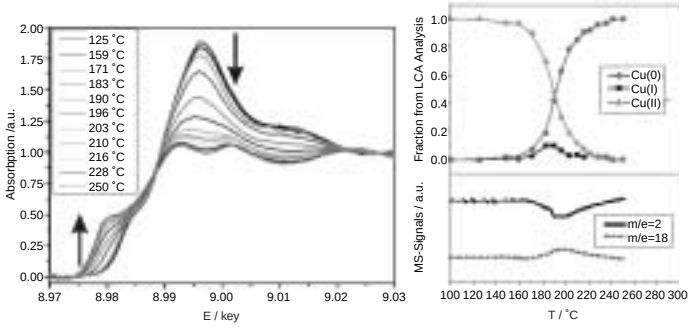

Fig. 4. In situ Cu K-edge XANES during reduction of 70%CuO/ZnO in 5%H_2/He with the corresponding results from fits to the data using a linear combination of reference spectra and mass spectrometric data.

combination of $Cu^{2+}/Cu^{+}/Cu^{0}$ reference data (LCA analysis) indicates that only a small fraction of Cu^{+} forms during the reduction. This is in agreement with previous studies [2, 7, 8]. Comparison to literature data and the extension of the study to further samples reveals that the reduction behaviour strongly depends on the preparation method (see also [19]). Hence, the effect of the preparation method on the reduction temperature and the catalytic activity is presently studied.

4. Conclusions

The examples illustrated here are the first studies on heterogeneous catalysts at the ANKA-XAS beamline. They demonstrate this beamline's potential for catalyst research. The beamline is well-suited for standard *ex situ* studies on new catalyst materials in the energy region 5–25 keV, providing new insight into the structure of flame-made and aerogel materials. The study on zirconia-silica materials revealed that the aerogel method and low ZrO_2 concentration result in optimal Zr dispersion and a high fraction of tetrahedrally coordinated Zr is found after dehydration of the samples. Bimetallic Au-Ag samples prepared by the flame method contain gold in metallic state already directly after preparation and Ag-Au alloy formation is observed after reduction. This example also shows that using a solid state detector for fluorescence detection not only *ex situ* studies but also *in situ* studies on a heterogeneous catalyst with the element of interest in the 1000 ppm range could be achieved (here 1000 ppm Au on TiO_2). The detector is, however, more bulky than the silicon drift detector [16]. Recently, studies of the Pt-reduction in PtO_x/Al_2O_3 during aerobic phenylethanol oxidation have also been performed successfully in the liquid phase at this beamline.

We confronted one of the beamline limitations during the CuO/ZnO catalyst study. Time-resolution, which is generally not too important during standard EXAFS scans but during dynamic studies, was low during the commissioning period of the beamline due to the preliminary set-up of the motor controllers and data acquisition software. This has been improved in the meantime. Recording good time resolved XANES spectra is limited to energies < 18 keV. The signal-to-noise ratio for EXAFS scans is only reasonably high at high k if the counting time is increased. This is due to the flux decrease at energies above $\sim$18 keV (the characteristic energy of the ANKA storage ring is 6.2 keV). However, EXAFS measurements with reasonable measurement times are feasible up to 20 keV.

In conclusion, the ANKA-XAS beamline has interesting potential for the characterization of heterogeneous catalysts or solids. The strength of the beamline is in the energy region 2.4–20 keV. It represents a new alternative in the network of existing European synchrotron radiation beamlines in catalyst research. This is important since the demand of hard X-rays at synchrotron rings in Europe cannot be met with the current number of existing beamlines.

Acknowledgements

We gratefully acknowledge beamtime at the ANKA-XAS beamline (Forschungszentrum Karlsruhe). We thank P. Kappen and C. Kiener for the help during the measurements and P. Hasselriis, W. J. Stark and C. Kiener for providing some of the catalyst samples. Our workshop at ETH is gratefully acknowledged for the assistance with construction of the *in situ* EXAFS set-ups, in particular the fluorescence EXAFS set-up tested at the ANKA-XAS beamline, and the Swiss Commission for Technology and Innovation (CTI, TopNano 21 grants 5978.2 TNS and 6740.1 TNS) for financial support of the flame-synthesized materials.

Abstract

In this study, *in-situ* XANES measurements of the Ru L_{III}-edge of one commercially available and a novel PtRu colloid catalyst, synthetized at the Max-Planck-Institut für Kohlenforschung, Mühlheim (Ruhr), Germany, at room temperature and at 80 °C in an atmosphere of 10% H_2 in N_2 are presented. During the process of heating at operating temperature, clear sample-specific changes are observed that can be correlated to structure and perfomance of the respective catalysts. The commercially available catalyst JM HiSpec 6000, Johnson Matthey company, and the freshly prepared novel colloid catalyst EUP-AA-25 show a reduction of the oxidation state of the Ru ions at operating temperature, demonstrating the existence of ruthenium sites which are accessible only under operating conditions. On the other hand, when examining the novel colloid catalyst extracted after 500 hours at working conditions, then declared as EUP-AA-21, no changes are observed while heating in a hydrogen containing atmosphere any more, indicating that the formerly active sites have been permanently blocked.

1. Introduction

PtRu nanoparticles are promising electrode materials for the Direct Methanol Fuel Cell (DMFC), because the small particle sizes (<3 nm) provide a large active surface [1–3]. The aim of this study is an improved characterization of the electronic structure of the Ru atoms, e.g. oxidation state, of such particles under conditions similar to the working conditions. Such an *in-situ* study is essential for two reasons: First of all, it is not clear whether the direct extrapolation of results obtained from *ex-situ* techniques is suitable for describing reactions occurring in the fuel cell under working conditions. Secondly, even if one assumes that results obtained from *ex-situ* investigations can be extrapolated, such studies cannot follow changes in the material that occur during operation and thus cannot provide a starting point for a possible refinement of the formation process. In fact, e.g. the reason for the higher CO and CO_2 tolerance of PtRu catalysts relative to pure Pt catalysts is still disputed, even though the effect was first observed in 1972 [4]. Possible explanations relate directly to H_2O activation by Ru [5] and electronic modification of the Pt d-DOS, which leads to a weakening of the Pt-CO bond [6, 7]. Consequently, obtaining direct access to the electronic structure at the Ru sites might open a promising pathway to the solution of this type of problems.

In-situ measurements at the Pt L_{III}-edge have e.g. been performed by Mukerjee *et al*. [8]. The *in-situ* access to the electronic structure of the ruthenium atoms is significantly more difficult, as the considerable life-time broadening smears out the K-edge structures, whereas photons in the Ru L-edge region lack the penetration depth. To our knowledge, this is the first investigation at working conditions at the Ru L_{III}-edge.

*e-mail: brendeba@physik.uni-bonn.de

2. Experimental

In-situ X-ray Absorption Near Edge Structure (XANES) measurements of the ruthenium L_{III}-edge of two PtRu-based catalysts were performed at the DCM-beamline at CAMD, Baton Rouge, USA, each at room temperature and at 80 °C in an atmosphere of 10% H_2 in N_2. A set of InSb(111) crystals was in use and spectra were taken in transmission mode. An argon spectrum was recorded for energy calibration setting the first inflection point to the 1s binding energy at 3205.9 eV [9]. Powder samples of metallic Ru, $RuBr_3$, RuO_2, and K_2RuO_4, purchased from the Sigma-Aldrich company, were measured as reference compounds, representing ruthenium atoms in oxidation states zero, three, four, and six, respectively. The maximum of the first derivative of the Ru powder spectrum, set to 2838 eV [9], was used for a refined energy calibration. The spectra were measured from 2750 eV to 2950 eV with a step size of approximately 1 eV in the pre- and post-edge region and 0.15 eV between 2810 eV and 2860 eV. A linear background was fitted to the pre-edge region and subtracted. The spectra were normalized to unity in the post edge region at 2900 eV.

3. Results

The focus of this study is centered on the description of the oxidation state of the binary nanocatalysts for fuel cells, as this elucidates the changes within the metal-metal and metal-oxygen-bonds between ambient and working conditions.

For example, within the commercially available catalyst JM HiSpec 6000 the Ru is highly oxidized at room temperature, but when heated at 80 °C in an atmosphere of partly hydrogen, a partial reduction reaction takes place as can be seen in the upper part of Fig. 1. Comparison with spectra of reference samples Ru powder, $RuBr_3$, RuO_2, and K_2RuO_4, shown in Fig. 2, clarify that the decrease of white line intensity at working conditions is related to a reduction of the number of oxidized Ru atoms. This behavior suggests the presence of active ruthenium sites within the catalyst which are only accessible under reaction conditions and appear oxidized otherwise.

To investigate whether these activated ruthenium sites are characteristic for highly active PtRu electrocatalysts, we have extended our analysis to a freshly prepared and a used sample of a novel Pt/Ru-based colloid catalyst, prepared by the MPI für Kohlenforschung, Mühlheim (Ruhr), Germany, by coreduction of $PtCl_2$ and $RuCl_3$ which initially shows similar electrocatalytic activity but whose performance is significantly worse after 500 hours of operation (c.f. Fig. 3).

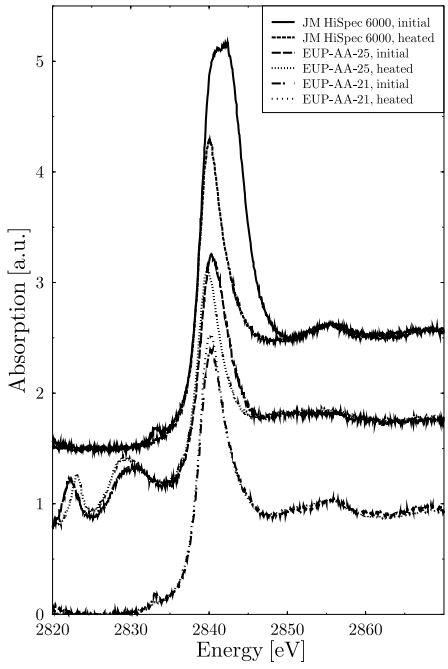

Fig. 1. XANES spectra of JM HiSpec6000 (upper), EUP-AA-25 (middle), and EUP-AA-21 (lower). Spectra are shifted along the *y*-axis for clarity.

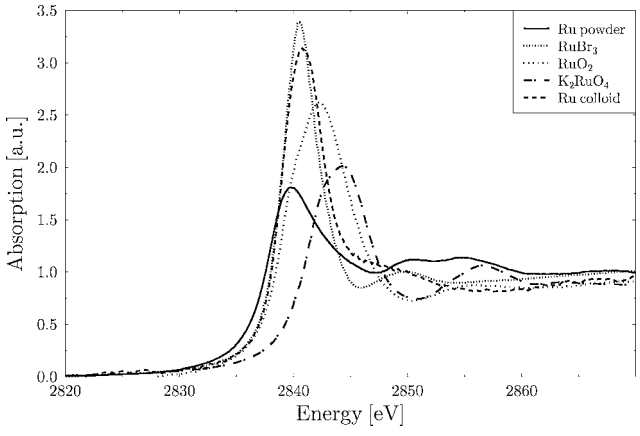

Fig. 2. XANES spectra of Ru reference compounds, the spectrum of the Ru colloid was taken out of [10].

The spectra of the freshly prepared catalyst, declared as EUP-AA-25, and after 500 hours at working conditions, then called EUP-AA-21, are shown in the middle and lower part of Fig. 1, respectively. Evidently, the pre-edge features in the spectra of sample EUP-AA-25 are relicts of the formation process. Platinum- and rutheniumchlorine are used as starting materials for the preparation of the nanoparticle catalysts. The positions of the peaks correspond to the Cl K-edge energy at 2833 eV. Interestingly, at room temperature the degree of oxidation observed for this catalyst is significantly lower than in the HiSpec sample, indicating a rather different site occupation. But under operating conditions the Ru L_{III} XANES spectra of the fresh catalyst – especially when correcting the normalization with respect to the influence of the Cl K-edge edge jump – are highly similar to the one acquired from the HiSpec catalyst, as shown in detail in Fig. 4. Thus, it seems reasonable to assume that in fact the spectrum of these two heated samples is a fingerprint for the electronic structure of the Ru atom which is favourable for electrocatalytic activity. This assumption is further supported

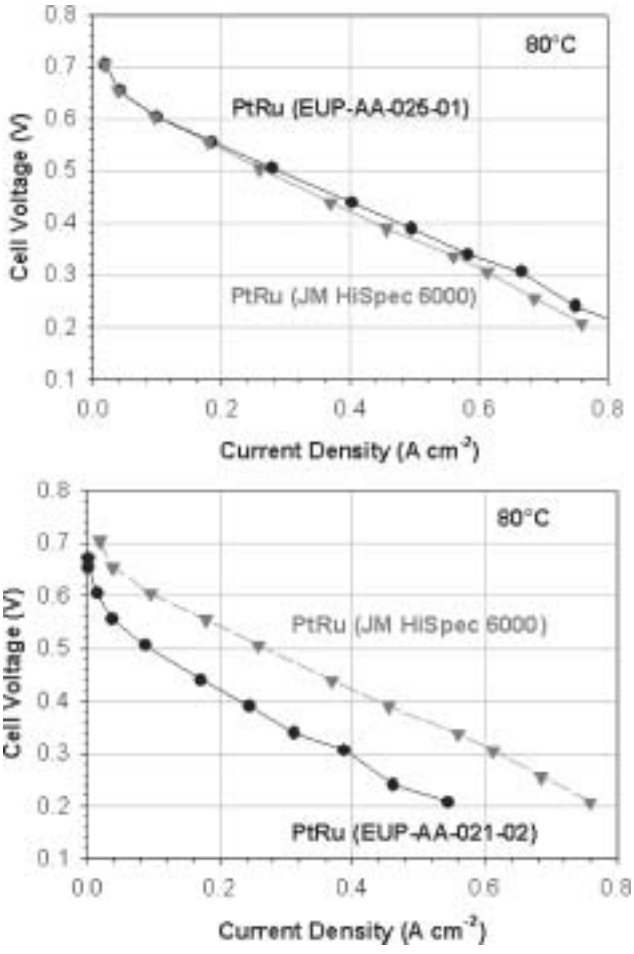

Fig. 3. Performance of EUP-AA-25 (upper) and EUP-AA-21 (lower) with respect to JM HiSpec 6000 [11].

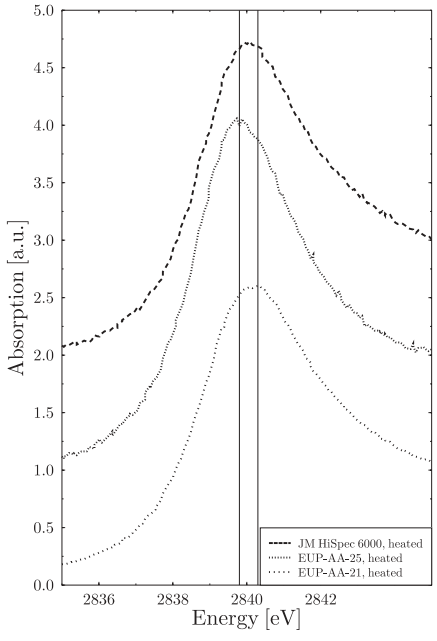

Fig. 4. XANES spectra of the catalysts at operating temperature (80 °C) in an atmosphere of 10% H_2 in N_2. Spectra are shifted along the *y*-axis for clarity.

by the observation that in contrast to the two cases discussed so far, after 500 hours of operation the Ru L_{III} XANES spectrum of the novel catalyst is clearly shifted to higher energies and is no longer susceptible to the change in the environmental conditions,

thus the deterioration of the electrocatalytical performance is accompanied by a clear change of the chemical environment at the Ru sites and it appears that the sites which are most active are blocked by permanent occupation with time. Unfortunately, so far, a sample of the JM HiSpec 6000 catalyst after 500 hours at working conditions, which would allow for the assessment whether this sample undergoes the identical aging process was not available.

Evidently, these results induce the desire to obtain an improved characterization of the active sites. Based on the data accumulated so far, only one statement can be made with respect to their nature: Earlier publications have shown that in a variety of Pt/Ru-based colloid catalysts enriched regions of Pt and Ru atoms, respectively, are formed and that a segregation of Pt atoms to the surface of the colloids is observed [12, 13]. When comparing the reference samples, only within the Ru powder and the $RuBr_3$ Ru-Ru bonds are present. Their spectra show a resonance at about 2850 eV which is missing the spectra of RuO_2 and K_2RuO_4, containing no Ru-Ru linkages. In addition, the spectrum of a pure Ru-containing colloid is also shown in Fig. 2, which as well shows a signature at the respective energy. Using that feature as a fingerprint for Ru-Ru bonds within a catalyst, the commercial JM HiSpec 6000 seems to be fully alloyed, because the spectra have a minimum at 2850 eV. When examining the spectra of the novel colloid catalyst small but significant features are visible at the respective energy which may lead to the assumption that they are not completely alloyed. If this should be the case, mixing of Pt and Ru states in the d-band should not be the decisive factor for the electrocatalytic activity of the sites. However, further detailed investigations are needed to solidify this hypothesis.

4. Conclusion

This study demonstrates that *in-situ* XANES measurements of the Ru L_{III}-edge at operating temperatures are feasible and monitor significant reactions at the Ru atoms and therefore serve as starting points for further refinements of Pt/Ru-based colloid catalysts which are promising anode materials for the Direct Methanol Fuel Cell (DMFC). In detail, *in-situ* XANES measurements of the ruthenium L_{III}-edge have been performed for one commercially available and one novel PtRu colloid catalyst at room temperature and at 80 °C in an atmosphere of 10% H_2 in N_2 simulating operating conditions, yielding a fingerprint for the Ru L_{III} XANES spectrum of the most active catalytic sites. Comparison with Ru reference samples in the oxidation state zero, three, four, and six show that the commercial catalyst and the freshly prepared novel catalyst contain active ruthenium sites which are accessible only under operating conditions and occupied under ambient conditions. In the case of the HiSpec catalyst, this occupation seems to lead to Ru(IV) states, which are not formed in the novel catalyst. Still, this material is also reduced to a lower oxidation state when heated in a hydrogen containing atmosphere in its initial state. Extracted after 500 hours at working conditions, the novel colloid catalyst remains unchanged and the active sites are no longer accessible. In spite of the significant differences in the XANES spectra under standard conditions, the active sites are identical. This is even more surprising as the novel colloid catalyst seems not to be fully alloyed whereas the spectra of the commercially available catalyst JM HiSpec 6000 do not show any indication of Ru-Ru bonds. Further studies are needed to elucidate the exact nature of the active sites and the mechanism which leads to their permanent occupation.

Abstract

Nanoparticles of Ag-Pt and Ag-Pd with high aspect ratios were synthesized using a radiolysis method. Gamma rays at dose rates below 0.5 kGy/h were used for irradiation. The nanoparticles were characterized by transmission electron microscopy (TEM), optical absorption spectroscopy and X-ray Absorption Fine Structure (XAFS) spectroscopy. Bright field micrographs show that Ag-Pt nanowires are composed of large particles with diameters ranging from 20–30 nm and joined by filaments of diameter between 2–5 nm. The Ag-Pd nanowires have diameters of 20–25 nm and lengths of 1.5 μm. For XAFS measurements, the Pt L_3 edge (11.564 keV), Ag K-edge (25.514 keV) and Pd K-edge (24.350 keV) were excited to determine the local structure around the respective atoms in the cluster. The Ag-Pt particles were found to possess a distinct core-shell structure with Pt in the core surrounded by Ag shell, with no indication of alloy formation. However, nanorods of Ag-Pd have formed an alloy for all the alloy compositions.

1. Introduction

Nanocrystalline materials are of great interest and are being widely studied because many physical and chemical properties of these materials are found to be dissimilar to those of conventional polycrystalline, coarse-grained materials. Such difference in properties arise because of the large fraction of atoms (5–50%) located at the surfaces and/or interfaces. Quantum size effects are observed in metal and semiconductor fine particles if their size is small enough so that the spacing between the discrete levels in the electronic energy spectrum becomes comparable with some of the characteristic energy parameters like kT, μH, $h\omega$, etc., thereby giving rise to changes in the thermodynamic, magnetic and optical properties respectively [1]. Nanocrystalline materials have been found to exhibit increased strength and hardness, enhanced diffusivity, improved ductility, reduced density, etc. compared to the bulk. Hence, these materials have found applications in microelectronic and optoelectonic devices, catalysis, sensing, drug delivery, etc. Metallic nanostructures with high aspect ratios are promising candidates for the development of sensors, catalysts and nanoscopic electrical connections.

Bimetallic nanoparticles are of greater interest than the monometallic ones, both technologically and scientifically [2]. The selective behavior of such bimetallic catalysts can be controlled by changing their composition ratios [3, 4]. Earlier studies have mostly been done on inorganic oxide-supported bimetallic nanoparticles [5]. Recently, novel techniques like microemulsion [6], decomposition of organometallic precursors [7], radiolysis [8], etc. have been developed for the synthesis of colloidal suspensions of these nanoparticle systems. Such systems are advantageous for study since the interference of substrate interaction is absent. A detailed review of bimetallic nanoparticles in dispersion has been published [9]. In this paper, we have used TEM and XAFS to investigate alloy formation in radiolytically synthesized Ag-Pt and Ag-Pd bimetallic nanoparticles in solution, possessing high aspect ratio. Such systems with high aspect ratio are particularly interesting because of their potential application as barcodes in sensors [3].

2. Experimental Section

2.1. *Synthesis*

Ag-Pt and Ag-Pd nanowires were synthesized by radiolysis [10, 11]. Radiolysis of aqueous solutions is an effective method to reduce metal ions and form homo- and heteronuclear clusters of transitions metals [10, 11]. In the radiolysis method, aqueous solutions are exposed to γ-rays (equation 1) to create solvated electrons, which in turn reduce the metal ions (equations (2) and (3)). The latter coalesce to form aggregates (equation (4)).

$$H_2O \rightarrow e^-_{aq}, H_3O+, H^*, OH^*, H_2O_2, \quad (1)$$

$$e^-_{aq} + M^{m+} \rightarrow M^{(m-1)+}, \quad (2)$$

$$e^-_{aq} + M^+ \rightarrow {M_0}^0, \quad (3)$$

$$n{M_0}^0 \rightarrow {M_2}^0 + (n-2)M0 \rightarrow \ldots\ldots\ldots {M^0}_n. \quad (4)$$

The samples were irradiated with γ radiation from the fission products of University of Missouri-Rolla's nuclear reactor pool. The reactor was operated at 180 kW for 1 hour and the samples were positioned 1 h after the reactor shutdown to prevent neutron bombardment and activation of samples. The dose rate was decreased exponentially from a value of 0.5 kGy/h in the first hour to about 0.05 kGy/h 48 hours after shutdown. Exposure to a total dose between 3 and 3.5 kGy typically required 36 to 48 hours. Total doses were measured with Thermoluminescent Dosimeters (TLD) placed in vials adjacent to the samples to be irradiated.

To obtain nanowires, parameters that were varied, were (a) total gamma ray dose and dose rate, (b) type of counterions added to the solution, (c) total and relative metal concentration, and, (d) polymer type and concentration. The most relevant parameters were the counter ions, the molar ratio between Ag and Pt or Pd, and the capping polymer. The data strongly suggests that polymer-metal ion complexes are formed, possibly in micellar form. Also, at least two conditions typical for nanowire formation, i.e. the presence of seeds and slow velocity of reduction, are met by the experiments. Samples were prepared with Ag-Pt and Ag-Pd

Table I. *Conditions for formation of Ag-Pt and Ag-Pd nanowires by radiolysis.*

Conditions for nanowire formation	Ag-Pt System	Ag-Pd System
Total Dose (kGy)	3.5	3.5
Mole Ratio (%)	80-20 to 20-80	40-60 to 80-20
Salts	H_2PtCl_6 and Ag_2SO_4	Ag_2SO_4, Ag_2NO_3 and $PdSO_4$
Capping Polymer	Poly (vinyl alcohol)	Poly (vinyl alcohol)
PVA Molecular Mass (amu)	31000–170000	88600–97000
Metal ion concentration in solution (mol/L)	0.5 and 2×10^{-3}	0.5 and 2×10^{-3}
Scavenger for H^* and OH^* radicals	0.2 mol/L of 2-propanol	0.2 mol/L of 2-propanol
Hydrolysis Degree (%)	87–89	87–89

mole ratios varying from 100% to 0% of Ag in steps of 20%. The conditions for nanowire formation of Ag-Pt and Ag-Pd systems are listed in Table I.

2.2. *Characterization*

Samples were characterized for their size, shape and chemical composition prior to the XAFS measurements. TEM measurements and selective area electron diffraction (SAED) was carried out for microscopic structural characterization of the samples. The chemical composition of the nanoparticles was determined with Energy Dispersive X-ray analysis (EDAX).

XAFS measurements were performed at the MR-CAT undulator beamline at Advanced Photon Source, Argonne National Laboratory. The samples were sealed in plastic cuvettes before exposing them to the X-ray beam. For the Ag-Pt samples, Pt L3-edge (11.564 keV) and Ag K-edge (25.514 keV) were excited. The Ag-Pd samples were studied by exciting the Ag K-edge and the Pd K-edge (25.34 keV). For all the three edges, the undulator parameters were optimized to obtain a large photon flux with nearly constant intensity within the XAFS energy range. For the Ag and Pd edges, the undulator was tuned to its third harmonic.

A double crystal Si (111) monochromator was utilized for energy selectivity. For the Pt L3-edge, a Rh harmonic rejection mirror was used to eliminate the higher harmonics whereas Pt mirror was used for the Ag and Pd edges. The incident photon intensity was measured by an ion chamber filled with 80% He–20% N_2 gas mixture for Pt edge and full N_2 for Ag and Pd edges. Measurements were done in fluorescence mode with a 13-element solid state detector (Canberra with XIA electronics). For each sample, 10 scans were taken at the required edge and were then averaged. The spectra for all the samples were calibrated with reference Ag, Pt, Pd foils at the respective edges.

The data was processed using the University of Washington FEFFIT software package [14]. Theoretical models were constructed with the program FEFF7 [15]. The FEFFIT program was used to fit the structural parameters of the model [16].

3. Results and Discussion

Figure 1(a and b) shows typical bright field micrographs of Ag-Pt and Ag-Pd nanoparticles (growth conditions given in Table I), respectively. For Ag-Pt, the nanowires are composed of two types of particles: large particles, with typical diameters of 20–30 nm, are joined by thin filaments, with diameters of 2–5 nm. EDAX suggested that the larger particles have a typical composition

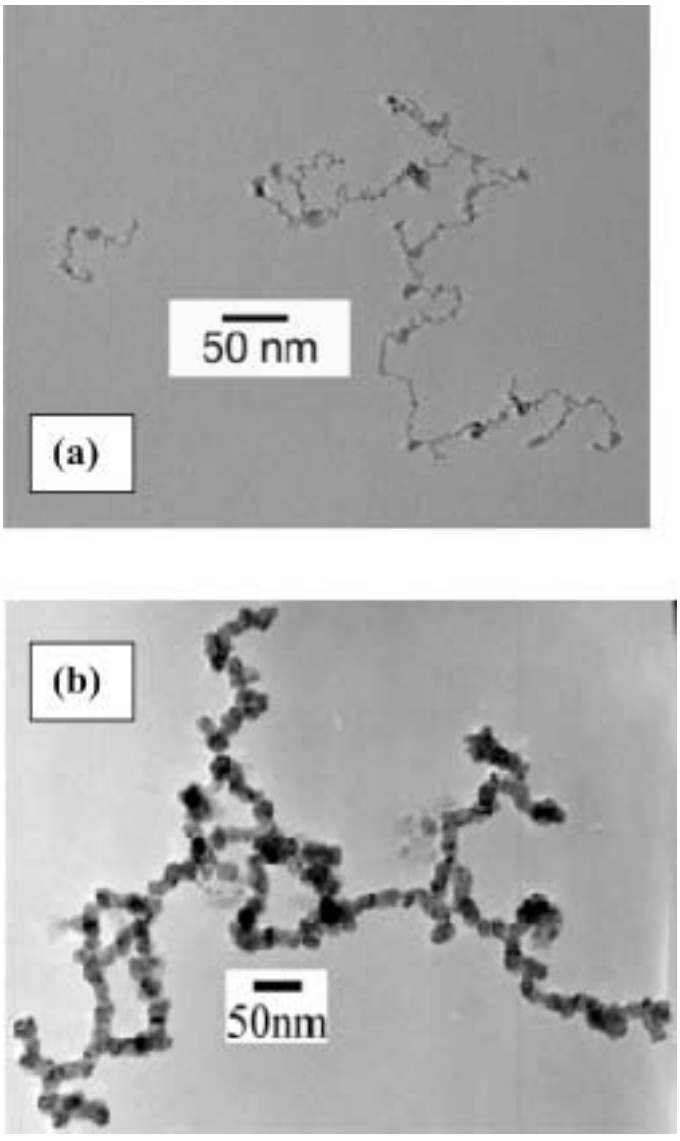

Fig. 1. Bright field TEM micrograph of Ag-Pt and Ag-Pd nanowires obtained after exposure to a total dose of 3.5 kGy, each.

of 80–90% of Ag and the filaments have composition close to 50% of silver. This implies that Ag particles are formed in the early stages of growth since reduction potential of Ag is more than that of Pt. The latter nucleated out of the Ag particles. In figure 1(b), we observe filament-like Ag-Pd particles with typical diameters of 20–25 nm and length of 1.5 μm. The lattice constant for the nanoparticles, calculated from the diffraction rings, showed an increase with the Ag concentration. The morphology of the particles was comparable for most metal mole ratios. EDAX showed that the ratio between the two metals varied within the same particle and between nanoparticles, but the variation was within ±20% of the mole ratio of the parent solution. The filaments have been observed to be polycrystalline in nature.

The XAFS data for all our samples have been shown in Figure 2. The lines in the Ag-edge data shows the frequency shift in *k*-space. The XAFS fit parameters for the Pt L3-edge from the Pt-Ag nanoparticles, are listed in Table II. A comparison of the fit with the data is shown in Figure 3. The apparent contraction in bond length can be explained from the effect of disorder in XAFS [17]. It suggests that the Pt atoms in this sample are in a disordered state compared to the Pt foil. The first shell does not show any conspicuous trace of Ag; the central Pt is coordinated by only Pt

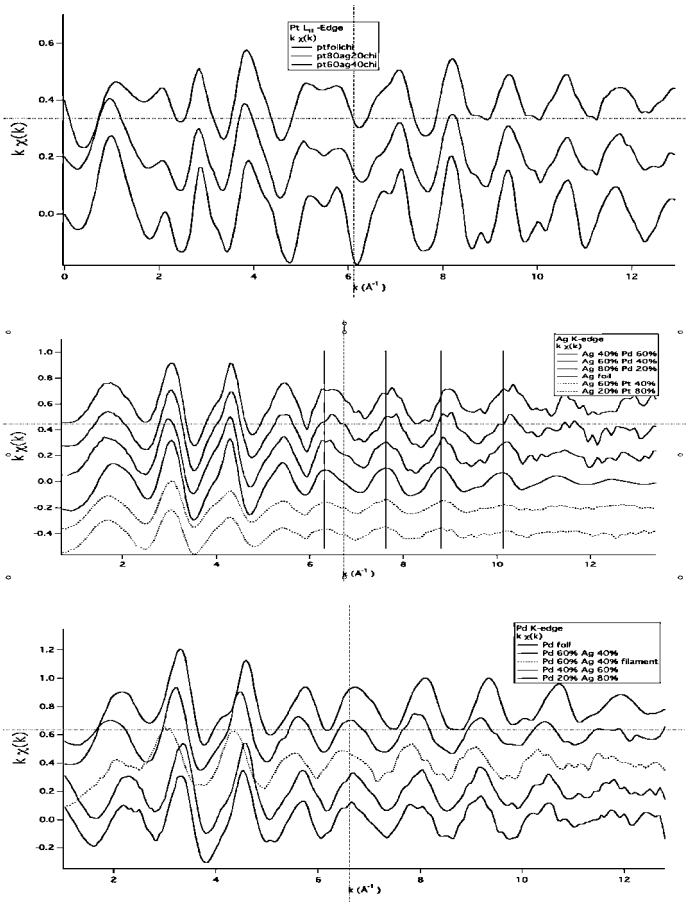

Fig. 2. Raw XAFS data for all the bimetallic nanoparticles at Pt, Ag and Pd edges. The plots are in the same order as they are listed in the figure legend.

atoms. The coordination number is much less than that of bulk Pt, which is reasonable because of the large surface to volume ratio of the nanoparticles. Alloy formation would instead have led to an expansion of the lattice parameter of Pt [18]. Such expansion has not been observed by us in this system. This implies that, in these Ag core-Pt shell particles, the two metals are not alloyed and retain their bulk lattice parameters.

The XAFS fit parameters for Pd-Ag samples were calculated from the fitting of Pd-edge and Ag-edge data. Since Pd and Ag are adjacent atoms in the periodic table, their backscattering amplitude and phase effects on the photoelectron wave are nearly identical. Hence, it is very difficult to distinguish between these two near neighbor species around the central atom and conclude

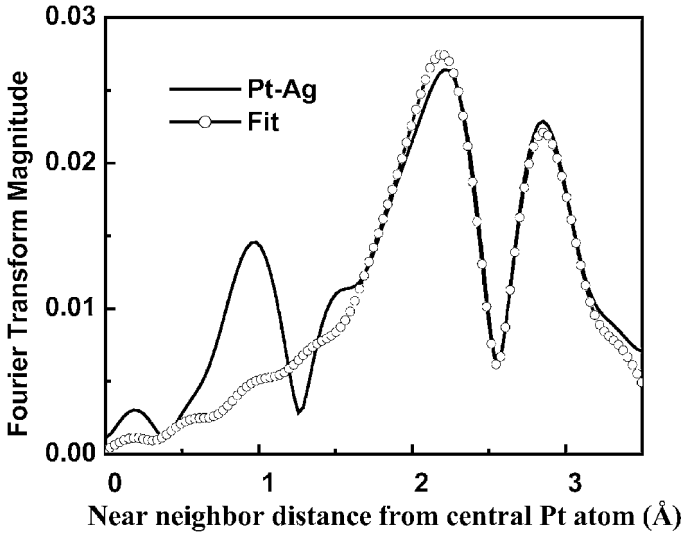

Fig. 3. Comparison of the fit with data for bimetallic nanorod system of Ag-Pt ($Ag_{0.6}Pt_{0.4}$) at Pt edge.

if they are alloying. Fortunately, the lattice parameters of Pd and Ag are significantly different. The shortest interatomic distance in Pd crystal is 2.75 Å while that in Ag crystal is 2.88 Å. Hence, in the case of alloying, the average interatomic distance around Pd in this bimetallic system should be observed to systematically increase from 2.75 Å towards 2.88 Å as more and more Ag is added. Correspondingly, the average distance around Ag should be observed to systematically decrease from 2.88 Å towards 2.75 Å with the decreased proportion of Ag.

Figures 4(a), 4(b) and 4(c) show the data (from Pd K-edge) and the fit for the samples (a) $Pd_{0.2}Ag_{0.8}$, (b) $Pd_{0.4}Ag_{0.6}$, and (c) $Pd_{0.6}Ag_{0.4}$. Of interest are the peaks in the region 2.25 and 3 Å since they represent the first shell or nearest neighbor distance. From figure 6(a), we observe that the nearest neighbor distance expands with increase in the mole percent of Pd. The results at the Pd edge are corroborated by results at the Ag edge. While doing the analysis for the Ag edge, the Debye-Waller factor was fixed from the fit results at the Pd-edge. Figures 5(a), 5(b) and 5(c) show the data (from Ag K-edge) and the fit for the samples (a) $Ag_{0.8}Pd_{0.2}$, (b) $Ag_{0.6}$ $Pd_{0.4}$, and (c) $Ag_{0.4}$ $Pd_{0.6}$. Around Ag atoms, we observe a contraction of the first shell. Figure 6(b) shows the change in the nearest neighbor distance with change in the mole percent of Ag in the bimetallic system. Together, these measurements indicate that the alloying of Ag and Pd has occurred in these nano-filaments. The detailed fit parameters are listed in Table II.

Table II. *Fit parameters for Ag-Pt and Ag-Pd nanowires.*

Sample Name	Edge	Near neighbor species	N^*	E_0 (eV)	R (Å)	σ (Å^2)
$Pt_{0.6}$ $Ag_{0.4}$	Pt	Pt	5 ± 1	3.56 ± 2.0	2.74 ± 0.01	0.005 ± 0.002
	Pt	Ag	2 ± 1	3.25 ± 2.0	2.75 ± 0.05	0.006 ± 0.002
$Pd_{0.2}Ag_{0.8}$	Pd	Pd	9 ± 1	-6.29 ± 0.8	2.79 ± 0.04	0.008 ± 0.001
$Pd_{0.4}Ag_{0.6}$	Pd	Pd	9 ± 5	-6.29 (fixed)	2.76 ± 0.04	0.007 ± 0.002
$Pd_{0.6}Ag_{0.4}$	Pd	Pd	9 ± 6	-6.29 (fixed)	2.77 ± 0.04	$0.006 \pm .0.002$
$Ag_{0.8}Pd_{0.2}$	Ag	Ag	10 ± 1	3.55 (fixed)	2.83 ± 0.02	0.008[1]
$Ag_{0.6}Pd_{0.4}$	Ag	Ag	9 ± 1	3.55 ± 0.2	2.8 ± 0.04	0.007
$Ag_{0.4}Pd_{0.6}$	Ag	Ag	12 ± 2	3.55 (fixed)	2.8 ± 0.01	0.006

[1]Debye-Waller factors at Ag-edge were fixed from Pd-edge results. When allowed to vary, they yielded values very close to those from Pd edge fitting.

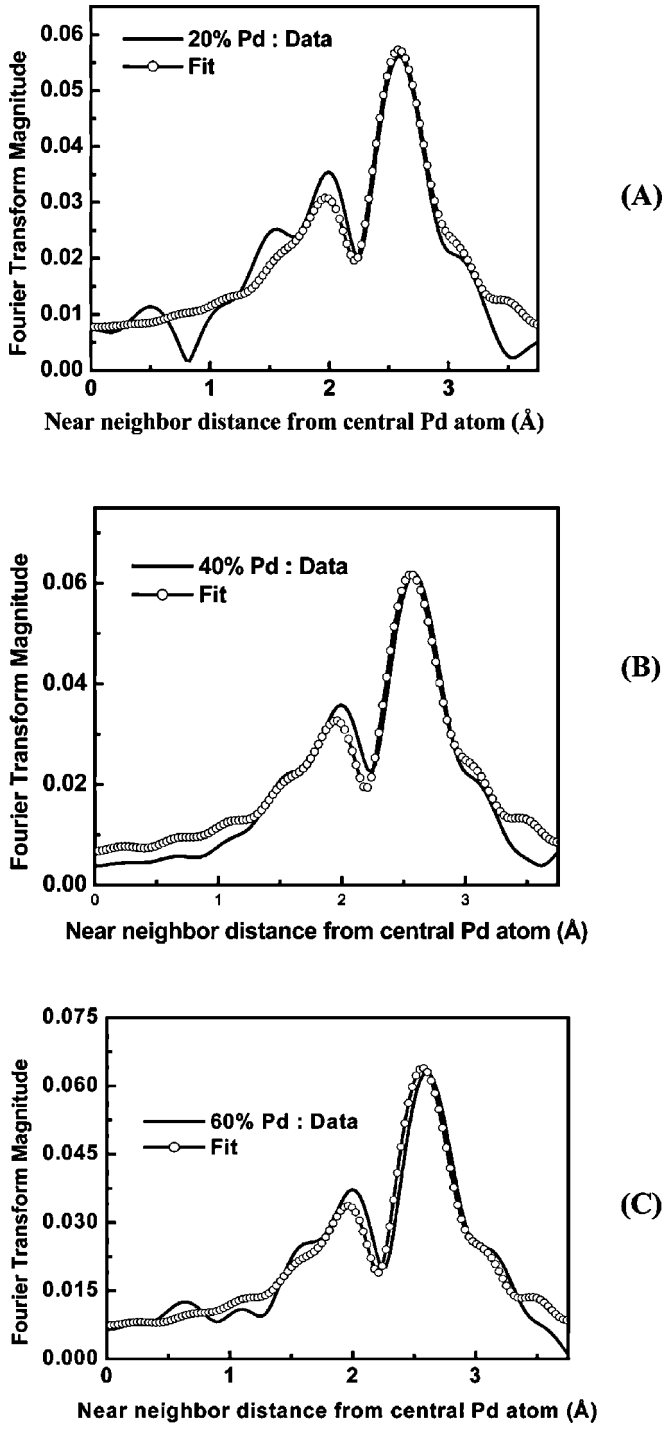

Fig. 4. Comparison of the fit with data for bimetallic nanorod system of Ag-Pd at Pd K-edge for the samples (a) $Pd_{0.2}Ag_{0.8}$, (b) $Pd_{0.4}Ag_{0.6}$ and (c) $Pd_{0.6}Ag_{0.4}$.

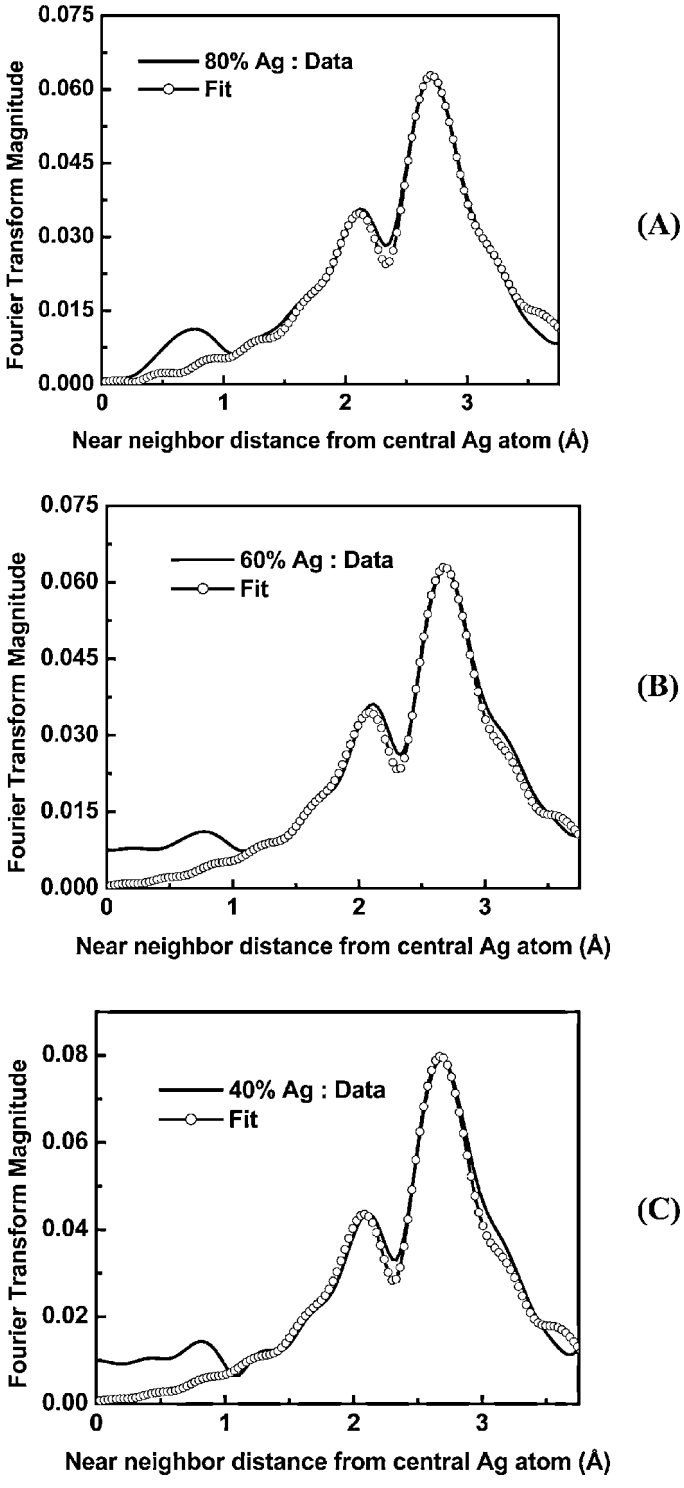

Fig. 5. Comparison of the fit with data for bimetallic nanorod system of Ag-Pd at Ag K-edge for the samples (a) $Ag_{0.8}$ $Pd_{0.2}$, (b) $Ag_{0.6}$ $Pd_{0.4}$ and (c) $Ag_{0.4}$ $Pd_{0.6}$.

The errors in the fitting parameters reflect a number of sources, one of which is the correlation between the various parameters. The fitting results varied as well, when we changed the near neighbor species. As mentioned in the previous paragraph, the backscattering amplitude and phase shift from Ag and Pd near neighbors are nearly indistinguishable. At each edge, we considered three different models for the nearest neighbors: (a) pure Pd atoms (b) pure Ag atoms and (c) a mixture of Ag and Pd atoms. The values obtained for the various fitting parameters varied slightly with the change in model. This variation has been included in our estimate of error. Despite all these errors, the change in the average near-neighbor distance, as a function of the % of impurity metal, is clearly systematic and significant. The change is however not linear and may be mistaken to be contradicting the well-established Vegard's law of alloying. This discrepancy may be resolved once we realize that Vegard's law is derived from diffraction experiments and depicts the average cell parameter from many unit cells. On the other hand, XAFS measurements probe the structure within a unit cell and hence the near neighbor distances, derived from XAFS, consist of a distribution of bond-lengths, which can lead to the observed deviation from linearity [19]. Also, in the case of our nanoparticle systems, there was a 10–20% distribution in the bimetallic composition ratios, which could contribute to the

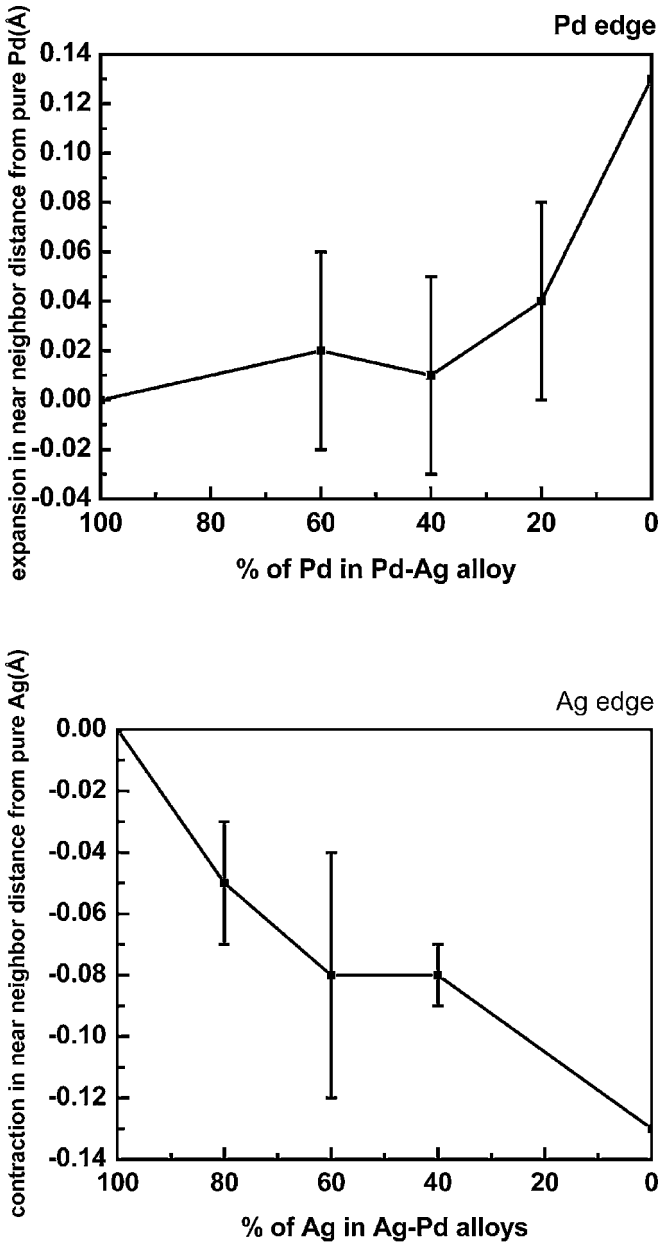

Fig. 6. (a) The expansion of the nearest neighbor distance in the Ag-Pd bimetallic nanoparticles as a function of the Pd molar ratio. (b): The contraction of the nearest neighbour distance in the Ag-Pd bimetallic nanoparticles as a function of the Ag molar ratio.

deviation. Surface relaxation could also contribute to the deviation from linearity. This nevertheless does not diminish our conclusion about alloying, since the changes in the near neighbor distance that we observe are clearly significant and systematic.

4. Conclusions

In conclusion, we have been successful in synthesizing bimetallic Ag-Pt and Ag-Pd nanowire systems by radiolysis. Ag-Pd nanowire systems have been found to form alloy whereas Ag-Pt does not form an alloy down to the lowest size obtained by us.

Abstract

We have carried out EXAFS analyses on polymer-protected CuPd nanoparticles with sizes of about 1.4 nm. We found that the Cu-Pd heterobond was preferentially created in the CuPd nanoparticle and we called this type of structure a "heterobondphilic structure". DFT calculation indicated the electron transfer from Cu to Pd which stabilized the CuPd nanoparticle. The catalytic activities and their relation to the heterobondphilic structure were discussed.

1. Introduction

Bimetallic nanoparticles show interesting behavior and composition-dependent physical and chemical properties which can not be found in monometallic nanoparticles. Stable and homogenous bimetallic nanoparticles dispersed in solution can be obtained in the presence of protecting polymers [1]. We have applied EXAFS on polymer protected bimetallic nanoparticles and found that there are a variety of inner structures in the nanoparticles such as core-shell model, solid solution model, and cluster-in-cluster structure [1]. CuPd bimetallic nanoparticle dispersed in glycol solution show unique composition dependence for diene hydrogenation and nitrile hydration reactions as shown in Figs. 4 and 5 [2, 3]. We found a new structure of the polymer-protected CuPd bimetallic nanoparticles, where Cu-Pd bond is preferentially formed [4]. We named this new structure a "heterobondphilic" structure. We also carried out DFT calculations to find the stability of the CuPd nanoparticles. We would like to discuss the stability of CuPd heterobondphilic structure and its relation to catalytic properties.

2. Experimental

CuPd bimetallic nanoparticles were prepared as described in previous literature [2]. EXAFS measurements were carried out at BL12B (Cu K-edge) and BL10B (Pd K-edge) in Photon Factory (KEK-IMSS-PF) [4]. CuPd foils (1 : 9, 1 : 1 and 9 : 1) were purchased from Tanaka Noble Metal Ltd. EXAFS analyses were carried out using Rex2000 (Rigaku Co.). The EXAFS oscillations were extracted using a cubic smoothing method and were Fourier transformed with k^3-weight. Inversely Fourier filtered data were analyzed by non-linear least square curve fitting methods. Backscattering amplitude and phase shift functions were derived from FEFF8 [5, 6].

3. Results and Discussion

Fig. 1 shows the EXAFS oscillations for CuPd bimetallic nanoparticles for both Cu and Pd K-edges. The EXAFS oscillations are tremendously damped for the CuPd bimetallic nanoparticles compared to those for the pure Cu and Pd nanoparticles. This is due to the destructive interference between Cu-Cu and Cu-Pd (or Pd-Cu and Pd-Pd) EXAFS oscillations. Pd is located one row below Cu in the periodic table and hence their phase shift is π radians different. This means that we have to be careful to determine the amplitude and phase shift functions to obtain the correct structure nanoparticles from the EXAFS analysis. As mentioned in the experimental section, we used FEFF8 for the determination of backscattering amplitude and phase shift functions. We checked the validity of these theoretically derived parameters by analyzing reference compounds such as Pd, Cu and CuPd bimetallic alloy foils. EXAFS oscillation of Cu foil was well reproduced by FEFF8 but that of Pd foil was not at low k-region, around 40–60 nm^{-1} [4]. Thus we corrected the Pd theoretical parameters less than 60 nm^{-1} using empirical values [4]. Consequently, we could successfully analyze the CuPd foils using backscattering amplitude and phase shift functions as shown in Table I. Note that we can obtain coordination numbers for CuPd 1 : 1 alloy foil which are equal to those expected from the random alloy structure within the limit of error. We applied these backscattering amplitude and phase shift functions to CuPd bimetallic nanoparticles. The fitting results were tabulated in Table II. Effects of asymmetric pair distribution have not been taken into account because the surface relaxation would be lifted by the interaction of the protecting polymer [4]. The necessary conditions imposed on the analyses of bimetallic materials such as $N_{\mathrm{PdCu}}C_{\mathrm{Pd}} = N_{\mathrm{CuPd}}C_{\mathrm{Cu}}$, $\gamma_{\mathrm{CuPd}} = \gamma_{\mathrm{PdCu}}$ were checked and we found these conditions were satisfied in the limit of error. There are three types of inner structures for bimetallic cluster, namely core-shell model, cluster-in-cluster model, and solid solution model. In the core-shell model, one component located in the core region should give larger total coordination numbers than the others located in the shell region. But in the EXAFS results both components have similar total coordination numbers (about 8). In the cluster-in-cluster model, coordination numbers of like pairs should be larger than those for unlike pairs but it was not the case. The facts that total coordination numbers were the same for both metals and the coordination numbers ratio followed the composition agreed well with the formation of solid solution model. However, the coordination number for unlike pairs seems to be larger than the values expected from the solid solution model. Fig. 2 shows the ratio of coordination numbers

of the unlike pairs to the total coordination numbers derived from EXAFS and calculated one based on solid solution model. The concave shape indicates that unlike pairs (hetero bond) such as Cu-Pd or Pd-Cu was preferably formed. We have carried out Monte Carlo simulations of the CuPd nanoparticle structure under the following simple assumptions. 1: The bond energy for Pd-Cu or Cu-Pd was larger than the average values for Cu-Cu and Pd-Pd. 2: The CuPd particle size was fixed to 1.3 nm (Average coordination number was 7.8). Table II contains the values expected from the model simulations. Thus the heterobondphilic structure can be realized if the unlike pair has a stronger bond than the like pair.

We have carried out DFT calculation based on 1, 3-atom clusters with fcc structure. When a Cu-Pd bond was formed, the total energies decreased as shown in Table III. Moreover, charge transfer from Pd to Cu occurred and the electron transfer from Cu 4s to Pd 4d stabilized the $CuPd_{12}$ or $PdCu_{12}$ cluster. The DFT calculations supported the stronger Cu-Pd heterobond than the homobond (Cu-Cu or Pd-Pd).

*Cu and Pd are located in the center of the nanoparticles of $CuPd_{12}$ and $PdCu_{12}$, respectively.

Figs. 3 and 4 show the composition-dependence of 1,3-cyclooctadiene hydrogenation activity and acrylonitrile hydration activity, respectively. The surface coordination number of Pd-Pd and Pd-Cu, which were obtained from the Monte Carlo simulation mentioned above, were also given in Fig. 3 and Fig. 4, respectively. In hydrogenation reaction, the reaction started with

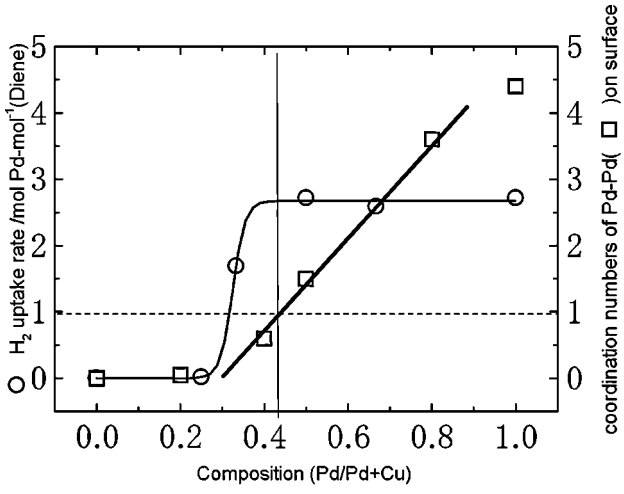

Fig. 3. Composition dependence of hydrogenation reaction rate (open circle) and surface coordination number of Pd-Pd (open square).

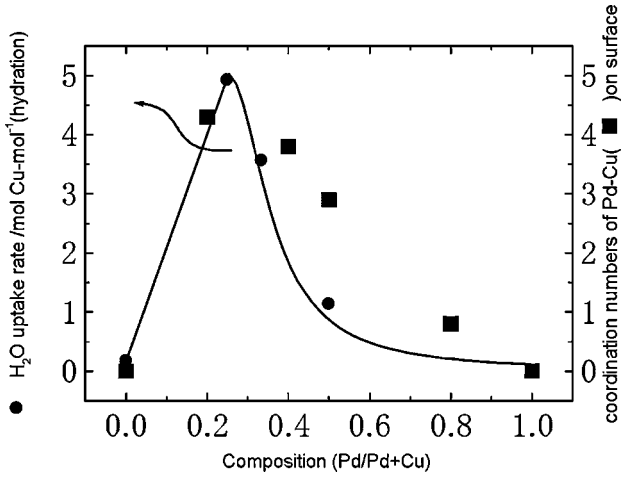

Fig. 4. Composition dependence of hydration reaction rate (filled circle) and surface Pd-Cu coordination number (filled square).

the appearance of Pd-Pd bond and the reaction was saturated when the Pd-Pd coordination number exceeded one. This result implies that the hydrogenation reaction requires at least one Pd-Pd ensemble. On the other hand, the hydration reaction requires Pd-Cu bond and the reaction rate is higher as the Pd-Cu coordination number increases. The hydration reaction may occur at the Pd-Cu ensemble in the synergistic catalysis of Pd and Cu [1].

The EXAFS analyses have shown that the Cu-Pd bimetallic nanoparticles have "heterobondphilic" structure as its inner structure. DFT calculation indicates that the Cu-Pd bond energy is stronger than that of homobond (Cu-Cu and Pd-Pd). The reactivity has a strong correlation with the composition of surface ensembles.

Abstract

The local structures of Pt thin films with thicknesses from 3 to 105 nm grown at 298 K have been studied by grazing incidence fluorescence XAFS technique. The results indicate that the bond length $R = 2.77$ Å and coordination number $N = 12.0$ of the first shell around Pt atoms in the Pt (105 nm) and Pt (30 nm) thin films are the same as those in Pt foil, except that the disorder degree σ increases by about 8%. The magnitude peaks (located at 2.77, 3.92, 4.80 and 5.55 Å) appearing in the radial distribution function curves suggest that the Pt (105 nm) and Pt (30 nm) thin films keep a long-range order. With thickness decreasing from 105 to 10 nm, the Debye-Waller factor σ^2 increases to 6.4×10^{-3} Å^2 ($\sigma^2 = 4.8 \times 10^{-3}$ Å^2 for the Pt foil). For the Pt (3 nm) ultra-thin film, R_1, N_1 and ${\sigma_1}^2$ are 2.78 Å, 10.1 and 7.1×10^{-3} Å^2, respectively. This implies that N_1 largely decreases and ${\sigma_1}^2$ strongly increases in the Pt (3 nm) ultra-thin film. Moreover, its magnitude peaks of the higher shells in the radial distribution function disappear for the Pt (3 nm) ultra-thin film. This result shows that the Pt lattice is largely distorted and the medium-range order around Pt atoms is completely destroyed for the Pt (3nm) ultra-thin film. We consider that the Pt lattice distortion of the Pt ultra-thin film originates from both interaction between Pt particles and SiO_2 substrate, and Pt grains with a smaller size forming a surface structure defect.

1. Introduction

Noble metal, such as Pt and Au, thin films are commonly used as electrodes extensively required for semiconductor devices with ultra-large-scale integration [1, 2]. In particular Pt thin film is a promising candidate for potential capacitor electrodes and gate metal material in gigabit dynamic random access memories and metal-oxide-semiconductor field effect transistors due to its high chemical stability in an oxidizing atmosphere and its high work function (5.6 eV) as well as other excellent electrical properties [3–5].

The performance of polycrystalline Pt thin film is strongly affected by its grain size distribution, impurity, defects, crystalline orientation, etc., and is intrinsically linked to the structure of the thin film [6–12]. Hiratani *et al*. [11] have found that the lattice shrinkage of Pt thin film fabricated by chemical vapor deposition increases with decreasing thickness below 35 nm, which can also lead to a higher resistance. Frenkel *et al*. [7] have reported that the bond length of the first nearest neighbors of Pt nano-clusters with an average size about 2.4 nm contracts. Lamber *et al*. [13] have shown a contraction in the lattice of Pd nano-clusters from their electron diffraction results. In order to clearly understand the nature of the Pt thin films and to optimize the growth conditions of Pt thin films, it is essential to determine the local structures of Pt thin films with different thicknesses from both fundamental and technological viewpoints.

In the present paper, grazing incidence fluorescence XAFS has been used to study the local structures of the Pt thin films fabricated by MBE in the thickness range from 3 to 105 nm. The local structures of Pt thin films depending on the thickness were accurately and reliably measured. This is favorable to optimize the growth conditions and fabrications of Pt film with a high quality.

2. Experimental

An ultrasmooth SiO_2 substrate with a surface roughness of 0.3 nm was cut into four pieces of approximately the same area. These small SiO_2 pieces were cleaned in acetone solution with an ultrasonic cleaner for 30 min. The Pt thin film was grown in a molecular-beam epitaxy (MBE) chamber. Before growing the Pt thin film, the SiO_2 substrate was cleaned by heating it to 1073 K for 1 h. Finally, the samples grown at room temperatures were fabricated with a growing rate of 0.10 nm/s. The thickness d of the samples is about 3, 10, 30, 105 nm, respectively. We have reported [6] that the surface topography of Pt (105 nm) thin film fabricated by MBE at 300 K is composed of three-dimensional, well-separated, mountain-like islands with about 1.81 nm roughness and grain sizes of about 10–20 nm.

The X-ray absorption spectra at the Pt L_{III}-edge for various Pt thin films were measured at the beamline of 4W1B of the Beijing Synchrotron Radiation Facility (BSRF) at room temperature. The electron beam energy was 2.2 GeV and the maximum stored current was about 80 mA. Fixed-exit Si (111) flat double crystals were used as monochromator. XAFS spectra of Pt thin films with thicknesses of 3 and 10 nm were collected in grazing-incidence fluorescence mode with an incidence angle of 0.19 degrees. The XAFS spectrum of Pt foil was collected in transmission mode. XAFS spectra of Pt thin films with thicknesses of 30 and 105 nm were collected in fluorescence mode with an incidence angle of 45 degrees. The XAFS data were analyzed by NSRLXAFS 3.0 software packages [14].

3. Results and discussion

Pt L_{III}-edge EXAFS functions $\chi(k)$ and their Fourier transformations (FT) for the Pt thin films with thicknesses of 3, 10, 30 and 105 nm are shown in Figure 1 and Figure 2, respectively. Figure 2 demonstrates that the FT curves of Pt (30 nm) and Pt (105 nm) thin films are similar to that of Pt foil. There are four obvious peaks located at 2.7, 3.9, 4.8 and 5.6 Å corresponding to the first four shells around Pt atoms in the fcc structural Pt crystal.

*Correspondent: Shiqiang Wei. E-mail: sqwei@ustc.edu.cn

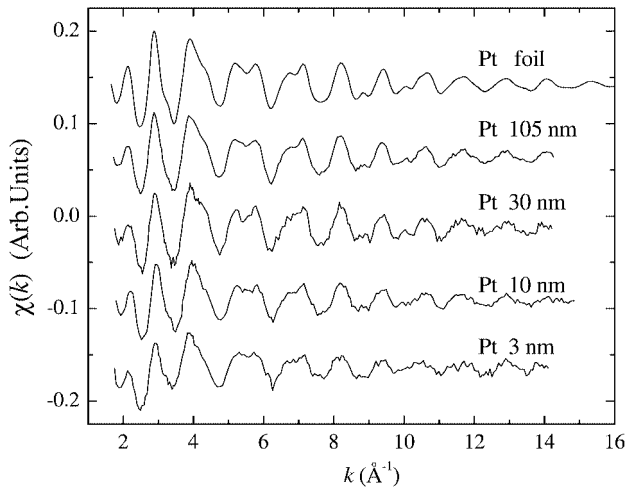

Fig. 1. EXAFS oscillation functions for Pt thin films with different thicknesses.

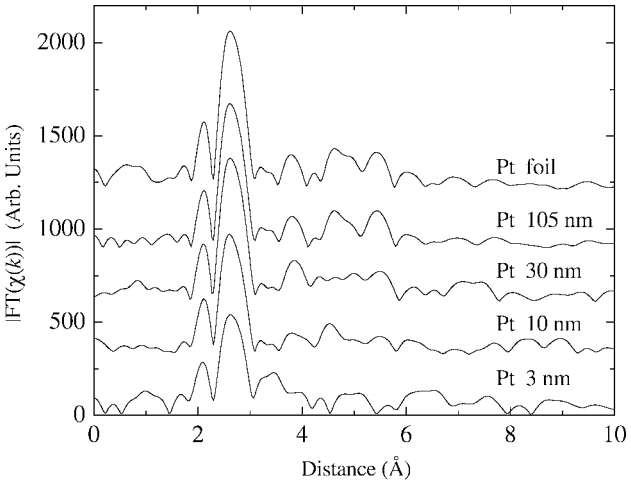

Fig. 2. Radial distribution functions for Pt thin films with different thicknesses.

For the Pt (3 nm) thinner film, the intensity of the first peak is much lower (about 70% of the Pt (105 nm) thin film), and the peaks of the higher shells disappear. It means that the medium-range order of Pt atoms has been destroyed for the Pt (3 nm) thinner film.

For obtaining the structural parameters of Pt thin films, a least-squares curve fit was performed for the data analysis by using the NSRLXAFS3.0 software packages [14]. The theoretical amplitude functions and phase shifts were calculated by FEFF7 [15]. The curve fits, based on single-scattering theory, were performed in the R-range between 1.9 and 3.1 Å. The fitting results are summarized in Table I.

Seen from Table I, the bond length R and the coordination number N is 2.77 Å and 12.0 for Pt foil, Pt (105 nm) and Pt (30 nm) thin films, respectively. However, the Debye-Waller factor σ^2 increases slightly from 0.0048 to 0.0052 and 0.0055 Å^2 with the reduction of the thickness of the Pt thin films. This indicates that the local structure of the Pt thin films with thicknesses of 30 and 105 nm are almost the same as that of Pt foil. This shows clearly that the Pt thin films keep the long-rang order and possess fcc structure when the thickness of the films is above 30 nm. An evident change occurs in the Pt (10 nm) thin film, and its R_1, N_1, and ${\sigma_1}^2$ is 2.77 Å, 11.3 and 0.0061 Å^2, respectively. This shows that there is a small lattice distortion in the Pt (10 nm) thin film. For the Pt (3 nm) thinner film, R_1, N_1, and ${\sigma_1}^2$ is 2.78 Å, 10.8 and 0.0077 Å^2, respectively. This result indicates that the local structure of the Pt (3 nm) thinner film is significantly different from those of the other Pt thin films.

In our previous work [16], it has been revealed that the densities of Pt thin films with thicknesses over 10 nm are larger than that of 94% of bulk Pt. This means that there is a smaller defect and a close compact in the as-deposited Pt thin films. Moreover, it has been shown that the root mean square (RMS) roughness on the surface of the Pt thin films is much lower than their thickness. Hence, the Pt atomic ratio of surface to bulk is very small for Pt thin films with thicknesses over 10 nm. This result is in good agreement with the XAFS results listed in Table I.

At the initial stage of growth of the Pt (3 nm) thinner film, it is favorable to grow the well-separated three-dimensional Pt islands that do not coalesce together. The lateral size of these grains is typically 10 nm as estimated by AFM [6], which has a higher ratio of surface to bulk in the Pt (3 nm) thin film. Therefore, we consider that the large lattice distortion is responsible for the reduction of coordination number (10.8) of the first shell in the Pt (3 nm) thin film as compared with that in bulk Pt foil. On the other hand, we have noted that σ^2 (0.0077 Å^2) of the Pt (3 nm) film is much larger than that ($\sigma^2 = 0.0052$ Å^2) of the Pt (105 nm) thin film. One of the most plausible explanations for the larger disorder degree is the relaxation of the bond lengths exhibited by surface atoms, driven by the substantial surface tension of a high curvature radius [17–19]. In response to this compressive tension, the atomic positions of the surface atoms shift away from the ideal fcc sites and cause lattice distortion. This process also destroys the medium-range order of the Pt (3 nm) thin film. Furthermore, the density measurement [16] shows that the density of Pt (3 nm) thin film is reduced to 87.8% of the density of bulk Pt, implying the existence of a large defect.

In summary, the fluorescence XAFS results show that the local structures of the Pt thin films with thicknesses between 30 and 105 nm remain of long-range order, and are nearly the same as that of Pt foil. With the Pt thin film thickness decreasing to 3 nm, the medium-range order around Pt atoms has been completely destroyed. We consider that the Pt lattice distortion of the Pt thin film with thickness of 3 nm originates from both the interaction between Pt particles and SiO_2 substrate, and Pt grains with smaller size forming a surface structure defect.

Abstract

The local structures around Mo supported on USY zeolites containing different amounts of extra-framework Al species (EFAL) were investigated to elucidate the effects of EFAL on the location and dispersion of Mo sulfide catalysts. Mo K-edge EXAFS analysis indicated that Mo sulfide catalysts were highly dispersed and located, at least in part, in the micropores of USY zeolites, independent of the EFAL amounts. The dispersion of Mo sulfide was found to decrease with increasing amount of EFAL in the zeolites. EXAFS analysis of Mo oxide catalysts, the precursor of the sulfide catalysts, suggested that Mo oxide catalysts deposited on EFAL during the catalyst preparation were reluctant to disperse into micropores and formed larger MoS_2 clusters during sulfiding that lowered the dispersion.

1. Introduction

Y-type zeolites with Mo sulfide are promising catalysts for hydrocracking petroleum fractions. Because zeolitic micropores cannot accommodate large molecules in the heavy petroleum fractions, the active catalytic sites of Y-type zeolites are limited to the external surfaces, which are classified into two categories; the external surface of zeolite particles and the surface of mesopores with diameters between 2 nm and 50 nm. The roles of the mesopore surface in the cracking reactions are quite important because the external surface area of zeolite particles is not large enough to achieve high catalytic activity [1, 2]. Mesopores of Y-type zeolite are formed in many cases by steaming over 800 K that extracts Al from the zeolitic framework. During the following calcination procedure, the extracted Al forms so-called extra-framework Al species (EFAL), which are mainly deposited in the mesopores and micropores. EFAL is supposed to affect the location and dispersion of Mo sulfide catalysts on the zeolites that are important factors to control the catalytic activities. In the present study, we prepared a series of Mo/ultrastable Y-type (USY) zeolite catalysts with different amounts of EFAL and analyzed the local structure around Mo. Based on the results, we discussed the effects of EFAL on the dispersion and location of Mo sulfide catalysts in the USY zeolites.

2. Experimental

Three kinds of zeolites were used in the present study. Tosoh 330HUA (framework Si/Al = 9.7) was chosen as the starting USY zeolite (USY-A) containing a considerable amount of EFAL. USY-B was obtained by treating USY-A in a 0.1 mol/l HCl solution for 1 h at 298 K, followed by washing with water and drying at 393 K for 12 h. USY-C was obtained from USY-B by repeating the above procedure. Mo/USY catalysts were prepared by incipient wetness impregnation of the above zeolite powders with an aqueous solution of ammonium heptamolybdate ($(NH_4)_6Mo_7O_{24}$). The Mo loading was 6.7 wt% as MoO_3. After the impregnation, the catalysts were dried at 393 K and calcined at 823 K in dry air. The porosity and mesopore size distribution of the catalysts were calculated by using N_2 isotherm at 77 K. The bulk composition of zeolite was measured by chemical analysis, whereas the Al/Si ratio of the zeolitic framework was calculated from the unit cell parameters obtained by X-ray diffraction (XRD) [3].

The Mo K-edge EXAFS spectra of the catalysts before and after sulfidation were measured at the BL-10B of the Photon Factory at the High Energy Accelerator Research Organization (Tsukuba, Japan). The EXAFS spectra of the catalysts before sulfidation were obtained by measuring the absorption spectra of the self-supporting disk made of the catalyst powders in the transmission mode at an ambient atmosphere. The disk was then placed in a glass cell with Kapton windows and sulfided at 673 K in a flow of 5% H_2S/H_2 for 2 h. After purging the cell by N_2, the EXAFS spectra of the catalysts after sulfidation were obtained. The phase shift and backscattering amplitude factor were corrected by using the calculated values of FEFF6 [4]. In the analysis of the catalysts after sulfidation, the average coordination number of Mo-Mo (CN(Mo)) was obtained using the following relation [5, 6],

$$N(Mo) = BIr^2 \tag{1}$$

where B is the proportionality constant for Mo-Mo scattering obtained from the crystal of MoS_2 that has six Mo atoms around each Mo atom, I is the peak intensity of Mo-Mo scattering, and r is the distance between the Mo atoms. Note that it is assumed that the thermal and static disorders are constant.

3. Results and Discussion

3.1. *EXAFS measurements for Mo/USY before the sulfidation*

Table I shows the physical properties of the USY zeolites. For USY-A, the Si/Al ratio of the framework was 9.7, which was almost as three times as large as that of the bulk (3.2). The discrepancies between the Si/Al ratios of the framework and that of the bulk decreased in the order of USY-A < USY-B < USY-C. Table I also showed that the mesopore and micropore volumes increased in the order of USY-A < USY-B < USY-C. These results indicate that the HCl treatment effectively removed EFAL deposited in the mesopores and micropores of the starting USY-A.

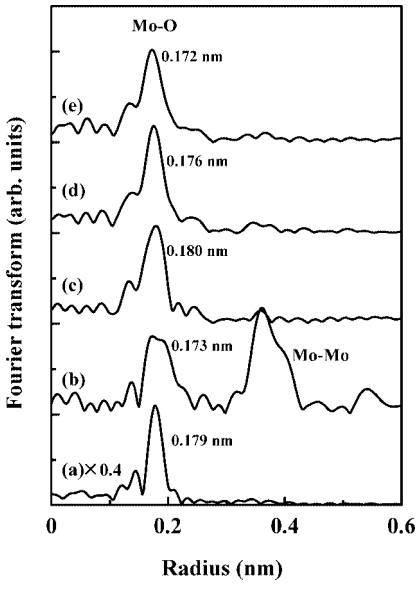

Fig. 1. Fourier transforms of the Mo K-edge EXAFS spectra for Mo/USY before the sulfidation. (a): $Na_2MoO_4 \cdot 2H_2O$, (b): MoO_3, (c): Mo/USY-A, (d): Mo/USY-B, (e): Mo/USY-C. The Mo-O distances are indicated in the figure.

Figure 1 shows the Fourier transformed EXAFS spectra of reference materials and Mo/USY catalysts before sulfidation. The spectrum of $Na_2MoO_4 \cdot 2H_2O$ (Fig. 1(a)) gave an intense peak at 0.178 nm that is assigned to tertahedrally coordinated Mo-O scattering. In contrast, the spectrum of MoO_3 (Fig. 1(b)) gave a broad peak between 0.17 nm–0.20 nm that is assigned to octahedrally coordinated Mo-O scattering and another peak at about 0.36 nm that is assigned to Mo-Mo scattering in the second nearest shell. Four oxygen atoms in MoO_4^{2-} are located at almost the same distance from Mo (0.175 nm–0.179 nm) [7], whereas MoO_6 octahedra are highly distorted and six oxygen atoms are located at 0.167 nm–0.223 nm with single or double bonding to Mo [8].

The spectra of all the three zeolites (Fig. 1(c)–(e)) gave peaks between 0.172 nm and 0.180 nm. Considering the relatively low and broad peaks, these peaks are likely assigned to Mo-O scattering of mixed MoO_4 tetrahedra and MoO_6 octahedra. Among the three USY zeolites, the Mo-O peak shifted from 0.180 nm of USY-A (c) to 0.172 nm of USY-C (e). The short Mo-O distance observed for USY-C is likely ascribed to dominant presence of octahedral Mo-O bonding, whereas the long Mo-O distance observed for USY-A is likely due to dominant presence of tetrahedral Mo-O bonding. Note that the Mo-O distance decreased with increasing EFAL amounts in zeolites.

Shimada *et al.* [9] reported EXAFS spectra of Mo oxide catalysts supported on various oxides. In their results, the ratio of tetrahedral Mo-O bonding relative to the total Mo-O bonding decreased in the order of $MgO > Al_2O_3 > SiO_2 > TiO_2$; the SiO_2 support favored the octahedrally coordinated MoO_3-like structure, whereas the Al_2O_3 support favored tetrahedral coordination around Mo particularly at low Mo loading. Their result is in good agreement with the present study described above. Namely, the relative ratio of octahedral Mo-O bonding increases with increasing amount of EFAL in the USY zeolites. Note that the surface of USY zeolite with high Si/Al ratios has similar chemical properties as those of SiO_2.

Previous papers [10, 11] indicate that Mo oxide catalysts are poorly dispersed on SiO_2 supports and sometimes give evidence to MoO_3-like structures. The spectrum of USY-C (Fig. 1(e)), however, showed no peak due to Mo-Mo scattering that was observed in the spectrum of MoO_3 (Fig. 1(b)). This suggests that Mo oxide species in USY-C are dispersed and distorted. Heptamolybdate anions ($Mo_7O_{24}^{6-}$), the precursor of Mo oxide catalysts, cannot penetrate into the micropores during the impregnation and are deposited on the mesopore surface. The deposited Mo oxide species are decomposed and can migrate into the micropores during calcination that is performed at higher temperatures than 573 K [12]. In the case of USY-C with the smallest amount of EFAL, Mo oxide species deposited on the USY zeolite surface relatively easily migrated and formed distorted octahedral Mo oxide in the micropores. Note that the USY micropores with a diameter of 0.74 nm hinder the growth of crystalline structures. On the other hand, heptamolybdate anions deposited on EFAL did not migrate into the micropores due to the relatively strong interaction between Mo oxide and EFAL. This is confirmed in the relatively large decrease in the mesopore volume of USY-A after Mo loading (Table I).

3.2. *EXAFS measurements for Mo/USY after the sulfidation*

Figure 2 shows the Fourier transformed EXAFS spectra of MoS_2 and Mo/USY catalysts after sulfidation. All the spectra exhibit two intense peaks at 0.239 nm and at 0.313 nm, which are assigned to Mo-S scattering and Mo-Mo scattering, respectively. The average coordination numbers (CN(Mo)) decrease in the order of Mo/USY-A (1.82) > Mo/USY-B (1.61) >Mo/USY-C (1.25). Because of high distortion of layered MoS_2 structures, the average size of MoS_2 clusters cannot be estimated directly from the CN(Mo) obtained from EXAFS [13–16]. Using a recently proposed relationship between the CN(Mo) and the average particle size of MoS_2 clusters that took into account the effects of the structural distortion and disorder on EXAFS [16], the

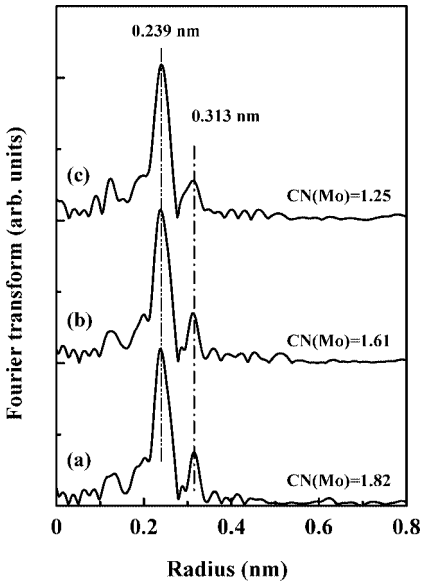

Fig. 2. Fourier transforms of the Mo K-edge EXAFS spectra for Mo/USY after the sulfidation. (a): Mo/USY-A, (b): Mo/USY-B, (b): Mo/USY-C.

average size of the MoS_2 clusters in the present catalysts were approximately estimated to 1.7 nm for USY-A, 1.6 nm for USY-B, and 1.4 nm for USY-C.

Considering the micropore size (0.74 nm) of USY zeolites, at least a part of the MoS_2 clusters were located inside the micropores. The above results on the CN(Mo) suggest that the relative ratio of the MoS_2 located inside the micropores to the total MoS_2 content decreases in the order of Mo/USY-C > Mo/USY-B > Mo/USY-A. This is consistent with the order of the micropore volumes after Mo loading (Table I). In other words, the amount of MoS_2 located on the mesopore surface increased with increasing EFAL in USY zeolites. This simultaneously resulted in the relatively large MoS_2 clusters in the zeolite with a large amount of EFAL. These discussions indicate that the location of Mo was likely fixed during the calcination, although it cannot be precluded that sulfidation promoted the migration of a part of Mo species from the mesopore surface into the micropores.

From the viewpoint of catalytic properties for advanced hydrocracking catalysts, even distribution of MoS_2 clusters in the mesopores and micropores is favorable to prevent overcracking or coking on the solid acid sites of USY zeolites. Furthermore, smaller MoS_2 clusters increase the number of active catalytic sites. The present results suggest that USY-C with the smallest EFAL has the most suitable properties as a support for hydrocracking catalysts.

4. Summary and conclusion

EXAFS spectroscopy was applied to the determination of the location and dispersion of MoS_2 clusters in three USY zeolites with different amounts of EFAL. The results indicated that a part of the MoS_2 clusters was located in the micropores, whereas the remainder was located on EFAL in the mesopores. This resulted in a better distribution and higher dispersion of MoS_2 clusters in the zeolite with a smaller amount of EFAL. Furthermore, large MoS_2 clusters suggested in Mo/USY-A might plug the mesopores of the USY zeolites. The analysis of the catalysts before sulfidation indicated that the location and dispersion of MoS_2 clusters were mostly fixed during the calcination procedure due to the stronger interaction between Mo oxide and EFAL than that between Mo oxide and the USY zeolite surface.

Abstract

CTAB (Cetyltrimethylammonium bromide) stabilized cobalt nanoparticles of three different sizes between 5.5 and 11 nm diameter were prepared using reverse-micelle method. Their geometric and electronic structure was characterized using X-ray Absorption Spectroscopy (XAS) at the Co-K-edge and Transmission Electron Spectroscopy (TEM). The as-prepared nanoparticles appear to have a cobalt core that is a "mixture" of the Co-α and β-phase and a shell, possibly, made of a cobalt(III) octahedral complex. The "shell" disappears when the particles are annealed to 250 °C and the particles are transformed into the "standard" hcp (α) phase. The short time stability of the particles against oxidation supports the presence of a core-shell structure with a Co core and a "protective shell". A longer exposure to air leads to a more or less complete oxidation of the entire particle to CoO.

1. Introduction

One of the most important challenges of nanoscience is to delineate the size-dependent properties of nanoparticles as it should – at least in principle – be possible to tune specific properties such as magnetism, heat capacity, optical, photoconductivity and charge transfer, electronic, melting point, catalytic by varying the size of the nanoparticles and/or the stabilizing surfactant coating. Despite the fact that several research groups have been focusing their attention to the correlation of macroscopic physical and chemical properties of nanoparticles with size [1], very little or no information is available about the size dependent electronic and geometric structure of nanoparticles [2]. In general, the power which changes morphology and thus also the electronic properties of nanoparticles is the increasing influence of the surface on the system. There are, however, several possibilities how these influences can modify the morphology and/or the electronic structure of such particles. On the one hand, especially for small metal particles, a chemical interaction at the surface may either lead to defined surface states or even influence the entire particle and its morphology [3]. On the other hand there is a pure crystallographic phase transformation, induced by the growing importance of the surface energy term to the total energy, in which the chemical composition of the sample remains identical and only changes in the arrangements of atoms and/or building blocks are responsible for changing particle properties. Examples for this effect occur rarely in a pure form [4], more often one finds that contributions of several phases are present simultaneously [5]. Finally, the formation of core-shell structures of different composition is possible [6]. Gaining this type of structural information is also crucial for an understanding of the magnetic properties of such particles, which deviate in most cases from what is expected from straightforward downscaling of the corresponding bulk magnetic properties.

In numerous recent studies, (e.g. ref. given in [3] and [4]) it has been shown that X-ray absorption spectroscopy can contribute significantly to the characterization of nanoparticles in general. Specifically, X-ray absorption spectroscopy is a useful technique for illuminating size dependent effects in these systems. This assertion is bolstered by calculation of theoretical spectra, which can at least partly compensate for the lack of "realistic" reference samples which is typical for investigations on nanoparticles.

Recently, cobalt nanoparticles have attracted a lot of interest not only because of their magnetic properties and potential to produce two and three dimensional self-assemblies [5, 7] but also as they are observed in various crystallographic phases as ε-Co [5, 7] bcc and fcc [8] but also a mixtures of hcp and fcc [9]. Until now it is not clear whether the actual phase depends on the size and/or the preparation route. The goal of this paper is to provide some additional information to solve these problems.

2. Experimental

2.1. *Reverse-micelle synthesis of cobalt nanoparticles*

Particles were synthesized using a reverse micelle technique. By varying the relative amount of water and surfactant used for preparation of microemulsion, three different sizes of cobalt nanoparticles were prepared. All the synthesis steps were carried out in Ar/N_2 atmosphere, using standard Schlenk technique, to avoid possible oxygen contamination.

2.2. *Transmission Electron Microscopy*

TEM studies were carried out using a JEOL TEM 2010 operating at 200 kV. The cobalt nanoparticles were dispersed in 5% octanol in octane and a drop of this solution was placed on a carbon-coated Formvar copper grid. The grids were allowed to dry undisturbed under ambient conditions for 15 min before TEM measurements were carried out.

2.3. *X-ray Absorption Spectroscopy*

Experiments were performed at the double crystal monochromator (DCM) and the X-ray Micro-Probe (XMP) beamlines at the 1.3 GeV electron storage ring of the Center for Advanced Microstructures and Devices (CAMD) synchrotron radiation facility at Louisiana State University. The experiments were performed in standard transmission using ionization chambers

filled with air at 1 atm. pressure as intensity monitor and as detector. The Lemmonier type monochromator was equipped with Si (311) crystals, and the photon energy was calibrated relative to the absorption spectrum of a standard 7.5 μm cobalt foil setting the first inflection point at an energy of 7709 eV. XANES spectra were collected in the −100 to +250 eV range relative to the Co K-edge, with approximate step sizes of 0.5 eV and 1 s integration time. Standard XANES data analysis was performed using the WINXAS97 software package, where raw spectra were normalized and background corrected by fitting the pre-edge region with a straight line, and the post-edge region with a third order polynomial.

To check the correlation between the XANES spectra and relevant model phases, the spectra of a number of reference phases were calculated using version 8.2 of the FEFF8 code [10].

3. Results and discussion

Average particle sizes as determined by TEM were 5.5, 8 and 11 nm respectively with a standard deviation of about 20%. Selected area electron diffraction (SAED) pattern analysis that averaged over several particles demonstrated that all three samples were composed of mixtures of hexagonal α-Co and face-centered cubic β-Co. No significant contributions from the ε-phase and/or any other compounds were detected.

Figure 1a shows the Co K-XANES spectra of CTAB-stabilized Cobalt nanoparticles of three different sizes. Evidently, clear and systematic changes in the spectra can be observed: with increasing particle size, the pre-edge structure located at 7708 eV gains intensity. In contrast to that, the maximum absorption in the edge region is reduced significantly.

Intuitively, one expects that with increasing particle size the similarity to the spectrum of hcp Cobalt, which is displayed in Figure 1b together with several other reference spectra, increases. At first sight, the observed size-dependent changes support this idea, as the observed changes in intensity in the spectra of the nanoparticle occur exactly at those energy positions where spectral features in the Co foil spectrum are located. However, even the spectrum of the largest particles with a diameter of about 11 nm is still significantly different from the one of pure hcp-Co. In fact, it is possible to reproduce the spectra of both the 11 nm and the 8 nm particles by linear superposition of the spectra of the smallest particles, whose average diameter is 5.5 nm, and that of hcp Co as shown also in Figure 1b. This basis set was chosen being aware of the fact that there are no "perfect" reference compounds available for the analysis of the spectra of nanoparticles. The spectrum of the 5.5 nm sample was chosen as it is a reasonable basis representing fcc contributions and the special (core-shell) structure of the here synthesized particles. From this fit, an hcp content of about 40% for the 11 nm particle and of about 19.5% for the 8 nm particle, respectively, can be derived. The error range for these numbers can be estimated to be ±5%. At the same time, the TEM pictures show homogenous (hcp and fcc) particles and no indication of additional phases and/or compounds. These observations together with the short time stability of the particles against oxidation (cf. below) can be interpreted assuming a core-shell type structure of the particles. Interestingly, a similar result has been obtained in a recent study on CTAB stabilized CeO_2 nanoparticles, which were reported to possess a Ce^{3+} shell.

If one assumes spherical particles, similar Co densities in core and shell, and the absence of significant amounts of hcp Co in the spectrum of the smallest particles, it is possible to extract the

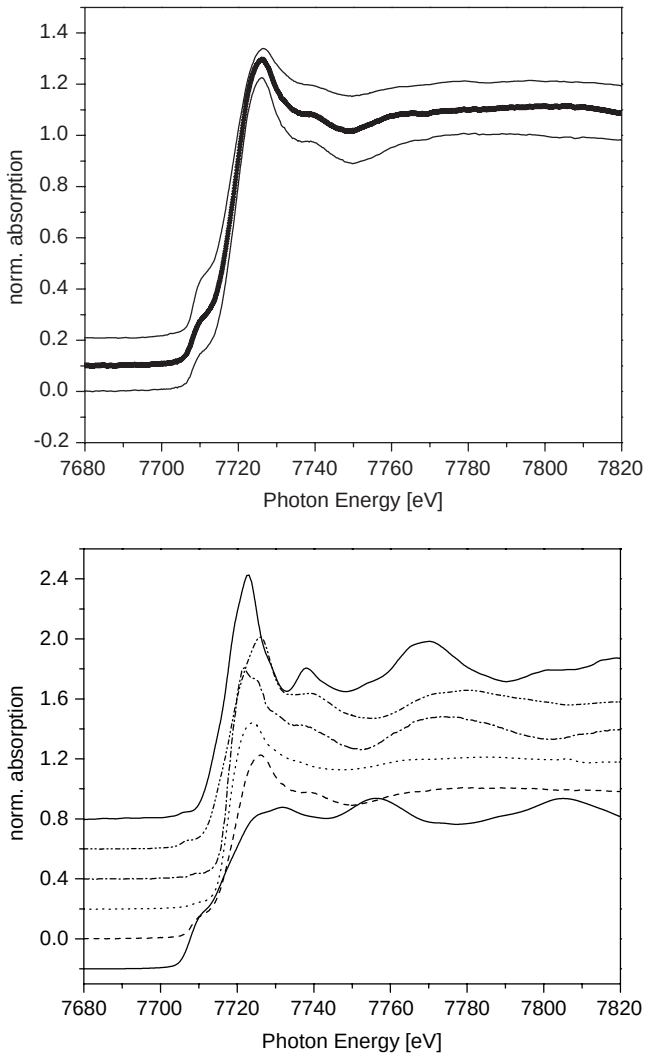

Fig. 1. a) Co-K-XANES spectra of the 3 nanoparticles: from top to bottom: 11 nm, 8 nm and 5.5 nm, the crosses in the spectrum of the 8 nm particles are the fitted spectrum (cf. text); b) Co-K-XANES spectra of some reference compounds: from top to bottom: CoO, Co_2O_3, $CoCl_2$, $CoBr_2$, Co (5 nm) sample Co-metal foil.

thickness of the respective cores and shells for the particles from the hcp Co contributions. For the 5.5 nm particle the hcp content can be estimated from the intensity of the pre-edge structure to be about 40%. The determined hcp Co contribution corresponds in this scenario to the quotient of the cube of the core radius r_c and the cube of the total radius r_t. Performing this calculation, we obtain a core radius of 4.75 nm for the particles with 11 nm diameter, a core radius of 3.15 nm for the particles with 8 nm diameter and a core radius of 2 nm for the 5.5 nm particle. Note that all values indicate an identical shell thickness for all three types of particles of about 0.8 nm, which in turn enhances the plausibility of the assumptions.

Evidently, this leaves us with the key problem of identifying the nature of the shell. Before tackling this problem directly, we shall gather some additional information on this shell based on the behavior of the particles during annealing and upon exposure to air.

Fig. 2 shows the Co-K- XANES spectra of samples exposed to air. First of all, it must be noted that there is a considerable resistivity against oxidation during short-term exposure to air, whereas after long-term exposure to air, the spectra of the particles are indistinguishable from the spectra of CoO. The degree to which conversion of the nanoparticles to CoO has happened at

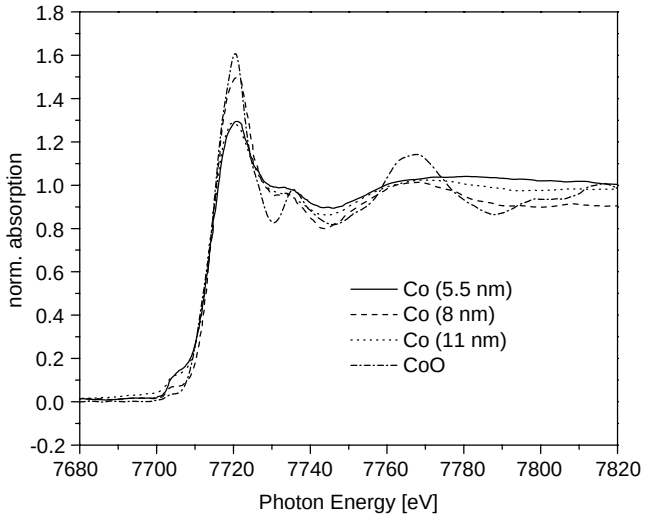

Fig. 2. Co-K-XANES spectra of the 3 nanoparticles after exposure to air for about 1 month in comparison with the spectrum of CoO.

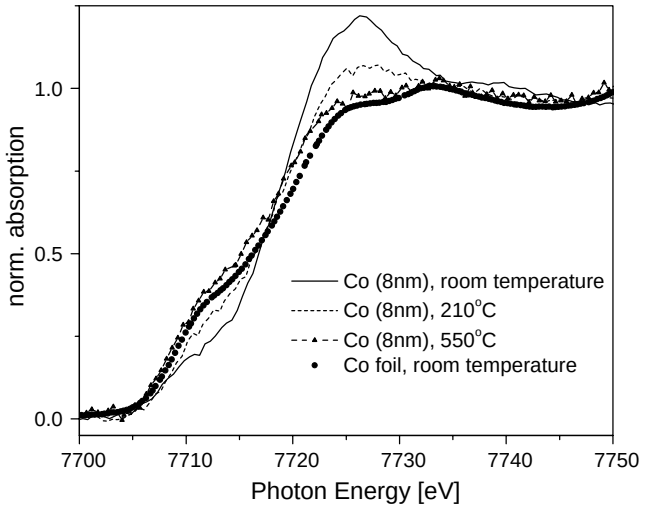

Fig. 3. Co-K-XANES spectra of Co (8 nm) measured *in situ* as a function of temperature in comparison with the spectrum of a Co-metal foil.

a given point of time is smallest for the smallest particles. At first sight, this is a seemingly counterintuitive behavior, as smaller particles usually show a significantly higher rate of oxidation, whereas here they appear to be most stable against exposure to air. This surprise is, however, quickly resolved if there is a core-shell structure of the particles, as already postulated above: The smaller the total particle size is, the higher is the relative contribution of the shell to the total spectrum. Consequently, a shell which offers more resistance against oxidation than the hcp Co core can easily induce the slower oxidation of a smaller particle, simply as the shell material oxidizes at a slower pace.

Figure 3 shows some of the Co-K-XANES spectra of the 8 nm sample recorded in situ during an annealing process under He-atmosphere. First significant changes in the intensity of white line and the structure in the rising edge are observed already at about 180 °C. Then, the spectra approach very fast that of the hcp-Co-foil. Already at about 360 °C there is hardly any difference between these two spectra indicating a complete transformation of the nanoparticles into hcp Co.

A likely candidate for the shell would be a cobalt oxide, such as CoO or Co_2O_3. (c.f. Fig. 1b). The latter compound appears to be the most likely candidate, as the similarity between the spectral features of this spectrum and the observed white line of the smallest nanoparticle is extremely. If this was the case, it should be possible to reproduce the XANES spectra of the smallest particle by a linear superposition of the spectra of hcp Co and the corresponding oxide, which fails completely for both types of Co-oxides as the white line intensity of the oxides is too high relative to their spectral contribution. One possible way to explain this observation is to postulate that we are witnessing indirectly a size effect on the spectrum of hcp cobalt. The pre-edge shoulder which is typical for the K-edge spectra of a 3d transition metal has been interpreted by several authors as an effect of pd-hybridization. If one follows this approach and bears in mind that decreasing the number of atoms in the system should decrease the width of the respective electronic bands and thus reduce their overlap, the intensity of the pre-edge structure should be reduced in a tiny Co particle. Consequently, the relative contribution of the Co spectrum, whose contribution is limited in the fit by the penalty obtained from an overshoot in the region of the pre-edge structure might be higher. In addition, the assumption of Co_2O_3 as being the compound forming the shell faces the problem that the long-time exposure to air converts the particles to CoO, which seems to be an unlikely reaction to happen from the thermodynamical point of view. Also the behavior upon annealing is of course inconsistent with assuming any type of oxide for the shell as all these compounds are very stable.

One of the factors which influence systematically the intensity of the whiteline of a given XANES spectrum is the formal electronegativity of the nearest neighbors. To visualize this effect, the Co-K-XANES spectra of CoO, $CoCl_2$ and $CoBr_2$ are also displayed in Figure 1b. As expected, the relative intensity of the white line decreases systematically, whereas the energy position of the spectral features of these Co(II) compounds varies only slightly. Whereas seemingly the shape and intensity of the whiteline of $CoBr_2$ agree rather well with the structures observed in the spectrum of the smallest nanoparticle, the attempt to achieve a good reproduction of the latter spectrum based on the linear superposition of the spectra of hcp Co and $CoBr_2$ fails.

However, the comparison of the spectrum of the smallest particle to the ones of the different Co(II) reference spectra indicates clearly that under the assumption that the shell material dominates the constituents of the smallest particle, this material must contain Co(III). Keeping also in mind that the shell gets destroyed completely at very low temperature of ∼210 °C, more likely candidates for the shell are Co(III) complexes such as $Co[(NH_3)_6]Br_3$ and $Co[(NR_3)_6]Br_3$. We are in the process of obtaining additional experimental evidence to confirm this assumption. The formation of these complexes and also the observed core-shell structure of the particles seem to be "typical" for CTAB as none of these effects had been reported for Co-nanoparticles stabilized with other surfactants.

Abstract

Promotion of sulfated zirconia (SZ) with Mn or Fe results in an orders of magnitude more active catalyst for the skeletal isomerization of *n*-butane. One explanation for this promotion effect, consistent with rapid deactivation observed for these catalysts, suggests that the promoter participates in non-catalytic redox reactions. In order to test this hypothesis it was necessary to measure the Mn valence under reaction conditions (in situ). However, it was found that the catalysts have a reduced activity when pressed into pellets for measurement. Therefore, we designed an in situ cell that could be used to measure spectra of a powdered catalyst sample. The cell consists of an internal powder bed reactor (heatable to 773 K), which is enclosed in a He-filled, temperature controlled outer cell to ensure that the window to the inner cell, and the catalyst it contacts, are at a well-defined temperature. The reactor characteristics of the new cell are shown to be comparable to those of a quartz tubular reactor. Spectra are measured in fluorescence mode with simultaneous measurement of a reference foil in transmission using a section of the beam that bypasses the catalyst bed. Contrary to previous reports, data obtained in situ, show that the Mn valence remains constant during reaction with *n*-butane (333 K) after the catalyst has been activated in He. Additionally, EXAFS measurements indicate that the local environment of the Mn changes significantly during activation in He. Neither the XANES, nor the EXAFS for the Fe K-edge of FeSZ change during activation or reaction. These results suggest that the promotion effect is either catalytic, or is indirect, perhaps through modification of the zirconia bulk.

1. Introduction

The promotion of sulfated zirconia (SZ) with Fe or Mn ions results in a catalyst which is 1-2 orders of magnitude more active for the skeletal isomerization of light alkanes than sulfated zirconia alone [1]. Although there is some controversy due to non-uniform testing conditions, it is clear that 5 transition metal ions can promote the activity of SZ, the ions and their relative effectiveness as promoter are Mn $>$ Fe $\gg$ Co $\gg$ Ni $>$ Zn [2]. The function of the promoters is not yet understood. It has been suggested that they are involved in stoichiometric redox reactions [3, 4], but there are indications that one of the major effects of addition of promoters in SZ is to modify the zirconia bulk. Mn and Fe have both been found to incorporate into the zirconia lattice [5] as has been observed previously with non-sulfated zirconia [6]. Therefore, to obtain information on the promoter oxidation state and local structure we have measured the Mn and Fe K edge X-ray absorption spectra of promoted sulfated zirconia samples under the reaction conditions of *n*-butane isomerization. Sulfated zirconia based catalysts pose a particularly difficult problem for spectroscopic analysis. When the samples are ground or pressed, as is common in preparation for spectroscopy either to homogenize the sample or to form a pellet or wafer from powdered samples to support them in the beam path [7, 8] the catalytic activity is severely diminished [9]. In order to measure the active catalyst under reaction conditions it was necessary to construct a powder bed cell for fluorescence measurement.

2. Experimental

a) Sample preparation

The promoted SZ catalysts were produced using a commercially available sulfated zirconium hydroxide precursor (MEL Chemicals) containing 5–6 wt% SO_3. The promoters were added using the incipient wetness technique [10] with aqueous solutions of $Mn(NO_3)_2 * 4H_2O$ or $Fe(NO_3)_3 * 9H_2O$ (both Merck, p.a.) sufficient to result in a final 2 wt% nominal promoter content. The precursors were dried at room temperature prior to calcination in quartz boats containing 10 or 26 grams of precursor at 923 K (3 K/min ramp) for 3 hours in flowing 21% oxygen in nitrogen [10]. In the following, the samples will be designated as MnSZ and FeSZ for Mn promoted SZ and Fe promoted SZ, respectively.

b) X-ray diffraction

X-ray diffraction measurements were conducted using a STOE STADI-P diffractometer in Debye-Scherrer geometry with Cu Kα radiation and a primary monochromator. The samples were mixed 1 : 1 by weight with sieved α-Al_2O_3 (through gentle shaking) for an internal standard. Diffractograms were recorded between $2\theta = 0$ and 100° using a curved position sensitive detector. PowderCell v 2.4 [11] was used to fit the diffractograms with patterns calculated from single crystal data.

c) X-ray absorption spectroscopy

The necessity to characterize catalyst samples while they are operating, and the sensitivity of the sulfated zirconia based catalysts to mechanical stress [9] prompted us to construct an in situ cell for the measurement of powdered samples. A detailed report on the design of the cell is presented elsewhere [12]. The powdered catalyst is contained in an internal reactor body with a Kapton window to support the side of the powder bed into a vertical wall for measurement (Figure 1). The bed is rectangular and 4 mm from front to back, 10–14 mm wide with a 45° wall (parallel to the beam). A hole is drilled through the entire cell, and parallel to the 45° wall with a small area of intersection between the hole and the catalyst bed. The hole provides for a fraction of the beam to bypass the cell to obtain a reference spectrum in transmission. The catalyst is separated from the hole by a Kapton tube inserted in the hole. The catalyst is supported with a glass frit, and reactant gases flow from top to bottom through the catalyst bed. The temperature of the internal reactor body is controlled to the temperature measured by a thermocouple in the catalyst bed. An external body contains circulating He, and the temperature of the He is controlled to ensure that the Kapton window, and the volume of catalyst directly behind the window, is maintained at a defined temperature. Heaters on the external body are controlled to the temperature measured by

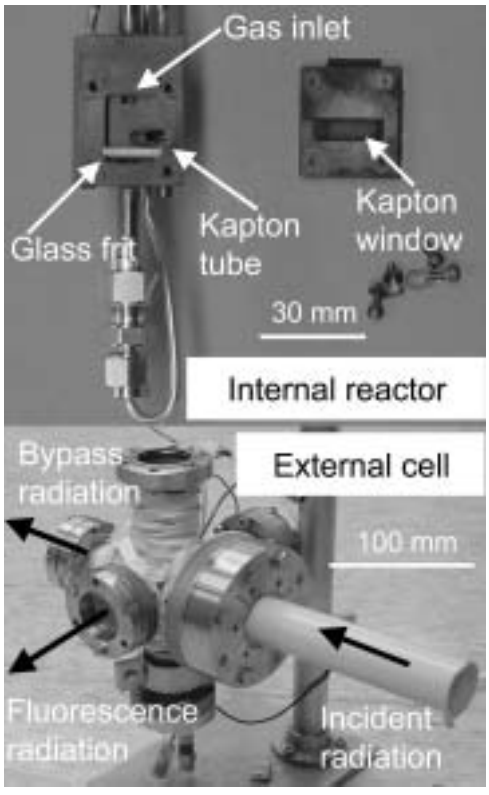

Fig. 1. New cell for measurement of powders under controlled gas phase and temperature. Internal reactor body to hold powder bed (top). External body for containment of constant temperature He (bottom).

a thermocouple terminating in the He near the window of the internal reactor. The cell can be operated with between 0.3 and 0.9 cm^3 of catalyst, and the interior reactor body can be heated to 723 K for catalyst activation or treatments. The gas phase is measured using an online mass spectrometer (Balzers, OmniStar). Conversion is calculated from the ratio of m/e = 29 to m/e = 42, and is calibrated using the fragmentation patterns for *n*-butane and isobutane.

X-ray absorption measurements were conducted at HASYLAB beamline E4 in the fluorescence mode using a single element Ge detector at 90° to the incident beam. The detector channels were windowed to a region of about 800 eV around the Mn or Fe Kα energy to minimize the measurement of scattered radiation. The spectra were energy calibrated to the first inflection point of the spectrum of a simultaneously measured Mn (6539 eV) or Fe (7112 eV) reference foil measured with the fraction of the incident beam that bypassed the catalyst bed. XANES spectra were taken from about 100 eV before the edge, and 200 eV after the edge with a total scan time of 11 minutes. Background correction and normalization was done with linear fits. The position of the Mn K-edge as measured by an arc tangent fit of the spectra is linearly related to the Mn valence [13]. The results of the Mn K-edge shift are summarized here, and presented in detail elsewhere [14]. The EXAFS measurements were about 90 minutes long and measured from 6480 to 6950 eV or 7030 to 7800 eV.

The samples were activated by heating in flowing He from room temperature to 703 K at 10 K/min and holding at 703 K for 30 minutes. Reactivation of the catalyst and reduction were carried out with the same heating program, but using 50% O_2 or 50% H_2 in He, respectively. Catalytic measurements were made at 333 K using a loading of 0.50 grams catalyst, 80 ml/min 1% *n*-butane in

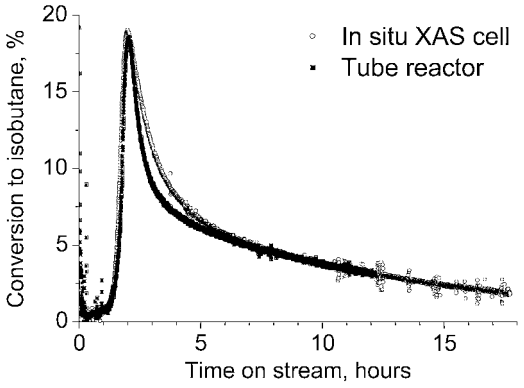

Fig. 2. Comparison of conversion vs. time on stream for a 2% FeSZ catalyst in a quartz, tubular plug flow reactor and the new in situ cell. Conditions: 0.5 g catalyst, 80 ml/min of 1% *n*-butane in He at atmospheric pressure, 333 K.

He at atmospheric pressure. The spectra were normalized using linear fits below and above the edge. The $\mu_0(k)$ fit for the Fe edge spectra was done between 2.65 and 11.5 $Å^{-1}$, and for the Mn edge spectra between 2.7 and 9.6 $Å^{-1}$ except for the spectrum of the reduced MnSZ sample which was fit between 2.2 and 9.6 $Å^{-1}$.

3. Results

Figure 2 shows a comparison of the time on stream behavior of the new cell, and of a quartz, tubular plug flow reactor. The time on stream behavior for both the in situ cell, and the standard laboratory reactor are nearly identical.

Figure 3 shows the Mn K-edge XANES during activation of Mn promoted sulfated zirconia. When MnSZ is activated in He the Mn valence reduces from an average valence of about 2.7 to about 2.5. The valence remains nearly constant during the skeletal isomerization of *n*-butane at 333 K, although the catalytic activity changes with time on stream as in Figure 2, and the valence remains constant during reactivation in 50% O_2 at 703 K. The valence is further reduced from 2.5 to about 2.3 when the catalyst is treated in 50% H_2 at 703 K [14]. The catalyst is active for isomerization after activation in He, and after reactivation in 50% O_2, but it is not active after the treatment in 50% H_2. The XANES spectra of the MnSZ sample presented in Figure 3, as well as those taken, in situ during the reaction, re-activation, and reduction treatments were all analyzed with principle component analysis (PCA). The differences among all

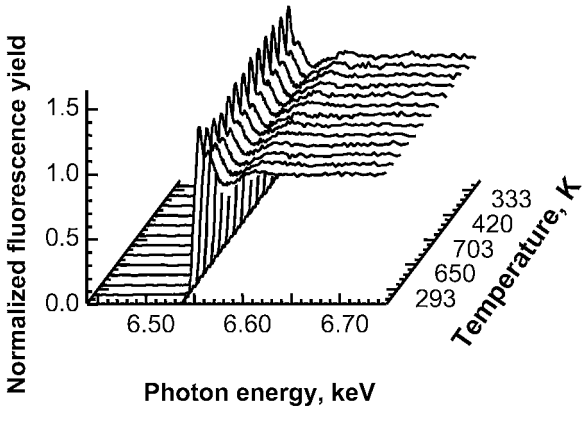

Fig. 3. Mn K-edge XANES measured in situ during the activation of a 2% MnSZ catalyst in flowing He.

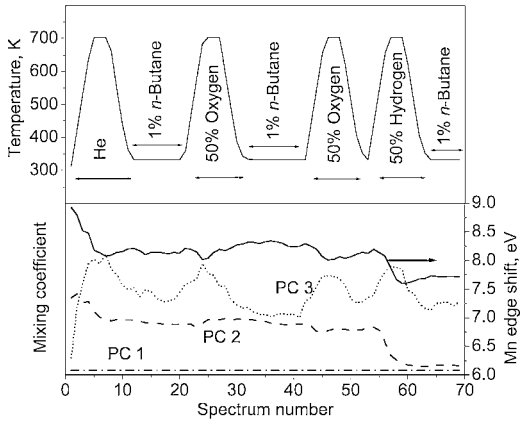

Fig. 4. PC analysis of Mn K-edge XANES measured in situ, during activation in He, reaction, reactivation, reaction, reactivation, reduction, and reaction. The upper part gives gas phase and temperature for each treatment. The lower graph gives the mixing coefficients for the three most significant principle components (broken lines), and the Mn K-edge energy shift relative to the Mn metal edge energy (solid line, right axis). Duration of experiment: 29 hours.

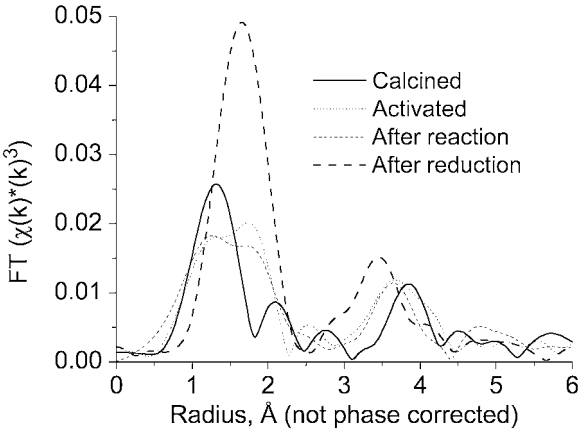

Fig. 5. The Fourier transformed ($\chi(k) * k^3$) of the Mn K-edge absorption spectra for MnSZ as calcined, after activation in He at 703 K for 30 minutes, after reaction with 1% n-butane at 333 K, and after reduction in 50% H_2 at 703 K for 30 minutes.

69 XANES spectra can be adequately described by three principle components. Figure 4 presents the mixing coefficients of the three most significant principle components along with the temperature and the gas phase composition in contact with the catalyst when the spectra were measured. In addition the Mn K-edge energy (relative to a Mn metal K-edge position) is given in the bottom half of Figure 4. It is clear that the second most significant component follows the Mn K-edge energy (and thus changes in the valence), and the third most significant component represents the effect of temperature on the XANES. The Fe K-edge XANES of the FeSZ catalyst taken in situ during activation in He, reaction with 1% n-butane, and reactivation in 50% oxygen show very little change during these treatments (spectra not shown). PC analysis of the XANES of the FeSZ sample indicated that two component were sufficient to describe the data. The mixing coefficients of the second most significant component followed changes in the temperature of the sample in a manner similar to that of the third component for the Mn K-edge XANES.

Extended spectra were taken at room temperature for the fresh catalyst and at 333 K for the catalyst before and after treatments (He, 50% O_2, or 50% H_2) and reaction (1% n-butane at 333 K). Distinctive in the $\chi(k)$ for these data are the lack of oscillations in the calcined MnSZ sample, and the much stronger oscillations after reduction. Figure 5 presents the Fourier transformed $\chi(k) * k^3$ (FT $\chi(k) * k^3$) for the MnSZ sample between the various treatments (not phase corrected). The calcined sample shows maxima at 1.3 and 3.85 Å. The sample as measured after activation, reaction, and reactivation, has quite similar structure, and shows maxima at 1.3, 1.75, and 3.65 Å. After reduction the FT $\chi(k) * k^3$ shows maxima at 1.65 and 3.45 Å. Figure 6 presents the radial distribution function for the FeSZ sample as calcined, and after activation, reaction, and reactivation. All measurements show a maximum at 1.57 and 2.7 Å with a shoulder at higher radius. For the calcined sample the first maximum has a higher magnitude, and there is an additional maximum at about 4.5 Å.

X-ray diffraction measurements were taken of the samples as calcined, and after the final reaction for the FeSZ sample, and after the final reduction and reaction for MnSZ (not shown). All reflections in the diffractograms can be attributed to the internal standard or tetragonal zirconia. For the FeSZ sample the structure of the zirconia did not change after treatment and reaction. For the MnSZ sample that underwent the additional treatment in 50% H_2 at 703 K there was a slight shift of the tetragonal lattice reflections to lower angles, and a slight increase in the amplitude of the reflections. A fit of the diffractograms for the MnSZ sample shows an increase in the unit cell volume of about 0.18% after the treatments.

4. Discussion

The new cell allows the measurement of powdered samples without the grinding and pressing necessary to produce a homogeneous self-supporting wafer. This can be critical for samples such as the SZ based catalysts, which are changed by such manipulations [9]. The time on stream profile of the new in situ cell is comparable to that of a tubular, plug flow reactor (Figure 2), and so the catalyst being characterized with XAS is the active catalyst. The utility for such measurements is highlighted by our results. When MnSZ is activated in He at 703 K, the Mn is reduced from an average valence of about 2.7 to about 2.5. When the MnSZ is exposed to 1% n-butane the Mn K-edge position does not change as indicated in Figure 4. PC analysis also tells us that, aside from the changes in the XANES that correlate to changes in the catalyst temperature (PC3, Figure 4), there are only two principle components required to describe the data. Therefore, changes in the XANES of the sample are due only to changes in two XANES spectra (more of one and less of the other), and both the reduction during activation in He, and the reduction in 50% H_2 are producing the same Mn species with a XANES distinct from a higher valent Mn species which is being reduced. In addition to these two Mn species there may be others which do not change. In contrast, the PC analysis of the FeSZ sample shows no changes in Fe K-edge XANES other than those attributable to changes in temperature. For the measurements during catalysis, this suggests that there are no detectable changes in the promoter ions during the reaction, and is contrary to earlier reports about the role of the promoter ions [3, 4, 15].

The EXAFS measurements taken in situ tell a similar story. The local structure around Mn in MnSZ does not change significantly during reaction, but the environment of the Mn does change during activation in He. The first maximum in the FT $\chi(k) * k^3$ of the calcined MnSZ sample is at about 1.3 Å. After activation, a second maximum appears at about 1.75 Å, and after reduction in 50% H_2

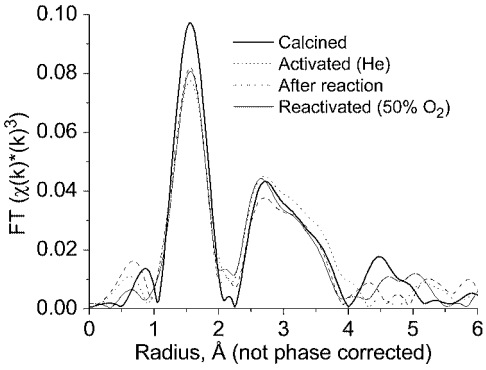

Fig. 6. The Fourier transformed ($\chi(k) * k^3$) of the Fe K-edge absorption spectra for FeSZ as calcined, after activation in He at 703 K for 30 minutes, after reaction with 1% *n*-butane at 333 K, and after reactivation in 50% O_2 at 703 K for 30 minutes.

the maximum at 1.3 Å is no longer discernable, but is replaced by a maximum of greater amplitude at about 1.65 Å. However, the meaning of the maxima in the FT $\chi(k) * k^3$ is problematic to determine. From the XANES we know that there are at least two species of Mn, one being reduced to the other during activation, and during heating in 50% H_2. Clearly the FT $\chi(k) * k^3$s show that this reduction causes a structural change in the Mn local environment. XRD results indicate that the zirconia lattice is tetragonal before and after all treatments for the MnSZ samples. Therefor, the changes in local order are either movement of the position of the Mn ions in the lattice, or more likely redistribution of the oxygen atoms around the reduced Mn ions. Additionally the decrease in valence is probably associated with an increase in oxygen vacancies in the zirconia lattice.

The FT $\chi(k) * k^3$s of the Fe in the FeSZ catalyst change very little during activation or reaction (Figure 6), consistent with the PCA analysis of the XANES which shows only one significant component other than that related to temperature. However, Fe oxide particles have been observed on the surface of promoted sulfated zirconia [16], and Fe also forms solid solutions with ZrO_2 [17]. Therefore, the FT $\chi(k) * k^3$s presented in Figure 6 represent the combination of at least two different structures.

5. Conclusions

The utility of the new in situ powder-bed, fluorescence mode XAS cell has been proven with the successful measurement of spectra from either Mn or Fe promoted SZ samples. The characteristics of the in situ cell as a reactor were demonstrated to be similar to that of a tubular laboratory reactor. The results demonstrate clearly that there is no detectable change in the Mn K-edge position during participation of the catalyst in the isomerization of *n*-butane. The majority of the Mn is not reduced. Additionally, neither the XANES nor the EXAFS of the Fe K-edge for the FeSZ catalyst change during activation in He or reaction. However, the Mn K-edge XANES for the MnSZ catalyst taken during activation, and during reduction in 50% H_2 do change, and one Mn species is changed into another during these treatments. EXAFS shows a consistent change in the local structure after activation and reduction.

Abstract

The structure of a TiO_2(anatase)-supported vanadium oxide powder catalyst was determined during a reduction-oxidation cycle at 623 K. A similar treatment was given to a pure V_2O_5 powder as reference system. The structural changes due to the reduction and oxidation on the supported and unsupported vanadium oxide were compared. A V_2O_5-like structure is present on the supported vanadium oxide after an initial oxidation at 623 K. The EXAFS fits point towards V_2O_5-clusters on the TiO_2 support. A reduction with H_2 at 623 K reduced the supported vanadium oxide to the V^{4+} valence state and had the same structural effect as on the V_2O_5. The successive re-oxidation restored the V_2O_5-structure on both systems.

1. Introduction

Vanadium oxides are important catalysts in different industrial processes, for instance in the oxidation of SO_2 to SO_3, in the partial oxidation of hydrocarbons like *o*-xylene to phthalic anhydride or *n*-butane to maleic anhydride, and in de-NO_x reactions [1, 2]. Supported vanadium oxides have better catalytic properties than unsupported ones and the effect can depend on the support type. In the oxidation of *o*-xylene to phthalic anhydride for instance, the TiO_2 anatase support is superior to other oxide supports like SiO_2, Al_2O_3 and MgO [3, 4].

The structure of calcined supported vanadium oxide on TiO_2(anatase) depends on its loading. Isolated VO_x species are present at very low concentrations ($\ll$1 monolayer); at higher loadings, but still less than one monolayer, a two dimensional surface phase is formed; a disordered V_2O_5 phase is found above one monolayer; and paracrystalline V_2O_5 forms at very high loadings (several monolayers), see [4] and references therein. The low surface coverages ($<$1 monolayer) favour tetrahedral co-ordination of supported vanadium oxide, while the higher coverages have more octahedral co-ordinated "VO_6" species. Furthermore, the tetrahedral co-ordination is the favoured bonding state in dehydrated samples [5].

In-situ reduction and oxidation measurements at reaction temperature are needed to reveal the structural changes of supported vanadium oxides during reactions. In this study a reduction and oxidation cycle was performed on a TiO_2(anatase) supported vanadium oxide powder catalyst at 623 K. The structural changes of the supported vanadium oxide are compared with a pure V_2O_5 powder.

2. Experimental

The V K-edge absorption spectra were collected at station D44 of the DCI storage ring at LURE (Laboratoire pour l'Utilisation du Rayonnement Electromagnétique) in Orsay (France) using a Si(111) monochromator with an energy resolution of 4×10^{-4} eV. The storage ring was filled with 1.85 GeV positrons and the storage ring current during measurements was 310 to 260 mA. All measurements were performed in transmission mode using ion chambers filled with air. The monochromator was detuned to 50% of the maximum intensity at the V K-edge (5465 eV) to minimise the presence of higher harmonics. To reduce noise, 6 scans were averaged for the VO_x/TiO_2(anatase) catalyst and 3 scans for the V_2O_5. The counting time was 1 to 5 s per data point, depending on the energy region. The V K-edge absorption spectra were recorded in five energy regions.

In-situ absorption spectra on the V_2O_5 and the VO_x/TiO_2 powder pellets were measured during a reduction/oxidation cycle at 623 K. The powders were first heated (10 °C/min) from room temperature (RT) to 623 K in He. Three spectra were recorded on the V_2O_5: one reference spectrum at RT in air (V_2O_5(RT)), a spectrum after reduction (V_2O_5(RED)) and after re-oxidation (V_2O_5(OX)). The VO_x/TiO_2 powder was first pre-oxidized (VO_x/TiO_2(pre-OX)), then reduced (VO_x/TiO_2(RED)) and finally re-oxidized (VO_x/TiO_2(OX)) at 623 K. Different V-O compounds were measured as references in air at RT.

Reduction and oxidation were carried out with flows of 100 ml/min at atmospheric pressure (5% H_2 in He and 5% O_2 in He respectively). The spectra were collected under flowing reducing or oxidizing atmospheres. Before measurements, the samples were pre-treated during several hours with the corresponding gas flow.

The samples were pressed in a stainless steel sample holder as self-supported pellets and mounted in an *in-situ* EXAFS cell equipped with beryllium windows [6]. The thickness of the pellets was chosen to give an absorption (μx) of 2.5 at the V K absorption edge for optimal signal to noise ratio. Typically 5 mg of V_2O_5 or VO_x/TiO_2 powder was pressed together with 40 mg of BN as inert filler. The VO_x/TiO_2(anatase) powder has 5.3 wt% vanadium and a BET surface area of 6.5–7.5 m^2/g. The VO_2(99%) powder was purchased from Alfa Aesar, the NH_4VO_3(99.99%), the $VOSO_4.3H_2O$(99.99%) and the BN (99%) powders were purchased from Sigma Aldrich and the V_2O_5(96%) powder from Merck.

The EXAFS data reduction and analysis were performed with the XDAP code [7]. The pre-edge was subtracted using a modified

Victoreen curve [8] and the atomic background was obtained using a cubic spline routine [9]. The spectra were normalised by division of the absorption data by the edge-step at 50 eV above the edge position. No reference spectrum could be measured simultaneously with the sample under study, so that the coordinate axes of all absorption spectra have calibrated monochromator energy values. The main edge is chosen at the half height ($\mu x = 0.5$) of the normalised data. The EXAFS fit parameters were determined by multiple shell fitting in *R*-space, by applying the difference file technique using Fourier Transformations [10].

3. Results

3.1. *XANES spectra*

Wong *et al*. [11] have shown that the pre-edge and main-edge positions of V-Kα absorption spectra shift towards higher energies with increasing valence of the vanadium cation, and that the symmetry of the vanadium-ligand co-ordination can be deduced from the pre-edge intensity. Symmetrical vanadium–ligand co-ordinations, as regular "VO_6" octahedra, have very small pre-edge intensities, while co-ordinations with no inversion symmetry, like distorted "VO_6" units or "VO_4" tetrahedrons, have significant to large pre-edge intensities.

Because no absolute energy reference was available, we have taken the difference, Δ, between main- and pre-edge positions as an estimate for the valence of the V cations. In the vanadium oxide series V_2O_5, V_6O_{13}, VO_2 the valence of the V cation decreases from 5+ to 4+ and corresponding Δ values from 9.9 to 8.2 eV were found. An integrated pre-edge intensity of 2.5 is found for NH_4VO_3 that has an almost regular tetrahedral "VO_4" co-ordination [12] and 0.82 for $VOSO_4.3H_2O$ that has a slightly distorted "VO_6" co-ordination [13].

Figure 1 shows the normalised XANES spectra taken after the treatments performed on the V_2O_5 and VO_x/TiO_2 powders. The pre-edge intensities, Δ-values, and estimated valences and V-O co-ordinations are summarized in Table I. As compared to the references the pre-edge intensity for V_2O_5(RED) suggests a distorted "VO_6" octahedral co-ordination and the Δ-value a vanadium valence of 4+. After re-oxidation the XANES spectrum is identical to the one of V_2O_5(RT): pre-edge intensity and Δ retake the values of V_2O_5.

The supported vanadium oxide has a 5+ oxidation state after the pre-oxidation and a V_2O_5-like structure is present as can be seen from the good correspondence in the XANES spectra between the V_2O_5(RT) reference and VO_x/TiO_2(pre-OX) (Figure 1). The XANES signals are smaller, but the V_2O_5-shape is unambiguously present. Distorted "VO_6" octahedrae with a 4+ valence are present on the VO_x/TiO_2(RED). The re-oxidation restores the V_2O_5-like structure that is already found on VO_x/TiO_2(pre-OX).

3.2. *EXAFS spectra*

The $\chi(k)$ spectra of V_2O_5(RT) and V_2O_5(OX) could be fitted with the co-ordination numbers and bonding distances of the V_2O_5 crystal structure from [14]. The fitted and experimental k^2 Fourier transforms can be found in Figure 2. The fit parameters for V_2O_5(RT) are given in Table II. Similar parameters are obtained for V_2O_5(OX) (not shown). The V_2O_5(RED) is fitted with a distorted 1O + 2O + 2O + 1O octahedral co-ordination, the resulting distances can be found in Table II.

As for the XANES spectra, the k^2 FT for the oxidised supported samples resemble the one for V_2O_5(RT), although some differences are present: e.g. there is a clear loss of intensity in the V-shell around $R = 2.6$–2.7 Å (Figure 2). The EXAFS signals for VO_x/TiO_2(pre-OX) and VO_x/TiO_2(OX) could be fitted with the structural parameters of V_2O_5(RT). Compared to V_2O_5 however there is an extra V-O contribution at 2.7 Å and there are less V neighbours, as the V-V bond at 3.56 Å is not found,Table II. The fit parameters for VO_x/TiO_2(OX) are not given as they are similar to VO_x/TiO_2(pre-OX).

Identical V-O distances are obtained on the reduced VO_x/TiO_2 as on V_2O_5(RED), see Table II. Again less V-V neighbours are found than in the pure vanadium oxide.

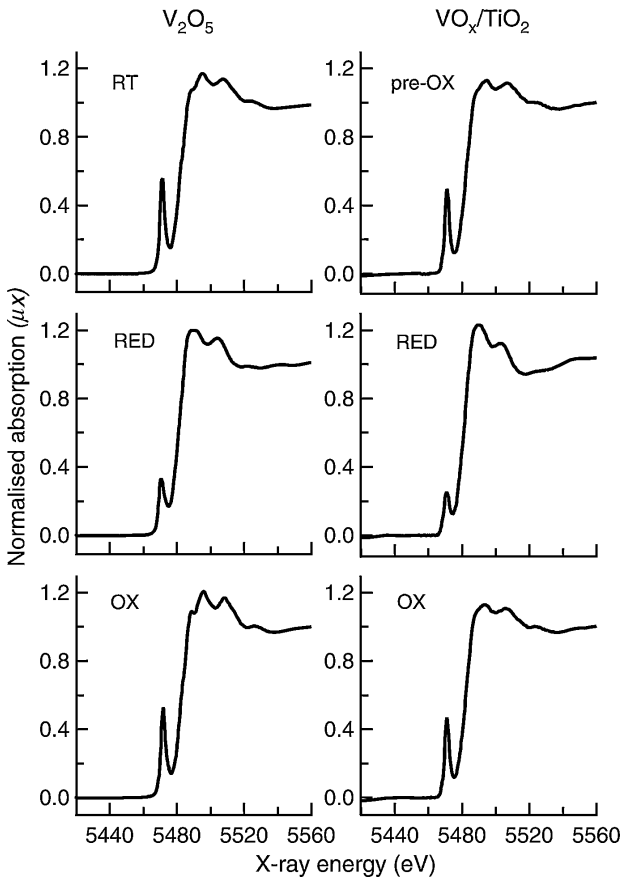

Fig. 1. Normalised XANES spectra of the V_2O_5 (left) and VO_x/TiO_2(anatase) (right) treatments.

Table I. *Pre-edge properties of the XANES spectra for the V_2O_5 and VO_x/TiO_2 treatments. Δ represents the difference between main-edge and pre-edge position.*

Sample	Δ (eV)	Estimated valence	Pre-edge intensity	Estimated co-ordination
V_2O_5(RT)	10.1	5	1.80	$= V_2O_5$
V_2O_5(RED)	9.1	~4	0.98	distorted "VO_6"
V_2O_5(OX)	9.9	5	1.80	$= V_2O_5$
VO_x/TiO_2(pre-OX)	10.5	5	1.53	V_2O_5-like
VO_x/TiO_2(RED)	9.0	~4	0.91	distorted "VO_6"
VO_x/TiO_2(OX)	10.5	5	1.57	V_2O_5-like

4. Discussion

The XAS measurements showed that a V_2O_5-like structure is present on the VO_x/TiO_2 after full oxidation. The number of deposited vanadium oxide monolayers can be calculated from the BET surface area of the support and the V_2O_5 loading.

*Fixed parameters, based on crystallographic data.

Unfortunately the BET surface area of the TiO_2 support is not known, therefore the BET of the VO_x/TiO_2 system is taken as an estimate, which amounted to 7 m^2/g. A support for this estimate can be found in the EUROCAT study [2]. This study on vanadium oxide supported on a 10 m^2/g TiO_2(anatase) powder has shown that the BET surface area changed less than 10% after depositions of V_2O_5 (1 and 8 wt%). For a complete coverage of a 7 m^2/g TiO_2 support with one bidimensional polyvanadate monolayer an amount of 1.05 wt% V_2O_5 is needed [2]. The supported vanadium oxide has 5.3 wt% V, which corresponds with 9.46 wt% V_2O_5. Several multilayers of vanadium oxide are thus present on the supported vanadium oxide. For such high loadings paracrystalline V_2O_5 is indeed found on supported vanadium oxides [1, 4]. The XANES features for VO_x/TiO_2 are smaller than for the unsupported V_2O_5 and less V-V neighbours are found in the EXAFS fits. Most likely V_2O_5 clusters are present on the supported vanadium oxide. No information on the cluster size could be obtained.

No structural support effect is found on the VO_x/TiO_2 during the H_2 reduction at 623 K as the structural changes on the VO_x/TiO_2 and V_2O_5 are similar. Probably the thickness and size of the V_2O_5-cluster on the anatase are large enough so that the supported vanadium oxide particles possess bulk properties.

The re-oxidation at 623 K restores the V_2O_5 structures on the supported and unsupported vanadium oxides showing that the H_2 reduction on the two vanadium oxide systems is reversible.

5. Conclusions

A reduction-oxidation cycle was given to a TiO_2(anatase) supported vanadium oxide (9.5 wt% V_2O_5) at 623 K. The structural changes of the supported vanadium oxide were followed with in-situ X-ray absorption measurements (XANES and EXAFS) and compared with unsupported pure V_2O_5. The supported vanadium oxide had a V_2O_5-like structure after full oxidation at 623 K. Most likely V_2O_5-clusters were present on the anatase support as less V-V neighbours were found in the EXAFS fits compared to unsupported V_2O_5. An H_2 reduction at 623 K had an identical effect on the structure of the supported vanadium oxide as on the unsupported V_2O_5: a distorted octahedral "VO_6" co-ordination was present and the mean vanadium oxidation state was V^{4+}. A re-oxidation restored the V_2O_5 structure on both systems.

No structural support effect was found for the supported vanadium oxide during this reduction-oxidation cycle at 623 K, as the supported V_2O_5 particles on the anatase behaved like bulk V_2O_5.

Abstract

Four kinds of cerium oxide nanoparticles coated, respectively, with Sodium bis(2-ethylhexyl) sulfosuccinate (AOT), cetyltrimethyl ammonium bromide (CTAB), poly vinyl pyrrolidone (PVP) and those (naked) without surface coating were prepared using chemical method. The particle sizes were identified to be $2 \sim 3$ nm by using transmission electron microscope (TEM) and X-ray diffraction (XRD). Mixed valences of Ce^{3+} and Ce^{4+} were detected by X-ray absorption near-edge-structure (XANES) spectra. Extended X-ray absorption fine structure (EXAFS) spectra of Ce L_3-edge were fitted with a core-shell model. The core parts are almost the same as bulk CeO_2 with Ce^{4+} characteristic, however their shell parts change with surface coatings. The local atomic structures at shell parts (surface) and the contents and thicknesses of the shell parts were evaluated. The averaged Ce-O bond lengths at surface are changed from 2.504 Å (AOT), 2.568 Å (PVP), 2.628 Å (CTAB) to 2.634 Å (naked). The contents of surface are changed from 49% (AOT), 15% (PVP), 19% (CTAB) to 15% (naked). The results demonstrate that surface coatings have different influences on the surfaces of cerium oxide nanoparticles. A detailed discussion is given in this paper.

1. Introduction

Due to the special physical and chemical properties originating from a large ratio of surface to volume, small particle size and so on, the preparation, structural characteristics, property measurement and potential application of nanosized materials attract wide interest. There are many methods and techniques used to prepare nanosized materials. Even if the nanosized materials are the same species and have the same size, their atomic and electronic structures could be different because of different preparation methods. This will lead to different properties due to the difference in atomic and electronic structures. Therefore, studying and comparing the structures of nanosized materials, which have the same size but are prepared by different methods, is helpful to better utilize their unique properties.

Cerium oxides have been widely studied because of their complex electron structures[1–5]. In our previous report [6, 7], two kinds of cerium oxide nanoparticles coated by Sodium bis(2-ethylhexyl) Sulfosuccinate (AOT) and Cetyltrimethyl Ammonium Bromide (CTAB) were studied, respectively. Here, another two kinds of cerium oxide nanoparticles with almost the same particle size were prepared. One was modified with Poly Vinyl Pyrrolidone (PVP), another is without coatings (the naked one). We would like to compare the influence of the four kinds of surface modifications on the local atomic structure, especially on the surface atomic structures. X-ray absorption fine structure (XAFS) technique, as a powerful tool, was used to probe the local atomic and electronic structures. We hope to get a clearer understanding of nanosized materials with different preparation methods.

2. Experimental

The cerium oxide nanoparticles coated by PVP were prepared as follows: 20 ml of 0.001 mol/l of cerium chlorine ethanol solution was added to a solution of 0.35 g of PVP ($(C_6H_9NO)_n$, MW = 8000, Aldrich) in 40 ml of propanol under vigorous stirring, and the mixture solution was stirred rapidly for 0.5 h. While continuing to stir, 20 ml of 0.0035 mol/l ammonium hydroxide ethanol solution was slowly added dropwise. On the basis of the dehydrated properties of alcohol, the cerium-oxide nanoparticles organic-sol was obtained. The resulting sol was stored at room temperature under an ambient atmosphere, and showed no sign of precipitation for two months. The cerium-oxide nanoparticles powder was obtained by removing the solvent from the organic sol.

Two kinds of cerium oxide nanoparticles coated, respectively, with AOT ($C_{20}H_{37}NaO_7S$) and CTAB ($C_{16}H_{33}(CH_3)_3NBr$) were prepared by using the microemulsion method [6, 7]. For getting similar particles sizes, CTAB-coated cerium oxide nanoparticles were heated at 350 °C for 2 h. Another set of naked cerium oxide nanoparticles without coatings was prepared by precipitation method [8]. The preparation details of these cerium oxide nanoparticles can be found elsewhere [6–8]. X-ray diffraction (XRD) patterns of the four samples and bulk CeO_2 are shown in Fig. 1. The particle sizes were evaluated to be about $2 \sim 3$ nm for the four kinds of nanoparticles. Similar particle sizes were confirmed by transmission electron microscopy (TEM) as shown in Fig. 2 for PVP-coated cerium oxide nanoparticles.

Cerium L_3-edge XAFS spectra were collected at ambient temperature with transmission mode at the Extended X-ray Absorption Fine Structure (EXAFS) station of Beijing Synchrotron Radiation Laboratory (BSRF). Samples were homogeneously smeared on Scotch adhesive tape. Several layers were folded to reach the optimum absorption thickness ($\Delta\mu d \approx 1.0$, $\Delta\mu$ is the absorption edge step, d is the physical thickness of the sample). The storage ring was run at 2.2 GeV with an electron current about 80 mA. Higher harmonics were eliminated by detuning the double crystal Si(111) monochromator. The incident and transmission X-ray intensities were, respectively, detected by ion chambers that were installed in front of and behind the sample. The energy resolution ($\Delta E/E$) is about 2×10^{-4}. The absorption spectra were collected from 200 eV below the absorption threshold to over 500 eV above the threshold until the L_2 absorption edge appears.

3. Data Analysis and results

X-ray Absorption Near-Edge Structure (XANES) spectra of the four kinds of cerium oxide nanoparticles are shown in Fig. 3. For comparison, the XANES spectra of Ce L_3-edge of bulk CeO_2

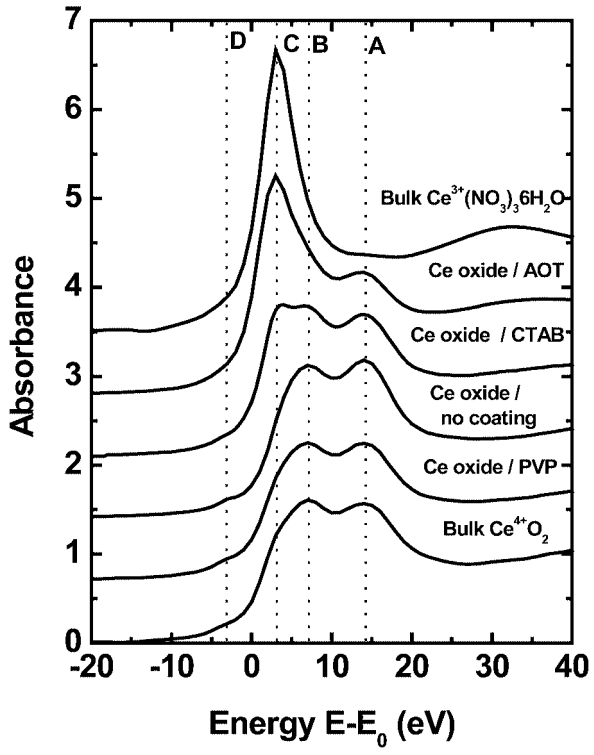

Fig. 3. XANES spectra of Ce-L_3 absorption for the four kinds of cerium oxide nanoparticles. For comparison, those of bulk CeO_2 and $Ce(NO_3)_36H_2O$ are also shown in this figure.

(quadrivalent Ce^{4+}) and bulk $Ce(NO_3)_36H_2O$ (trivalent Ce^{3+}) are also shown in Fig. 3. There are four XANES features [1] A, B, C, and D existing at the XANES spectrum of bulk CeO_2 and the nanoparticles. But the XANES spectrum of bulk $Ce(NO_3)_36H_2O$ only contains one main peak which coincides with the feature C of bulk CeO_2. The AOT- and CTAB-coated nanoparticles [6, 7] were identified to contain both Ce^{3+} and Ce^{4+} components. However, the PVP-coated cerium oxide nanoparticles and the naked ones have almost the same XANES features as bulk CeO_2. It implies that there are only Ce^{4+} components in the PVP-coated and the naked nanoparticles. The different spectral characteristics of the four kinds of cerium-oxide nanoparticles can be attributed to the different coatings and preparation procedures.

Four Gaussian-broadened Lorentzian functions were used to simulate the XANES features [9–10]. An arctan function was used to simulate the absorption background. The spectroscopic valences [9]were calculated to be about 3.48, 3.54, 3.52, 3.49, and 3.51, respectively, for AOT-coated, CTAB-coated, PVP-coated, the naked nanoparticles, and bulk CeO_2. The corresponding f-electron counts are 0.52, 0.46, 0.48, 0.51, and 0.49, respectively. The contribution from feature C is in the level as in bulk CeO_2 for PVP-coated and naked nanoparticles. This further demonstrates that the Ce^{3+} component is negligible in the PVP-coated and the naked nanoparticles. Their XANES spectra were also simulated by a linear summation of bulk CeO_2 and $Ce(NO_3)_36H_2O$ XANES spectra. The Ce^{3+} component is also negligible in the PVP-coated and the naked nanoparticles. While Ce^{3+} components were, respectively, reported to be 19% and 49% in the CTAB-coated and the AOT-coated nanoparticles [6, 7].

Multielectron excitation [11–18] affects seriously the EXAFS signal at the L_3-edge of Ce-absorption. After removing the multielectron excitation effect which was simulated with a Lorentzian function, the absorption curves were transferred to k space using the formula: $k = (2m(E - E_o)/\hbar^2)^{1/2}$. The post-edge absorption background was fitted and subtracted by using a spline function. Then, the resulting EXAFS functions were Fourier-transformed to R space with k^3-weight. Hanning windows were used in the Fourier transform and filter process. The Fourier transform and the first coordination peak filter regions are, respectively, about 7.8 Å^{-1} and 1.5 Å. More than seven fitting parameters are allowed for the nearest coordination. The Fourier-transform spectra and the nearest-neighbor coordination EXAFS functions were, respectively, shown in Fig. 4 and 5.

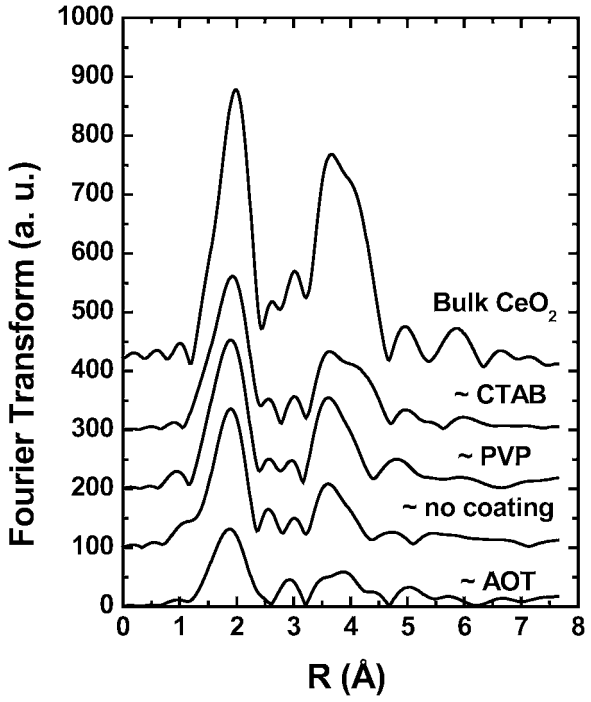

Fig. 4. Fourier transform spectra of Ce-L_3 absorption with k^3-weight for bulk-CeO_2 and the cerium oxide nanoparticles without coating and with coatings (AOT, PVP and CTAB).

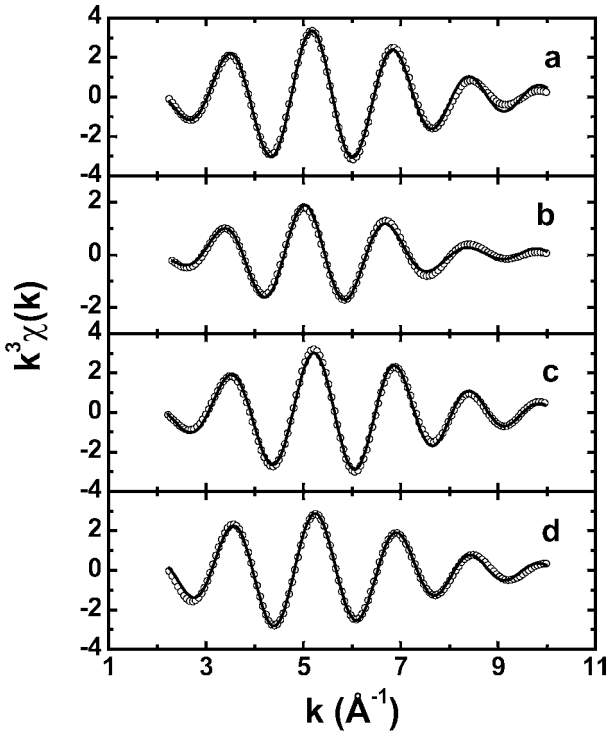

Fig. 5. EXAFS curves of Ce L_3-edge with k^3-weight, in cerium oxide nanoparticles coated by PVP (a), AOT (b), CTAB (c), and without coating (d). Symbols are experimental values, solid line are fitting ones.

Figure 1 shows that the nanoparticles have the same crystalline structure as bulk CeO_2, the wider diffraction peaks are due to the small particle-size and surface-effect. However, a single-shell fitting cannot give robust parameters. Two sub-shells (core-shell model [6, 7, 19]) were used to describe the local atomic structures. One corresponds to the core part; another corresponds to the shell (or surface). Bulk CeO_2 was used as a reference sample to get the amplitude and phase shift of Ce-O bond. The conventional EXAFS formula was used to fit the experimental signals. The first sub-shells were fixed to have the same structural parameters (8×2.343 Å) as the bulk CeO_2 [20] as indicated by X-ray diffraction patterns. It is the core parts that give the X-ray diffraction patterns as shown in Fig. 1 and these are less affected by the coatings (AOT, CTAB, or PVP). The second sub-shells are changeable with different coating, which describes the coating influence on the surface of nanoparticles. The fitting results are given in Table I. Although the second coordination peaks on the FT spectra could be well isolated, we cannot obtain its accurate structural parameters. This is because the mixed Ce-Ce and Ce-O multi-shells are included in the second coordination peak.

4. Discussion

Cerium oxide nanoparticles are well described by two sub-shells. The first sub-shell is almost the same as bulk CeO_2. We attribute this sub-shell to the contribution of the core-parts. Eight oxygen atoms surround the central cerium atom in the core part and these cerium atoms present Ce^{4+} characteristic. Another sub-shell describes the contribution of the shell-parts. The obtained coordination numbers as shown in Table I are nominal coordination numbers. The content (α) of the core part can be evaluated according to $\alpha = N_{\text{nom}}/N_{\text{true}}$. Here, N_{nom} is the nominal coordination number as listed in Table I, $N_{\text{true}} = 8$ is the real coordination number in core part as in bulk CeO_2. From the content $\beta(= 1 - \alpha)$ of the shell part, the real coordination number of shell part can be evaluated according to $N_{\text{true}} = N_{\text{nom}}/\beta$. Finally, the content of the core-part was evaluated to be about 51% (AOT), 81% (CTAB), 85% (PVP) and 85% (naked), respectively.

The second sub-shells are mainly the contribution of the shell part (surface) of the nanoparticles. The real coordination-numbers in the shell part were evaluated to be about 7 for AOT- and CTAB-coated cerium-oxide nanoparticles, and 8 for PVP-coated cerium-oxide nanoparticles and the naked ones. That is to say, there are about 7 oxygen atoms around cerium in an average Ce-O distance of 2.504 Å in the shell part of AOT-coated nanoparticles. Similarly, seven oxygen atoms surround the central cerium atom with an average Ce-O bond length of 2.628 Å in the shell part of CTAB-coated nanoparticles. But, eight oxygen atoms surround the central cerium atom, respectively with an average Ce-O bond length (2.568 Å and 2.634 Å) in the shell-part for PVP-coated nanoparticles and the naked ones. The shell part of AOT-coated nanoparticles is similar to Ce_2O_3 [21] (average, 7 O at 2.5047 Å). We also note that there are 9 oxygen atoms surrounding the central cerium atom in $Ce(OH)_3$ [22]. Here, six Ce-O bond lengths are 2.567 Å, which is similar to the surface Ce-O bond length (2.568 Å) in PVP-coated cerium oxide nanoparticles, the other three Ce-O bond lengths are 2.529 Å. The cerium atoms are coordinated by 10 oxygen in $Ce(NO_3)_3 4H_2O$ [23] with 10 different Ce-O bond lengths distributed from 2.487 to 2.689 Å in which one Ce-O bond length is 2.627 Å and similar to the surface Ce-O bond length (2.628 Å) in CTAB-coated cerium oxide nanoparticles. A total of 11 oxygen atoms around cerium in $Ce(NO_3)_3 6H_2O$ [24] have 11 different Ce-O bond lengths distributed from 2.494 to 2.882 Å in which two Ce-O bond lengths are, respectively, 2.632 and 2.635 Å and similar to the surface Ce-O bond length (2.634 Å) in naked cerium oxide nanoparticles. Partial cerium presents Ce^{3+} characteristics in AOT- and CTAB-coated nanoparticles, which just originate from the shell part

Table I. *Oxygen coordination parameters around Ce in naked cerium oxide nanoparticles (without coatings) and those coated, respectively, by AOT, CTAB, and PVP. of the nanoparticles. Obviously, the two kinds of cerium oxide nanoparticles are the mixtures [25–28] of Ce^{3+} and Ce^{4+}. While for PVP-coated cerium-oxide nanoparticles and the naked ones (without coating), there are always 8 oxygens surrounding the central cerium atom, but their Ce-O bond lengths in the shell part are different from the bulk one. Evidently in the later two cases, the shell-part Ce still keeps the Ce^{4+} characteristics. This is consistent with the XANES spectral characteristics as shown in Fig. 3.

Assuming the nanoparticles taking a spherical shape and having uniform mass density, and D is the diameter of the nanoparticle, then the thickness (δ) of the shell-part of the nanoparticles can be approximately evaluated as $\delta = D(1 - \alpha^{1/3})/2$. The naked nanoparticles have thinner shell thickness ($\delta \approx 0.5$ Å), because they are not affected by the coating. But in the surface modification nanoparticles, the shell thickness is, respectively, 0.5 Å (PVP), 0.6 Å (CTAB) and 2.0 Å (AOT). The obtained contents (β) of the shell-part and their thickness (δ) are listed in Table I.

Because of the small particle size, the surface effect of nanoparticles is not negligible. The content (β) and thickness (δ) of nanoparticles surface correspond to the surface effect. As the thickness is equal to zero, it means that the nanoparticles are exactly the same as bulk. While the thickness is equal to the radius of nanoparticles, it means that the nanoparticles are completely different from bulk. Therefore, the thickness of 0.5 Å in PVP-coated and naked cerium oxide nanoparticles demonstrates that: even on the surface there are still partial Ce atoms keeping the same coordination number and bond lengths as in bulk. In other word, the surface coatings only cause partial Ce atoms on the surface having different Ce-O coordination number and bond lengths. Obviously in the core-shell model, the content (β) and thickness (δ) of nanoparticles surface are only relevant to the partial volume which has different Ce-O bond length compared with bulk.

From Table I, it can be seen that more than 80 percent of absorbed atoms (Ce) locate at the core part of the nanoparticles except the AOT-coated ones. Even on the surface of the nanoparticles, it is easy for the cerium atoms to get oxygen from the atmosphere to occupy and compensate the oxygen vacancies originating from the surface effect. Besides, the possible O and N atoms that come from the coatings and the preparation procedure are also bonded to the surface Ce atoms. These always result in a high coordination (coordination number: 7 or 8) of the cerium at the surface of the nanoparticles. Evidently, for pure metallic nanoparticles prevented from oxidation, due to the small particle size, the coordination number of surface atoms and the average coordination number over the whole nanoparticles will dramatically decrease.

By comparing the four kinds of nanoparticles, their shell-part atomic structures were found to be different from the core part, and the Ce-O bond length in the shell part is elongated. We attribute these to the different coatings and sample-preparation methods. AOT is an anionic surfactant, CTAB is a cationic surfactant. But PVP is a neutral coating. AOT- and CTAB-coated nanoparticles have the same starting materials $Ce(NO_3)_3 6H_2O$, their shell-part all present Ce^{3+} characteristics and the same coordination number (7), although their contents and thickness are different. However, the neutral coating PVP has less effect on the nanoparticles surface, it likes the case without coating. Although the starting materials for PVP-coated nanoparticles and the naked ones are different (respectively, $CeCl_3$ and $Ce(SO_4)_2 4H_2O$), their shell-parts only present the Ce^{4+} characteristics and have the same coordination number (8) as in bulk. It seems that the chemical valence (Ce^{3+} or Ce^{4+}) of surface cerium is related to the coatings and the preparation procedure. Certainly, a suitable heat treatment for the nanoparticles will make the Ce^{3+}transfer to Ce^{4+}, and the nanoparticles transfer to pure CeO_2 [6].

Due to the large ratio of surface to volume and the small particle size, these nanoparticles show larger Debye-Waller factor. Surface modification makes the length of partial Ce-O bonds different. In the four kinds of nanoparticles, the naked nanoparticles have the longest Ce-O bond length at the shell part, and then CTAB-coated and PVP-coated nanoparticles. The AOT-coated ones have the shortest Ce-O bond length at the shell part. However, because of the different thickness of the shell part in the four kinds of nanoparticles, the total average coordination number and Ce-O bond length over the core and shell parts are listed as follow: 7.5×2.416 Å in AOT-coated nanoparticles, 7.9×2.394 Å in CTAB-coated nanoparticles, 8.0×2.387 Å in the naked nanoparticles (without coating) and 8.0×2.377 Å in the PVP-coated nanoparticles.

5. Conclusion

Four kinds of cerium oxide nanoparticles with different coatings were prepared. The local atomic structures of shell parts (surface) in these nanoparticles were obtained. The conclusion are summarized as follows:

The local atomic structures, thickness and contents of the shell part are affected by the surface modification in the nanoparticles. The anionic surfactant (AOT) has the strongest influence on the thickness and contents of surface, and then it is the cationic surfactant (CTAB) and the neutral coating (PVP). The naked nanoparticles (without coating) have the longest surface Ce-O bond length, while AOT-coated nanoparticles have the shortest surface Ce-O bond length.

Except the AOT-coated nanoparticles, the other three kinds of nanoparticles have almost the same average atomic structures. Except the elongated Ce-O bond lengths, the average atomic structures are quite similar to the bulk CeO_2.

The chemical valence of cerium at the shell part seems to be related to the coatings, the starting materials and the preparation procedure. In our cases, starting material $Ce(NO_3)_36H_2O$ with AOT or CTAB surfactants results in a shell part with Ce^{3+} characteristics. While starting materials $CeCl_3$ and $Ce(SO_4)_24H_2O$ with neutral coatings (PVP) or without coatings result in a shell part with Ce^{4+} characteristics. These were confirmed by the XANES features of cerium L_3-absorption.

Abstract

Mesoporous silica supported Nb catalyst (imp Nb/SBA-3) was prepared by impregnation of $NbCl_5$ to the SBA-3 support. The mesoporous silicate-wall incorporated Nb catalyst (inc Nb-SBA-3) was synthesized by introducing $NbCl_5$ into an SBA-3 precursor solution. Both catalysts were carburized by a temperature programmed reaction (TPR) method under CH_4/H_2 gas stream. Nb K-edge *in-situ* XAFS analysis revealed that Nb_2O_5 was reduced to NbO_2 in the first stage of TPR and converted into NbC in the second stage. The silica-wall incorporated Nb species were highly dispersed and hardly reduced nor fully carburized. The difference in the carburization process between imp Nb/SBA-3 and inc Nb-SBA-3 was clarified.

1. Introduction

It is well recognized that an introduction of nitrogen or carbon into molybdenum lattice significantly alters its physical and chemical properties [1, 2]. Although early transition metal carbides (ETMC) are well known for their superior refractory, electronic and magnetic properties [3], not yet developed are their applications as catalysts. It is known that ETMC have demonstrated their resemblance in activities to those of the group 8-10 metals (Pt, Pd, Rh, etc.).

Most of the work on the catalytic application of early transition-metal carbides have been focused on Mo_2C and WC [3], and very few results have been reported on other compounds such as NbC. The focus on Mo_2C and WC has occurred in part because they can be prepared in high surface area form at moderate synthesis temperatures in the range between 900–1100 K. On the other hand, it is reported that the carburization of bulk Nb_2O_5 into NbC requires high temperatures as 1370 K [4]. The high temperature was required to carburize Ta oxide to TaC causing a sintering process and diminished surface area [5]. We have demonstrated that the carburizing temperature could be lowered to 1073 K by supporting the Nb species to amorphous silica [6]. Moreover, the smaller particle size of NbC could be prepared by using the highly ordered mesoporous material SBA-3, possessing 1.5–5 nm pores, instead of amorphous silica.

The conversion of Nb oxide to NbC and the particle size growth were not fully understood yet. X-ray Absorption Fine Structure (XAFS) is a suitable technique for the structural analysis of the conversion process under *in-situ* conditions. In this study, we prepared NbC/SBA-3 catalysts and SBA-3 wall incorporated NbC catalysts, and collected *in-situ* XAFS data to investigate the growth process of NbC on the support. The differences between imp Nb/SBA-3 and inc Nb-SBA-3 are discussed.

2. Experimental

2.1. *Catalyst preparation*

Hexagonal mesoporous silica SBA-3 was synthesized using tetraethylorthosilicate (TEOS) and $[CH_3(CH_2)_{15}N(CH_3)_3]Br$ (CTMABr) at 293 K for 24 h, followed by calcination under dry-air flow at 823 K. The SBA-3 was impregnated with $NbCl_5$ methanol solution overnight. The solvent was evaporated and calcined at 773 K in air [imp Nb/SBA-3]. The mesoporous silica-wall incorporated Nb catalyst was synthesized under acidic conditions using TEOS, $NbCl_5$ and CTMABr at 293 K for 24 h. Products were dried and calcined under dry-air flow at 823 K [inc Nb-SBA-3]. Carburization of Nb species was performed by TPR method. The precursor oxides were carburized in 20% CH_4/H_2 mixed gas stream to produce NbC samples by TPR process; the samples were heated at a linear rate of $10\,K \cdot min^{-1}$ or $5\,K \cdot min^{-1}$ to the final temperature, and kept there for 30 min.

2.2. *XAFS measurements*

The XAFS measurements were performed at BL-10B of the Photon Factory of the Institute of Materials Structure Science, Higher Energy Accelerator Research Organization (PF, KEK-IMSS). Nb K-edge spectra were collected in transmission mode with a Si(311) channel cut monochromator by using two ion-chambers filled with (50% Ar + 50% N_2) and (100% Ar) for I_0 and I, respectively. The monochromator was stepwise scanned for 1 s dwelling per each point in TPR process.

Catalysts were pressed into self-supporting disks and settled in a cell designed for carburization process as depicted in Fig. 1. The specially designed SUS cell can be heated up to 1273 K by an infrared gold-image furnace. The cell has two acrylic windows (3 mm thickness) at both ends of the X-ray path. The absorption of X-rays by the windows seemed to be sufficiently small at the Nb K-edge [7]. Carburization by TPR process was performed from room temperature to the final temperature under a flow of CH_4 ($30\,cm^3 \cdot min^{-1}$) and H_2 ($120\,cm^3 \cdot min^{-1}$). The heating rate was regulated to $5\,K \cdot min^{-1}$.

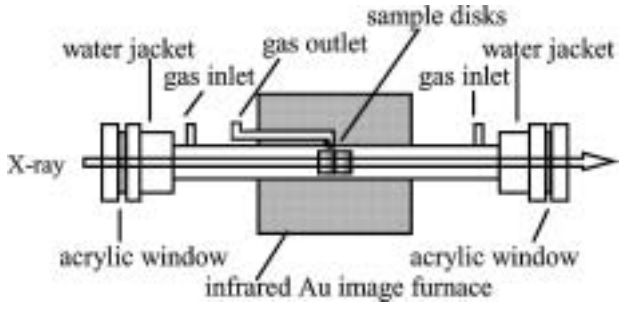

Fig. 1. Schematic of *in-situ* XAFS cell for carburization process.

*e-mail: ichikuni@faculty.chiba-u.jp

The collected data were analyzed by using the program REX2000 (Rigaku Co.). Curve-fitting (CF) analysis was conducted on $k^3\chi(k)$ in k-space, where k indicates the wave number of a scattered photoelectron and χ represented normalized EXAFS oscillations. Model parameters for curve-fitting analysis (back scattering amplitude and phase shift) were extracted from an EXAFS oscillation observed for bulk NbC ($N_1 = 12$, $r_1 = 0.315\,\text{nm}$).

3. Results and discussion

3.1. *Static structures*

The hexagonal mesoporosity of synthesized SBA-3 was confirmed by X-ray diffraction (XRD) pattern and transmission electron microscopy (TEM) measurements. The BET surface area was determined to be $1100\,\text{m}^2 \cdot \text{g}^{-1}$.

3wt% of Nb loaded SBA-3 was also characterized. Although the mesoporosity was maintained for imp Nb/SBA-3 and inc Nb-SBA-3 by XRD analysis, XRD peaks corresponding to d_{100} diffraction became weaker as TPR carburization performed. BET surface areas of both imp Nb/SBA-3 and inc Nb-SBA-3 was $1040\,\text{m}^2 \cdot \text{g}^{-1}$, the same as that of original SBA-3. On the other hand, BET surface areas of imp NbC/SBA-3 and inc NbC-SBA-3 were 730 and $870\,\text{m}^2 \cdot \text{g}^{-1}$, respectively. This surface area diminishment by carburization corresponded to the decrease of the mesoporosity. No Nb_2O_5 phase was observed for both imp Nb/SBA-3 and inc Nb-SBA-3 catalysts, suggesting high dispersion of Nb species.

3.2. *In-situ measurements*

Nb K-edge *in-situ* XANES spectra during TPR carburization for imp Nb/SBA-3 and inc Nb-SBA-3 are shown in Fig. 2 and Fig. 3, respectively. It takes about 10 min to collect one spectrum. NbC shows the distinct band at around 19040 eV, however, Nb_2O_5 does not show [6] this. Although there is no change at around 19040 eV for imp Nb/SBA-3 in the TPR process (solid lines), band growth is observed for the second stage of TPR (maintained at 1223 K, dotted lines) as shown in Fig. 2. Moreover, the 1s-4d

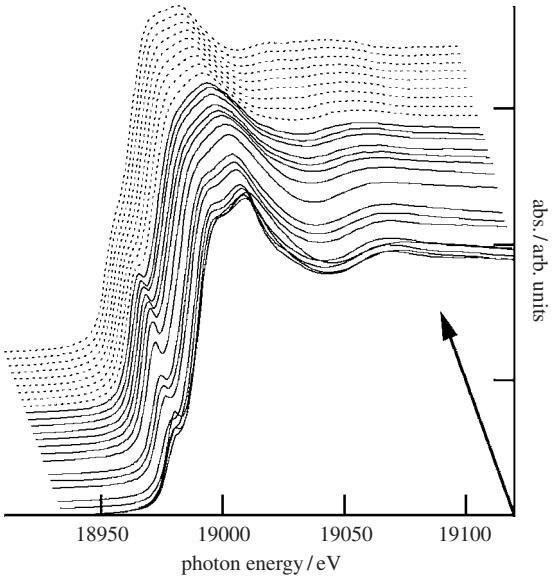

Fig. 2. In-situ XANES spectra observed during TPR carburization (dotted lines show retention stage) for imp Nb/SBA-3.

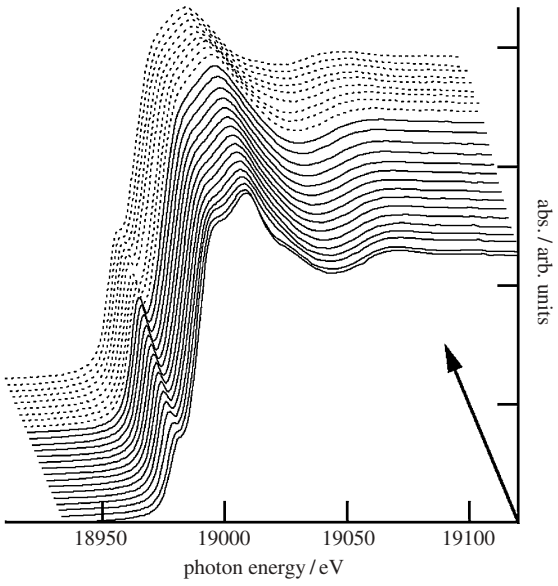

Fig. 3. In-situ XANES spectra observed during TPR carburization (dotted lines show retention stage) for inc Nb-SBA-3.

transition peak (at around 18990 eV), which was observed for starting materials, decreased gradually in the second TPR stage. Thus, it can be said that Nb_2O_5 on the SBA-3 support was reduced to NbO_2 in the first stage of TPR and converted into NbC in the second stage.

In the case of inc Nb-SBA-3, NbC band (at around 19040 eV) was not clearly observed at the end of TPR carburization. Moreover, the pre-edge peak did not fully disappear as shown in Fig. 3. It can be said that the silica-wall incorporated Nb species hardly carburized and remained as oxide. The pre-edge peak became more distinct in the first few spectra and then became smaller. These phenomena can be explained as dehydration from Nb-oxide. Thus, all Nb species in inc Nb-SBA-3 were not fully incorporated into silica-walls. Some of the Nb species remains on the mesoporous silica walls as imp Nb/SBA-3.

To clarify the growth process of NbC, CF analysis to the second TPR stage was carried out by using empirically extracted Nb-Nb parameters (from bulk NbC). The second stage of TPR kept the high temperature (1223 K and 1173 K for imp Nb/SBA-3 and inc Nb-SBA-3, respectively) under 20% CH_4/H_2 flow. To remove the thermal effect on the Debye-Waller (DW) factor, temperature dependencies of the DW factor were measured for bulk NbC under He flow and applied for the CF analysis. Figure 4 shows the

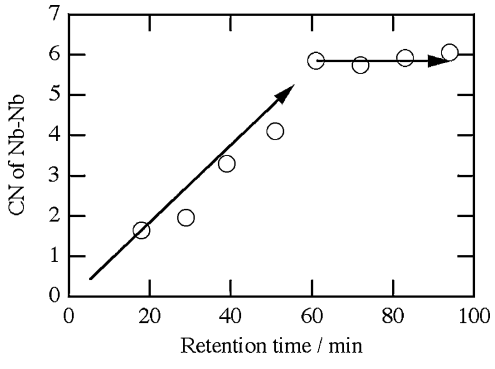

Fig. 4. Nb-Nb coordination number in the second stage of TPR (retention stage) at 1223 K for imp Nb/SBA-3.

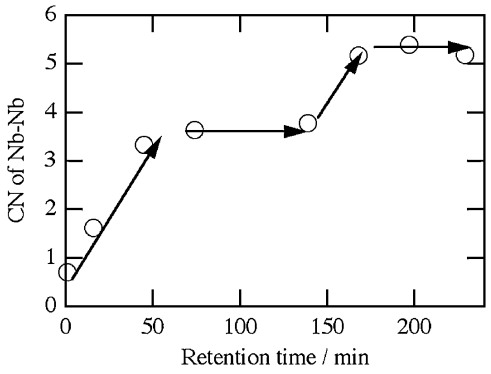

Fig. 5. Nb-Nb coordination number in the second stage of TPR (retention stage) at 1173 K for inc Nb-SBA-3.

change of CN for imp Nb/SBA-3. CN of Nb-Nb coordination increased gradually from ca. 1 to ca. 6, and did not change by further carburization at 1223 K. Thus, it can be said that the growth of NbC occurred in the second stage of TPR as reported before [8].

In the case of inc Nb-SBA-3, increase of CN took place in 2 steps as shown in Fig. 5; (1) CN increased from 1 to 4, (2) CN increased from 4 to 5.5. These phenomena can be explained from the Nb site. The Nb species existed in two sites, one is on the silica-wall and the other is in the silica-wall, as explained above. In the first step, exposed Nb species were reduced and carburized to produce NbC with CN of ca. 4. Further carburization treatment at 1173 K lead to carburization of silica-wall incorporated Nb species, which migrated to the NbC particles previously produced at the first step. At this point, CN became up to 5.5. However, there still remained un-carburized Nb species in the silica-wall, which showed oxide character. It can be said that highly dispersed silica-wall incorporated Nb species were hardly reduced and carburized.

4. Conclusion

Mesoporous silica SBA-3 with high surface area was synthesized and applied to the support. SBA-3 supported Nb catalyst and SBA-3 wall incorporated Nb catalyst were prepared and characterized. Both Nb loaded SBA-3 were carburized to produce supported NbC species under 20% CH_4/H_2 stream by TPR process.

The conversion and growth process of NbC during the TPR process were characterized by *in-situ* XAFS technique and revealed that the conversion to NbC and the growth of NbC occurred in the second stage of TPR. Conversion of SBA-3 wall incorporated Nb species to NbC followed two steps; (1) carburization of exposed Nb species on the wall, (2) carburization of incorporated Nb species inside the wall. The transformation of the Nb oxides to NbC species and their structure during carburization process could be observed by this *in-situ* XAFS technique.

Abstract

Mn- and Co-containing silicalite-1 (MnS-1 and CoS-1) were synthesized hydrothermally. Template-free samples were obtained by calcination at 550 °C for 6 hours in oxygen flow. X-ray diffraction, elemental, thermogravimetric and cation exchange analyses suggested a possible incorporation of Mn and Co cations into the framework positions of the silicalite-1. The valence state and local environment of both cations in the samples were examined by XANES and EXAFS analyses. Results show that Mn and Co cations isomorphously substitute silicon in the silicalite-1 framework only if they are in trivalent oxidation state. Divalent cations are incorporated on extra-framework positions. In the template-free MnS-1 sample all Mn cations are in trivalent state and substitute Si in the framework, forming a distorted and coordinatively unsaturated 3-fold symmetry, which is characteristic for Lewis acid sites. In the template-free CoS-1 sample only part of Co cations are in trivalent state substituting silicon in the framework.

1. Introduction

Zeolites with aluminosilicate framework are crystalline oxides comprising corner-sharing TO_4 tetrahedra (T = Si, Al) [1]. They possess regular pore system with diameters in the range from 0.3–1.4 nm and act as sieves at molecular level.

Silicalite-1 is an aluminium-free zeolite with the MFI structural topology [1]. Modification of silicalite-1 by isomorphous substitution of silicon by transition-metal elements enhances its catalytic activity. Incorporation of tetravalent (e.g. Ti, V) transition metals into the framework of silicalite-1 results in novel molecular sieves with selective oxidation properties [2]. Incorporation of trivalent (e.g. Cr, Fe) transition metals into the framework of silicalite-1 results in high-quality inorganic membranes used for catalytic membrane reactors [3]. So far all attempts of incorporation of divalent transition metals (e.g. Mn, Co) lead to the formation of the silicalite-1 with divalent cations on extra-framework positions [4].

In this paper we report on the isomorphous substitution of silicon in the framework of silicalite-1 by manganese and cobalt cations. Mn and Co K-edge XANES analysis is used to probe directly the valence state of the transition metal cations in the as-synthesized and template-free samples, while their local environment and therewith the site of the incorporation is examined by EXAFS.

2. Experimental

Manganese-containing silicalite-1 (MnS-1) was syntesized hydrothermally using tetraethylammonium hydroxide (TEAOH) as a structure-directing agent (template) [5]. Cobalt-containing silicalite-1 (CoS-1) was synthesized by similar procedure using tetrapropylammonium hydroxide (TPAOH) as a template. Template-free products were prepared by calcination at 550 °C for 6 hours in oxygen flow. Cation exchange was performed at room temperature by stirring the solid sample in a 1 M solution of NaCl for 24 hours with solid/liquid mass ratio 1/10. X-ray powder diffraction (XRPD) patterns of the products were collected on a Siemens D-5000 diffractometer with CuK_α radiation. Thermogravimetric analysis (TGA) was performed on a TA 2000 thermal analyzer in static air. Elemental analysis was carried out using an EDXS (energy dispersive X-ray spectroscopy) anaysis within the LINK ISIS 300 system, attached to the scanning electron microscope JEOL JSM 5800.

X-ray absorption spectra of MnS-1, CoS-1 and reference samples in the respective energy regions of the Mn and Co K-edge were measured at E4 beamline of HASYLAB synchrotron facility at DESY in Hamburg. The beamline provided a focused beam from an Au-coated torroidal mirror and a Si(111) double crystal monochromator with about 1 eV resolution at 7 keV. Harmonics were effectively eliminated by a plane Au-coated mirror, and by a slight detuning of the monochromator crystals, keeping the intensity at 60% of the rocking curve with the beam stabilization feedback control. Powder samples were prepared on multiple layers of adhesive tape. Several layers were stacked to obtain optimal attenuation above the K-edge of the investigated element. Reference spectra were measured under the same conditions on empty tapes without the sample. The standard stepping progression within [−250 eV ... 1000 eV] region of the Mn and Co K-edge was adopted for EXAFS spectra with an integration time of 4 s/step. Exact energy calibration was established with the simultaneous absorption measurements on Mn and Co metal.

3. Results and discussion

The as-synthesized MnS-1 and CoS-1 were identified from XRPD patterns as single crystalline phase products with MFI structure. Elemental and thermogravimetric analyses of the as-synthesized and template-free MnS-1 and CoS-1 suggested that 0.5% Si was isomorphously substituted by Mn and Co, respectively. Cation exchange procedure revealed that there were no exchangeable cationic sites in the template-free MnS-1, while some exchangeable cationic sites were present in the template-free CoS-1 sample. This indicated that all incorporated manganese atoms in the template-free sample isomorphously substituted framework silicon in the silicalite-1, while the Co substitution in the template-free CoS-1 sample was only partial.

To determine the valence state of the transition metal cations in the as-synthesized and calcined samples we examined Co and Mn K-edge energy shifts in the absorption spectra of the samples. The

*e-mail: iztok.arcon@p-ng.si

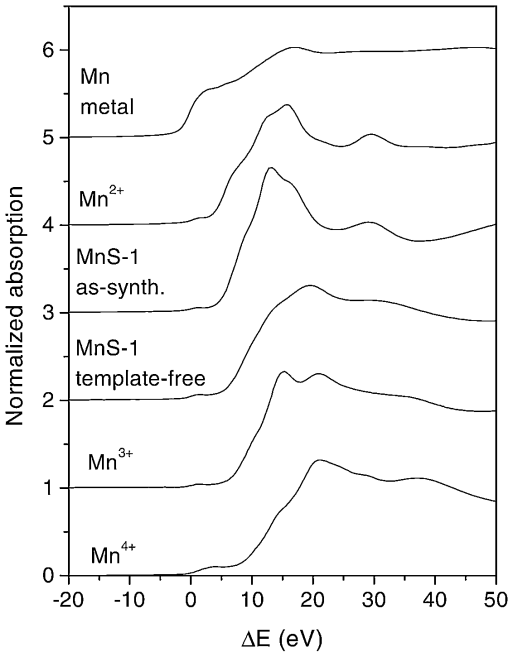

Fig. 1. Normalized Mn K-edge XANES spectra of the as-synthesized and template-free MnS-1 and Mn reference samples Mn metal, $Mn^{2+}O$, $K_3[Mn^{3+}(C_2O_4)_3].3H_2O$, and $Mn^{4+}O_2$. The spectra are displaced vertically for clarity. The zero energy is taken at the first inflection point of the Mn K-edge in the spectrum of Mn metal (6539.0 eV).

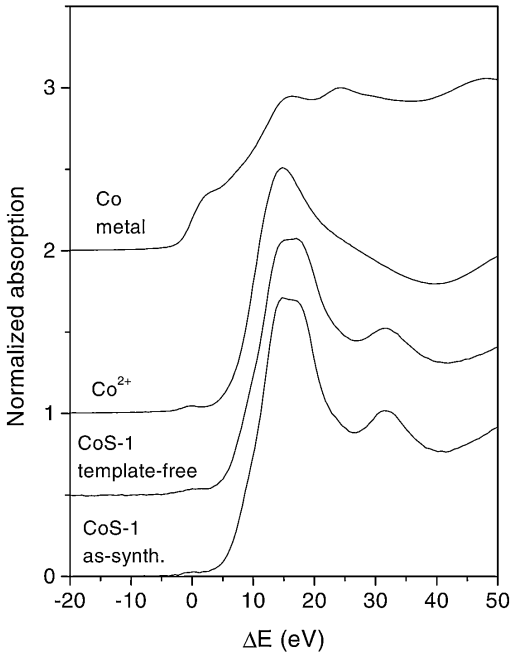

Fig. 2. Normalized Co K-edge XANES spectra of the as-synthesized and template-free CoS-1 and Co reference samples Co metal and $Co^{2+}(CH_3COO)_2.4H_2O$. The spectra are displaced vertically for clarity. The zero energy is taken at the first inflection point of the Co K-edge in the spectrum of Co metal (7709.0 eV).

precise energy position of the edge was taken at the edge inflection point. A linear relation between the edge shift and the oxidation state was established for the atoms with the same type of ligands [6–9]. For manganese atoms coordinated to oxygen atoms a shift of 3.5 eV per oxidation state was found [7], while for cobalt atoms shifts of 1.5–3 eV per valence were reported [9].

In Fig. 1 the Mn XANES spectra of the as-synthesized and template-free MnS-1 sample together with the spectra of the reference manganese compounds $Mn^{2+}O$, $K_3[Mn^{3+}(C_2O_4)_3].3H_2O$, and $Mn^{4+}O_2$ with known oxidation states are shown. The edge shift in the as-synthesized MnS-1 is the same as in the $Mn^{2+}O$ compound, indicating that the average oxidation state of manganese in the as-synthesized MnS-1 is 2+. The Mn K-edge in the template-free MnS-1 sample is shifted and coincides with the edge shift in the $K_3[Mn^{3+}(C_2O_4)_3].3H_2O$ compound. We can thus conclude that during calcination all Mn^{+2} cations oxidize to Mn^{+3}.

The Co XANES spectra (Fig. 2) reveal completely different behaviour of Co cations in the CoS-1 samples. The same energy position of Co K-edge is found in both as-synthesized and template-free CoS-1 samples, demonstrating that the valence state of the incorporated Co cations does not change during the process of calcination. Furthermore, the Co K-edge in the CoS-1 samples is shifted for about 1 eV relative to the edge in the reference Co^{2+} acetate sample, which indicates the presence of Co^{2+} and Co^{3+} cations in the silicalite samples.

Mn and Co K-edge EXAFS spectra of the as-synthesized and template-free MnS-1 and CoS-1 samples were quantitatively analyzed for the coordination number, distance, and Debye-Waller factor of the nearest coordination shells of neighbor atoms using the University of Washington UWXAFS package [10] and FEFF6 code [11]. The amplitude reduction factor ($S_0^2 = 0.80$) is kept fixed in the fits of all spectra. Its value is obtained from previous experimental results [12]. Fourier transforms of Mn and Co EXAFS spectra are shown in Figs. 3 and 4 together

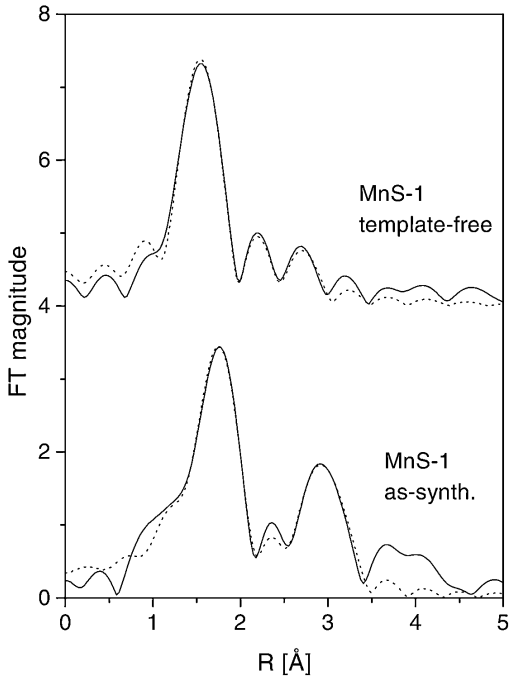

Fig. 3. Fourier transforms of the k^3-weighted Mn EXAFS spectra of the as-synthesized and template-free MnS-1 sample, calculated in the k range of 5–12 $Å^{-1}$ (solid line – experiment, dotted line – EXAFS model).

with best-fit EXAFS models. Complete lists of best-fit parameters are given in Tables I and II.

Two shells of neighbours are found around Mn cations in the as-synthesized MnS-1 sample. The fit in the R range from 1.2 Å to 3.5 Å shows that the first shell is composed of four oxygen atoms at 2.18 Å, while the second shell comprises about two Mn atoms at 3.35 Å. The presence of Mn-O-Mn links indicates

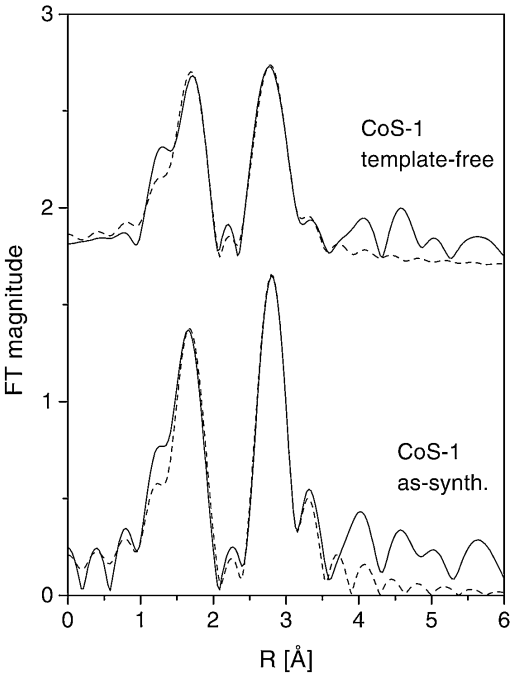

Fig. 4. Fourier transforms of the k^2-weighted Co EXAFS spectra of the as-synthesized and template-free CoS-1 sample, calculated in the k range of 3.5–12 Å^{-1} (solid line – experiment, dotted line – EXAFS model).

Table I. *Structural parameters of the nearest coordination shells around Mn atom in as-synthesized and template-free MnS-1: type of neighbor atom, average number N, distance R, and Debye-Waller factor σ^2. Uncertainties in the last digit (estimated by UWXAFS fitting program) are given in the parentheses.*

Neighbor	*N*	*R* (Å)	σ^2 (Å^2)
As-synthesized MnS-1			
O	3.6(3)	2.18(1)	0.008(1)
Mn	1.6(3)	3.35(1)	0.008(1)
Template-free MnS-1			
O	2.1(2)	1.93(1)	0.003(1)
O	0.8(2)	2.15(2)	0.005(2)
O	1.0(5)	2.81(2)	0.004(2)
O	1.1(5)	3.04(2)	0.004(2)
Si	0.9(6)	3.52(2)	0.020(5)

that Mn cations (divalent as shown by XANES) are located at extraframework sites, most probably in the form of metal-oxo species coordinated to the framework, but simultaneously bearing extra-framework oxygen atoms [7].

Significantly different local Mn neighborhood (within the same R range) is found in the template-free MnS-1 sample. Mn is coordinated to three oxygen atoms in the first coordination shell, two of them at a shorter distance of 1.93 Å and one at a longer distance of 2.15 Å. The short distance of 1.93 Å is consistent with the average tetrahedral Mn^{+3}-O distance of 1.93(4) Å reported for $MnAsO_4$ [13]. In the second coordination shell two oxygen atoms were identified at 2.81 Å and 3.04 Å. Additionally, at a larger distance of about 3.5 Å a presence of silicon atoms is indicated. Taking into account XANES results we can conclude that Mn^{3+} cations substitute Si in the framework of the template-free MnS-1, forming a distorted and coordination-wise unsaturated 3-fold symmetry, which is characteristic for Lewis acid sites (manganese framework sites) [14].

Table II. *Structural parameters of the nearest coordination shells around Co atom in as-synthesized and template-free CoS-1: type of neighbor atom, average number N, distance R, and Debye-Waller factor σ^2. Uncertainties in the last digit (estimated by UWXAFS fitting program) are given in the parentheses.*

Neighbor	*N*	*R* (Å)	σ^2 (Å^2)
As-synthesized CoS-1			
O	3.8(7)	2.11(1)	0.002(1)
Co	3.2(7)	3.16(1)	0.002(1)
O	4(1)	3.64(3)	0.002(1)
Template-free CoS-1			
O	2.9(4)	2.12(1)	0.002(1)
Co	3.2(5)	3.16(1)	0.005(2)
Si	2.5(5)	3.50(3)	0.011(2)

In modeling Co EXAFS spectra, the fit in the R range 1.3 Å–3.5 Å shows that in the as-synthesized sample cobalt atoms are coordinated to four oxygen atoms at 2.10 Å, while the second shell is composed of Co and O atoms. The local Co neighborhood in the template-free sample is slightly different (Fig. 4, Table II) but the Co-O-Co links are retained. Combining Co cation exchange, XANES and EXAFS results, we may conclude that the template-free CoS-1 sample contains two Co species (Co^{2+} and Co^{3+}), where trivalent cobalt cations substitute silicon in the framework sites while divalent Co cations are located at extra-framework sites in the form of metal-oxo species.

In conclusion, the results show that Mn and Co cations substitute silicon in the silicalite-1 framework isomorphously only if they are in the trivalent oxidation state. Divalent cations incorporate into the silicalite-1 on the extra-framework positions.

Abstract

Quantitative determination of platinum oxidation state on supported platinum catalyst was examined by using Pt L_{III}-edge XANES spectra. The nano-sized platinum particles on the support were partially oxidized under oxidative atmosphere. The atomic ratio of oxygen to platinum (O/Pt) for these particles could be determined by the amount of desorbed oxygen in He carrier (O_2-TPD) during elevated temperature. On the other hand, the XANES spectrum of the platinum catalysts oxidized under each corresponding condition was recorded under the same condition, then the area intensity of the white line of these spectra was evaluated by a simple simulation using a set of Gaussian and arctangent functions. A good linear relationship was confirmed between the white line intensity and the atomic ratio of oxygen to platinum, meaning that the oxidation state of the platinum could be quantitatively determined by a simple XANES analysis.

1. Introduction

It is known that the catalytic performance of supported platinum catalyst is affected by the properties of the support material and additive as well as the particle size of platinum. Further, in oxidative reactions such as catalytic combustion, the oxidation state of platinum is also one of the important factors to determine the catalytic activity, since the platinum of metallic state usually shows higher catalytic performance than in oxidized state [1, 2].

Since we reported that the use of solid super acid as the support remarkably enhanced the catalytic activity of platinum in propane combustion [3, 4] and that the self-inhibition effect of oxygen was much greater over basic support [5, 6], we have investigated the effect of the support [6–10] and the additive [10–12] as well as the particle size of platinum [7] on the supported platinum catalyst by focusing on the oxidation state of platinum. It has been confirmed that more metallic state of platinum is suitable for propane combustion. Further, it has been clarified that more electrophilic property of support materials and additive elements provide more metallic state of platinum, resulting in higher catalytic performance [6–12].

In these studies, the oxidation state of platinum has been discussed on the basis of the white line intensity at Pt L_{III}-edge XANES, which was evaluated by a simple curve fitting method. Since the white line, intense absorption peak, at the Pt L_{III}-edge is mainly assigned to electron transition from $2p_{3/2}$ to $5d_{3/2}$ and $5d_{5/2}$, it is an informative index for the oxidation state of platinum; a large white line is observed on oxidized platinum due to electron vacancy in the d-orbital, while a small while line is observed on metallic platinum due to lack of electron vacancy. However, the quantitative correlation between the platinum oxidation state and the white line intensity has not been clarified. It is very important to confirm the correlation between them for the further detailed quantitative study of platinum catalyst. In the present study, we evaluated both the oxidation state of platinum on supported catalyst by O_2-TPD method and the white line intensity at Pt L_{III}-edge XANES, and confirmed the relationship between them.

2. Experimental

The support materials used in the present study were MgO, Al_2O_3 and SiO_2-Al_2O_3, all of which were reference catalysts of Catalysis Society of Japan (MGO-1, ALO-4 and JRC-SAL-2) [13, 14]. The acid strengths (H_0) of them was 22.3, 3.3 and −12.0, respectively [8]. The sieved support material (+25 − 50 mesh) was immersed in $Pt(NO_2)_2(NH_3)_2$ aqueous solution, and excess water was removed by a rotary evaporator with suction at room temperature. After drying at 383 K for 12 h, the resultant powder were calcined at 673 K for 3 h, and then reduced at 623 K for 3 h in a flow of hydrogen. The platinum loading was 2 or 5 wt% as platinum. Additional reduction at 623 K for a moderate period was carried out on some samples in order to obtain catalysts having similar platinum dispersion to others. The CO uptake of platinum catalyst was measured by pulse-adsorption of CO in a flow of helium at room temperature [13, 14]. The platinum dispersion was calculated from the total CO uptake by assuming that carbon monoxide was adsorbed on surface platinum atom at a 1 : 1 stoichiometry.

The oxidation state of the oxidized catalyst was evaluated by O_2-TPD (Temperature Programmed Desorption of Oxygen) method on a TPD instrument (Bel Japan, Inc.) as follows. Prior to measurement, the sample was sequentially treated in H_2 (66.7 kPa), in vacuo and in O_2 (66.7 kPa) at selected temperature (473, 673 or 823 K) for 30 min each, followed by cooling down to room temperature and evacuation. Then, under monitoring O_2 desorbed from the sample by mass spectrometer (ANELVA, AQA-100R), the temperature of the sample bed was elevated (5 K min^{-1}) in a flow of He and held at 1073 K for more than 30 min. From the total area intensity of the spectrum, the amount of desorbed oxygen was evaluated, and the ratio of desorbed oxygen atom to platinum (O/Pt) was calculated.

Pt L_{III}-edge XANES spectra of the samples were recorded in transmission mode by a laboratory EXAFS instrument [15], EXAC820 (Technos Co. Ltd). The X-ray source was a rotating anode X-ray generator (22 kV, 200 mA, target anode: Mo, filament: LaB_6). A single monochromator was employed using a Johansson-type Ge(400) bent crystal curved with Rowland circle geometry ($R = 300$ mm) and the 1st order of the reflection was used. The sample disk was put in an *in-situ* cell in which temperature and flowing gas composition could be controlled. Before each measurement, the same treatment as that before TPD experiment was done. The measurement of such oxidized samples

*e-mail: yoshidah@apchem.nagoya-u.ac.jp

was carried out at room temperature in a flow of He. The X-ray intensity before passing the sample, I_0, was detected with a semi-transmitting sealed proportional counter (S-PC) filled with 0.5 atm of Ar and the intensity after the sample, I, was detected with a pure-Ge solid state detector (SSD).

The background subtraction and normalization were performed by using a modified Victoreen equation with a constant correction term (eq. (1)) [16]. The white line area intensity of normalized Pt L_{III}-edge XANES spectrum was evaluated by a curve fitting analysis [17] using a set of a Gaussian and an arctangent function (eq. (2)):

$$\mu(\lambda) = \mathrm{A} + \mathrm{C}\lambda^3 - \mathrm{D}\lambda^4, \quad (1)$$

$$I(E) = a(E) + g(E), \quad (2)$$

$$a(E) = h_1[0.5 + \pi^{-1}\tan^{-1}\{(E - E_1)/w_1\}],$$

$$g(E) = h_2\exp[-\ln 2(E - E_2)^2/w_2^2]$$

where I: simulated spectrum, E: X-ray energy (eV), $a(E)$: arctangent function, $g(E)$: Gaussian, h_i: height, w_i: width, E_1: inflection point (eV), E_2: peak position (eV). In the present simulation, h_1 was 1 and w_1, which is related to the lifetime of 2p electron, was fixed as 0.33, and the relative energy positions of the two functions were fixed as $E_1 = E_2 - 5.4$. E_1 was around 11567 eV.

3. Results and discussion

Six kinds of catalysts with different acid strengths of support and particle size of platinum were systematically prepared. There were two groups of prepared catalysts; one is catalysts of 2 wt% loading with 60% dispersion, while the other is catalysts of 5 wt% loading with around 30% dispersion. The mean particle size of these catalysts was estimated to be around 2 and 3.7 nm, respectively.

Fig. 1 shows O_2-TPD profiles of the representative samples. PtO_2 (Fig. 1a) exhibited two sequential desorption peaks around 800 K, which corresponds to the decomposition temperature of PtO_2 to Pt and O_2. The amount of oxygen desorption was determined and the ratio of oxygen to platinum (O/Pt) was calculated to be 2.02 for PtO_2 (Table I). This result indicates

Table I. *The ratio of O/Pt and white line intensity.*

Catalyst	Oxidation temperature (K)	O/Pt from O_2-TPD	White line intensity (arb. unit)
PtO_2	–	2.02	6.6
2wt.% Pt/MgO	823	1.72	6.1
2wt.% Pt/MgO	673	1.32	4.9
2wt.% Pt/MgO	473	0.72	3.4
2wt.% Pt/Al_2O_3	823	0.69	3.2
2wt.% Pt/SiO_2-Al_2O_3	823	0.92	2.0
5wt.% Pt/MgO	823	1.68	5.8
5wt.% Pt/MgO	673	1.40	4.7
5wt.% Pt/MgO	473	0.67	3.6
5wt.% Pt/Al_2O_3	823	0.44	2.4
5wt.% Pt/SiO_2-Al_2O_3	823	0.48	2.5

that this method is available for determination of O/Pt. As for the catalyst samples, the oxygen desorption peak was observed at different temperature from that of PtO_2. This means that the stability of the oxidized platinum particles on the support was affected by the support [10]. Especially on the MgO support, the decomposition temperature was clearly higher than the others, which means that oxidized platinum was well stabilized as reported [8, 10, 18]. However, in the present study, we want to focus not on the property of this oxidized platinum but the ratio of oxygen to platinum. Further studies are required to discuss the differences in the profiles.

The peak area intensity of the supported catalyst was obviously lower than that of the bulk PtO_2, which is due to low platinum contents on the supported samples. The O/Pt values for these oxidised catalyst samples were listed in Table I. The O/Pt values of the supported catalyst samples were obviously lower than 2, indicating that the platinum on the support was not fully oxidized. As a whole, the O/Pt of the catalyst sample was widely ranged from 0.4 to 1.7 with the variations of particle size, support material and oxidation temperature.

Fig. 2 shows Pt L_{III}-edge XANES spectra of the representative samples, which were measured by the laboratory EXAFS instrument. PtO_2 (Fig. 2a) exhibited the largest white line at 11567 eV among the samples, while the Pt foil (Fig. 2e) showed a very small white line. The white line intensity for the supported catalyst was larger than that of Pt metal and smaller than that

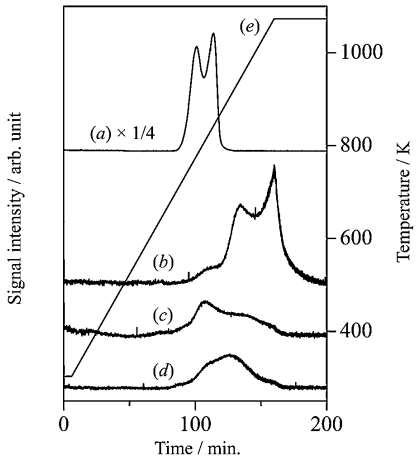

Fig. 1. The O_2-TPD profiles of (a) bulk PtO_2, (b) 2wt% Pt/MgO, (c) 2wt% Pt/Al_2O_3 and (d) 2wt% Pt/SiO_2-Al_2O_3. The sample was oxidized under oxygen (66.7 kPa) at 823 K for 30 min before measurement. The signal intensity of (a) was reduced to one fourth. The line (e) indicates the programmed temperature of the sample.

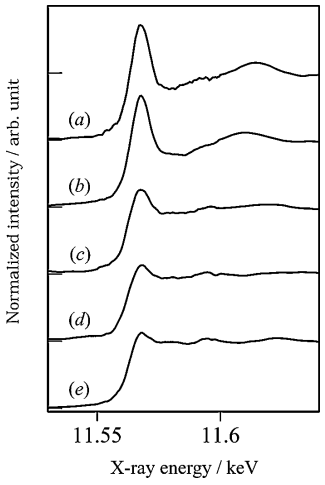

Fig. 2. Pt L_{III}-edge normalized XANES of (a) PtO_2, (b) 2wt% Pt/MgO, (c) 2wt% Pt/Al_2O_3 and (d) 2wt% Pt/SiO_2-Al_2O_3, and (e) Pt foil. The catalyst sample was oxidized at 823 K before measurement.

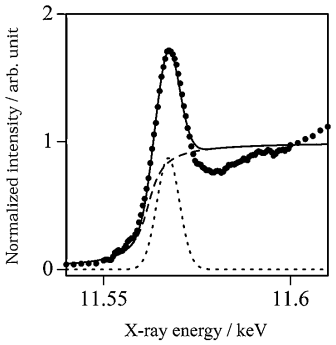

Fig. 3. A curve fitting analysis of XANES by using a set of an arctangent function (broken line) and a Gauss function (doted line). The dots show the experimental spectrum and the solid line shows the simulated curve.

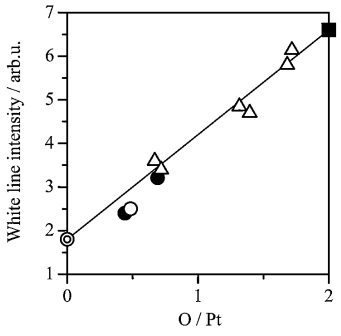

Fig. 4. Relation between the atomic ratio of oxygen to platinum (O/Pt) and the white line intensity of Pt L_{III}-edge XANES of PtO_2 (closed square), Pt foil (double circle) and supported Pt catalyst samples; Pt/MgO (open triangle), Pt/Al_2O_3 (closed circle), and Pt/SiO_2-Al_2O_3 (open circle). O/Pt was determined by O_2-TPD (see text).

of PtO_2, indicating that these platinum particles on the support materials partially oxidised.

To evaluate the white line intensity, a simple curve fitting analysis was carried out by using a set of a Gaussian (dotted line) and an arctangent function (broken line) as shown in Fig. 3. The simulated curve (solid line) seems to fit the experimental spectrum in the lower energy region including the white line. The white line intensity was expressed by the area intensity of the Gauss function and listed in Table I. Note that this simulation method was employed not for strict determination of the transition from 2p to 5d but simply for evaluation of the spectrum intensity.

As for PtO_2, Pt metal and supported catalysts, the obtained white line intensity was plotted versus O/Pt in Fig. 4. The plots clearly show a linear relationship between the two parameters, white line intensity and O/Pt. This means that the measurement of Pt L_{III}-edge XANES followed by a simple curve fitting analysis provides a quantitative estimation of platinum oxidation state even though the samples exhibited much different TPD profiles from each other. The linear relation can be described as:

$$R_{O/Pt} = A \times I_W - B \quad (3)$$

where $R_{O/Pt}$ denotes the ratio of oxygen to platinum, I_W denotes the white line area intensity, A and B are constants. In the present case, A was 0.42 and B was 0.73. This clear result suggests that, once the relationship and the constant values were confirmed in the given conditions, the oxidation state of platinum could be quantitatively evaluated from the white line intensity.

At the same time, both O_2-TPD and the white line intensity at Pt L_{III}-edge XANES were confirmed to be available for quantitative determination of the oxidation state of platinum. Although the H_2-TPR (Temperature programmed Reduction) method is often employed to know the platinum oxidation state, a reduction of support materials might occur under such conditions. It seems better to employ the O_2-TPD to know the oxidation state of platinum.

This linear relationship allows us to find the oxidation state of platinum quantitatively through the measurement of XANES; in other words, measurement of the EXAFS region was not necessary for this purpose. This would provide the following advantages: 1) quick measurement is possible even when we use a normal set up of EXAFS instruments since the region for recording is not wide. 2) Since the signal intensity of XANES is apparently larger than the EXAFS oscillation, it would also be possible to find the oxidation state of low loading platinum catalyst from even a very noisy or small XAFS spectrum. These advantages make it possible, for example, to record the dynamic variation of the platinum oxidation state in situ under reaction conditions.

4. Conclusion

The study of the oxidation state of platinum nano-particles through measurements of O_2-TPD profile and Pt L_{III}-edge XANES clarified the linear relationship between the ratio of oxygen to platinum (O/Pt) and the white line intensity. Thus, the O_2-TPD method and the simple simulation of the white line intensity of Pt L_{III}-edge XANES are confirmed to be suitable for quantitative determination for the ratio of oxygen to platinum.

Abstract

Spontaneous dispersion and clustering processes of Pd were measured by means of energy-dispersive XAFS. The spontaneous dispersion of bulky metal Pd into highly dispersed PdO was directly observed on the H-type zeolite in the atmosphere of O_2. Various clustering processes of metal Pd was observed over different kind of zeolite supports. The selective formation of Pd_6 and Pd_{13} clusters were found over H-ZSM-5, H-Mordenite and H-Y supports, respectively. It was concluded that the crystal structure and acid sites of zeolites had significant influences on the dynamic behavior and the genesis of Pd clusters.

1. Introduction

Metal-support interaction in supported metal catalysts is important in understanding the structure and catalysis of supported metal. Previous studies concerning palladium catalysts revealed that the catalysis of the Pd center was significantly affected by the acid property of the support [1]. For instance, Brønsted acidity of zeolite was essential for selective reduction of NO by methane over Pd. In addition, the methane combustion activity of Pd was affected by the support surface [2]. One of the reasons for these effects could be the strong interaction between Pd and acid sites of supports. Indeed, we have observed spontaneous migration of agglomerated metal Pd into the highly dispersed PdO on acid sites under O_2 atmosphere at elevated temperature [3, 4]. This spontaneous dispersion of PdO was reversible upon repetition of reduction and oxidation treatments. The highly dispersed PdO was considered to be active center in the selective reduction of NO by methane in the presence of O_2 [4]. These observations imply that the interaction between palladium and acid sites of zeolites play an important role in the determination of dynamic behavior as well as the structure of palladium clusters generated in zeolite pore system. In this study, in order to elucidate the dispersion process of PdO onto acid sites of zeolites and to elucidate the clustering process of metal Pd, zeolites with various structures and cations were employed as supports for Pd. Although previous studies were primarily carried out under static conditions, the dynamic structural change could be directly observed using *in situ* and quick measurement of Pd structure. For this purpose, energy-dispersive XAFS (DXAFS) technique was undertaken for structural analysis of Pd loaded on various kinds of zeolite in an atmosphere of oxygen and hydrogen.

2. Experimental

Na-, H-ZSM-5 ($Si/Al_2 = 23.8$), H-Mordenite ($Si/Al_2 = 20$) and H-Y ($Si/Al_2 = 5.5$) were used as supports for Pd. Pd was loaded on these zeolites through an ion exchange method using $Pd(NH_3)_4Cl_2$ solution. The prepared samples were calcined in an N_2 flow at 773 K as a pretreatment. 0.4 wt% of Pd was loaded on each zeolite.

Pd K-edge DXAFS was measured at BL28B2 station of Japan Synchrotron Radiation Research Institute (SPring-8). The storage ring was operated at 8 GeV. Si polychrometer crystal was switched to a Laue configuration with (422) net plane to obtain an X-ray beam with dispersed energy region. The X-ray energy was calibrated with Pd foil as a reference. The sample was placed in a quartz *in situ* cell. The thickness of the sample was 1.5 cm. The sample was heated from room temperature to 773 K with a ramping rate of $5\,K\,min^{-1}$ in an O_2 flow ($50\,mL\,min^{-1}$) or 8% H_2 diluted with He ($90\,mL\,min^{-1}$) flow at atmospheric pressure. Typically, spectra measured for 0.3 s were accumulated 10 times for every 10 K. For extended X-ray absorption fine structure (EXAFS) analysis, the oscillation was extracted from the EXAFS data by a spline smoothing method [5]. The oscillation was normalized by the edge height around 50 eV above the threshold. The Fourier transformation of the k^3-weighted EXAFS oscillation from k space to r space was performed over the range 20–110 nm^{-1} (temperature programmed oxidation) or 30–120 nm^{-1} (temperature programmed reduction) to obtain a radial distribution function. The inversely Fourier filtered data were analyzed with a usual curve fitting method. For the curve fitting analysis, the empirical phase shift and amplitude functions for Pd-O and Pd-Pd were extracted from the data for bulk PdO and Pd foil, respectively. Debye-Waller factors of Pd-Pd (metal Pd) and Pd-O, Pd-(O)-Pd (Pd scattering in Pd oxide) were extracted from the spectra of Pd powder and PdO, respectively. In the analysis of spectra of samples, the Debye-Waller factors were extracted from the reference materials measured at the same temperature.

3. Results and Discussion

3.1. *Spontaneous dispersion of Pd onto acid sites of ZSM-5 [6]*

Fourier transforms of the $k^3\chi(k)$ EXAFS for Pd loaded zeolites are given in Figure 1. Initially, the formation of metal Pd was confirmed from the appearance of an intense nearest-neighboring Pd-Pd peak situated at 0.25 nm in every sample. From the coordination number of the Pd-Pd peak, the diameter of metal Pd was estimated to be larger than 1 nm. This indicates the generation of agglomerated metal Pd after the calcination of ion-exchanged Pd complex in N_2. In the case of Pd/Na-ZSM-5 (Figure 1(a)), the intensity of Pd-Pd (metal) gradually reduced accompanied by raising the temperature in an oxygen flow. Alternatively, new peaks appeared at 0.15 and 0.32 nm. These peaks could be assigned to the Pd-O and Pd-(O)-Pd characteristic of bulk PdO from a comparison with the reference spectrum of bulk PdO. In the spectra of Pd/HZSM-5 (Figure 1(b)), the Pd-Pd peak steeply

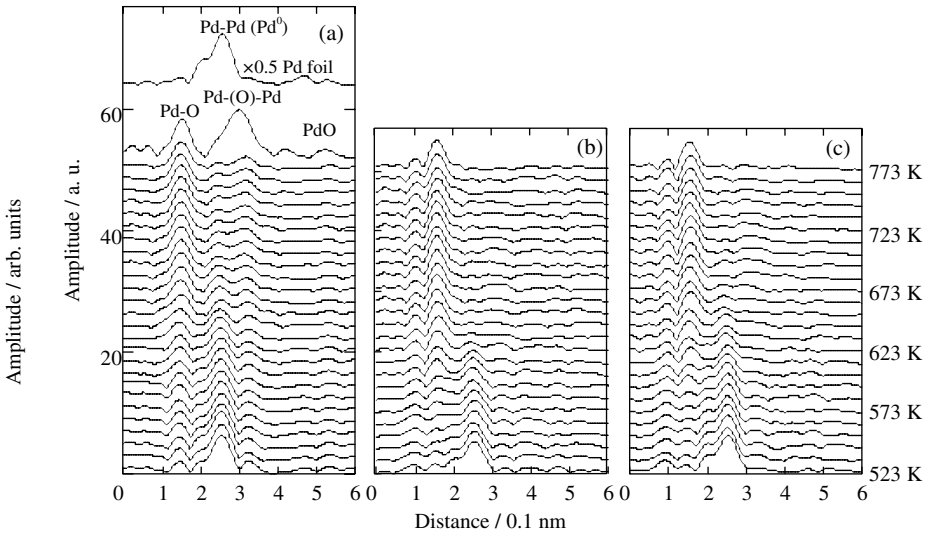

Fig. 1. Pd K-edge EXAFS Fourier transforms for Pd loaded on (a) Na-ZSM-5, (b) H-ZSM-5, (c) H-Mordenite measured in an O_2 flow; Pd loading, 0.4 wt%; Temperature ramping rate, 5 K min^{-1}; The spectra of PdO and Pd foil were measured at room temperature.

disappeared at 643 K. At the same time, the intensity of the Pd-O peak increased, indicating the oxidation of metal Pd progressed with increasing temperature. However, no Pd-(O)-Pd peak due to agglomerated PdO appeared. Although a similar feature was observed in Pd/H-Mordenite (Figure 1(c)), the temperature for disappearance of Pd-Pd and growth of Pd-O was higher than that of Pd/H-ZSM-5.

Figure 2 shows the coordination numbers (CN) of Pd-O, nearest-neighboring metal Pd-Pd, Pd-(O)-Pd of Pd oxide plotted as a function of oxidation temperature. The CN values were calculated based on the curve fitting analysis. As shown in Figure 2(a), Pd-O and Pd-(O)-Pd peaks appeared in place of the decrease in Pd-Pd due to metal on Na-ZSM-5 accompanied by increase in temperature. The generation of Pd-(O)-Pd meant that Pd metal was simply transformed into agglomerated PdO on the external surface of Na-ZSM-5 at elevated temperature. On H-ZSM-5 ($Si/Al_2 = 23.8$), the disappearance of Pd-Pd peak and the growth of Pd-O was observed at 643 K. However, in contrast to the Na-form of zeolites, Pd-(O)-Pd peak which is a characteristic of the agglomerated PdO did not appear even after the disappearance of metal Pd. This means that the agglomerated metal Pd migrated into the acid sites of zeolite to generate a highly dispersed PdO, because the intensity of Pd-(O)-Pd shell seemed to reflect the size of PdO. In addition, the data suggested that the migration of Pd occurred immediately after the oxidation of metal Pd particles, since the oxidation and the dispersion of Pd took place at the same time. Another dispersion process of PdO was revealed from the comparison with findings on H-ZSM-5 and Na-ZSM-5. Namely, the transformation of metal Pd-Pd into Pd-O was sharp and occurred at lower temperature over the H-ZSM-5 with respect to on the Na-ZSM-5. Taking this fact into account, it could be supposed that, in addition to the spontaneous dispersion of PdO, the oxidation of metal Pd was promoted through a strong metal-support interaction between acid sites of H-ZSM-5 and PdO, which possessed basic character. The disappearance of metal Pd-Pd and the alternative growth of Pd-O accelerated over H-ZSM-5 with respect to that for H-Mordenite. Thus it could be noted that the dispersion of Pd on H-ZSM-5 was easier than that of Pd/H-Mordenite. Probably, the pore structure of zeolite or the character of acid center affected the oxidation and migration process of Pd.

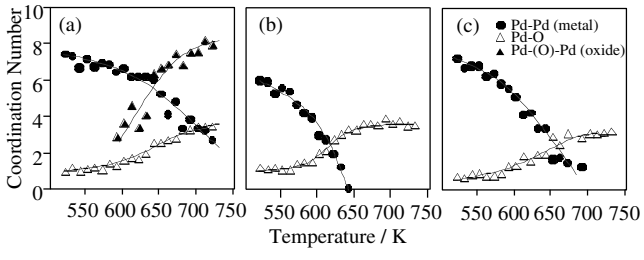

Fig. 2. Dependence of coordination number on temperature for Pd loaded on (a) Na-ZSM-5, (b) H-ZSM-5, (c) H-Mordenite measured during temperature programmed oxidation with O_2.

3.2. *Generation of metal Pd cluster in zeolites [7]*

In order to elucidate the clustering process of metal Pd in zeolite, DXAFS was measured every 10 K during the temperature programmed reduction (TPR) of Pd. Three kinds of zeolites, namely Na-ZSM-5, H-Mordenite and H-Y, were used as supports for Pd. The samples were preliminarily oxidized in an O_2 flow at 773 K for 4 h. After cooling to room temperature, an 8% H_2 flow was introduced to the *in situ* cell. Figure 3 gives the Fourier transforms of DXAFS spectra measured during TPR. After the oxidation pretreatment of Pd/Na-ZSM-5, the generation of agglomerated PdO was confirmed from the appearance of Pd-(O)-Pd peak at 0.3 nm in Fourier transform, which is characteristic of bulk PdO. In contrast, highly dispersed PdO was generated on H-Mordenite and H-Y type zeolites, no Pd-(O)-Pd peak was observed in the spectra of these zeolites. Then the flowing gas was switched to H_2 (8%) and the TPR measurement was conducted. The coordination numbers (CN) of nearest-neighboring Pd-Pd peaks calculated based on the curve-fitting method are summarized in Figure 4. In the beginning of the TPR over Pd/Na-ZSM-5, the formation of agglomerated Pd metal was already confirmed from the appearance of an intense Pd-Pd (metal) peak. The diameter of the agglomerated metal Pd could be estimated to 2 nm. The CN gradually increased with increasing reduction temperature from room temperature to 773 K. This fact indicated that the simple sintering and growth of metal Pd particles progressed when raising the temperature. However the feature

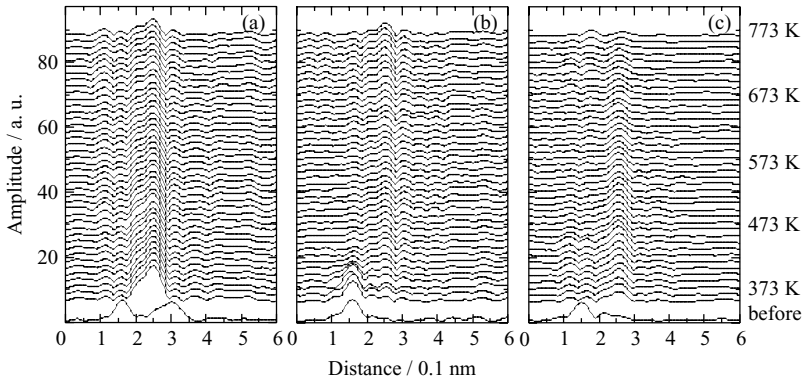

Fig. 3. Pd K-edge EXAFS Fourier transforms for Pd loaded on (a) Na-ZSM-5, (b) H-Mordenite, (c) H-Y measured in an 8% H_2 flow; Pd loading, 0.4 wt%; Temperature ramping rate, 5 K min^{-1}.

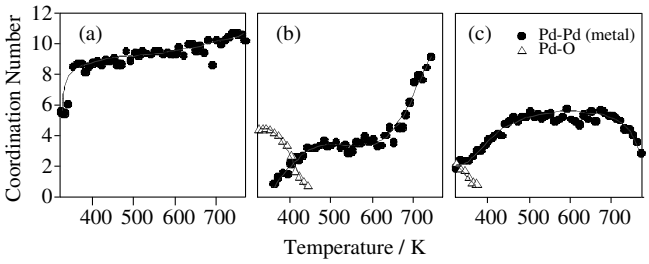

Fig. 4. Dependence of coordination number on temperature for Pd loaded on (a) Na-ZSM-5, (b) H-Mordenite, (c) H-Y measured during temperature programmed reduction with H_2.

of Pd loaded on H-Mordenite was considerably different from that of Pd/Na-ZSM-5 (Figure 4(a)). A slight increase in Pd-Pd was observed between 363 K and 443 K. At the same time, the reduction of PdO into Pd^0 proceeded, which could be seen from the reduction of the Pd-O peak. After the completion of the reduction, a plateau could be observed in the temperature range between 443 and 623 K. This suggests the generation of stable metal Pd clusters in the pore of H-Mordenite. From the Pd-Pd coordination number, the Pd cluster was estimated to be composed of 6 atoms. A similar phenomenon was observed on Pd/H-ZSM-5 ($Si/Al_2 = 23.8$).

Figure 4(c) shows CN plotted as a function of temperature for reduction of Pd loaded on H-Y type zeolites. The CN of Pd-Pd increased in the temperature range between 323 K and 503 K. Alternatively, the Pd-O bond decreased, suggesting the reduction of PdO progressed at this temperature similarly to the Pd/H-Mordenite case. After completion of the reduction, the CN of Pd-Pd became constant between 463 K and 673 K. Therefore, the generation of stable Pd metal cluster was suggested in the temperature region. Judging from the CN of nearest-neighboring Pd-Pd bond, the size of stable metal Pd in H-Y was slightly larger than those observed in H-ZSM-5 and H-Mordenite. Interestingly, further raising the temperature resulted in the decrease of CN of nearest-neighboring Pd-Pd. After the treatment of Pd/H-Y at 773 K, highly dispersed metal Pd cluster composed of three Pd atoms was generated. The fact was confirmed from the EXAFS data measured at room temperature. The tendency was different from those observed on other zeolites, namely Pd/Na-ZSM-5 and H-Mordenite, which exhibited simple agglomeration and the growth of metal Pd at high temperature above 673 K.

4. Conclusions

DXAFS technique was successfully applied for the measurement of dynamic structural change of Pd induced by the interaction of zeolite support and Pd. Firstly, we observed the spontaneous dispersion process of PdO over acid sites of H-ZSM-5 and H-Mordenite. On these zeolites the dispersion of PdO and oxidation of Pd took place at the same time, which was considerably different from the oxidation process observed on Pd loaded on Na-ZSM-5. Secondly, we observed the generation of stable metal Pd clusters in H-Mordenite and H-Y zeolites after the completion of the reduction. The phenomenon was quite different from that of Pd loaded on Na-ZSM-5, which had no acid sites.

Abstract

CuO/ZnO catalysts, prepared in an automated synthesis by coprecipitation, were tested for methanol synthesis by high throughput screening using a 49-channel parallel flow reactor. The activity strongly depended on the preparation conditions and the calcination temperature. Interesting samples were selected for deeper characterization by EXAFS including *in situ* spectroscopic studies during temperature programmed reduction. Both ageing time and calcination temperature had a strong influence on the reduction behaviour of CuO/ZnO samples and thus resulted in an altered catalytic activity. In all cases, only a small fraction of Cu(I) species was formed during reduction.

1. Introduction

X-ray absorption spectroscopy is known to be a powerful technique in catalysis research. It does not only provide structural information on the crystalline phases but also gives (element-specific) information on the amorphous part of the catalyst [1–5]. In addition, structural transformations of solid catalysts both in gaseous or liquid reaction environment can be studied *in situ* and in a time-resolved manner [4–7], which allows to establish structure-activity relationships.

High-throughput experimentation (HTE)-technology for the preparation of heterogeneous catalysts using synthesis robots and multichannel parallel flow reactor systems has emerged as a powerful tool in catalysis research in recent time [8–11]. The method is effective to screen catalysts with respect to composition or preparation parameters.

Although a number of materials can be produced and tested using both synthesis robots and parallel reactor technology, this approach cannot substitute a rational design of catalysts, considering that the number of materials to be prepared is principally unlimited. Therefore, a combination of both approaches seems most promising. A structural characterization of all samples tested would be extremely time-consuming. More efficient is the selection of samples with distinct properties, as indicated from pre-characterization and catalytic tests for gaining structure-activity relationships. In this contribution, we illustrate how the EXAFS technique can contribute to this strategy.

For this purpose, the Cu/ZnO system is a well-suited example. During the past years it has been thoroughly investigated [12–19], also with respect to preparation parameters (composition, pH dependence of precipitation, calcination temperature, ageing). In particular, calcination and ageing seem to play a crucial role. Testing of the catalyst samples usually takes about one week considering the activation and equilibration time and thus parallel testing is advantageous. The future role of EXAFS in this area is discussed in this contribution.

2. Experimental

2.1. *Catalyst preparation and testing*

Automated synthesis and a 49-fold parallel reactor system, applicable at elevated pressure (50 bar), were used for the preparation of the samples and for activation/catalytic testing in methanol synthesis, respectively. The principal procedure is shown in Figure 1. Catalysts were precipitated at constant pH. During ageing, the pH just recorded and samples were taken from the suspension at certain times. More detailed information on the preparation procedure and the catalyst testing conditions can be found in ref. [20]. The prepared samples were characterized by X-ray diffraction, thermal analysis, and for selected samples reactive frontal chromatography was used to determine the copper surface area.

2.2. *X-ray absorption spectroscopy*

Reduction of the Cu/ZnO samples is an important feature in the understanding of the catalytic performance of the catalysts, which can be monitored with respect to Cu^{II}, Cu^{I} and Cu^{0}-species with X-ray absorption near edge structure. The XAS experiments were performed at beamline BM1B (Swiss-Norwegian Beamline) at ESRF (Grenoble, France) and at ANKA-XAS (Karlsruhe, Germany) in a reactor for pellet-shaped samples. Pellets with diameter of 13 mm and thickness of 1.5 mm were pressed from finely ground catalyst diluted with boron nitride and loaded in an *in situ* reactor cell with X-ray transparent windows and oven. The XAS data were obtained in transmission geometry using a Si(111) monochromator in both cases and EXAFS and XANES data were taken around the Cu K-edge (8.979 keV). The fraction of Cu^{II}, Cu^{I}

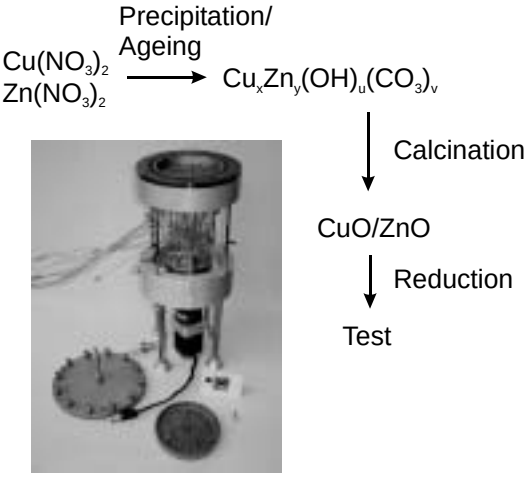

Fig. 1. Synthesis procedure of Cu/ZnO catalysts used in high throughput screening activity tests at 50 bar (picture depicts 49-fold high throughput reactor).

*e-mail: grunwaldt@tech.chem.ethz.ch

and Cu^0-species was determined by linear combination analysis (LCA).

3. Results and Discussion

Figure 2 gives an overview on the catalytic performance of selected catalysts calcined at different temperatures and aged for different time intervals. In particular, the ageing time turned out to be an important parameter in the synthesis process.

It shows that there are extreme dependencies on the ageing times of the (Cu,Zn)-hydroxycarbonate precipitates. In addition, calcination of the samples was necessary before activation by the reduction in hydrogen. One interesting series turned out to be the differently aged samples precipitated at pH 8.5 and calcined at a temperature of 330 °C. With increasing ageing time the methanol production rate first increased, but at very long ageing times the activity decreased again.

The typical reduction behaviour of sample 1 in Figure 2 is depicted in Figure 3 while the data of all five selected samples are gathered in Figure 4. It turned out that the fraction of formed Cu^I was relatively low (<10%) and that the formation of Cu^0 started right from the beginning. This can also be concluded from the fact that the pre-edge feature at 8.879 keV, typical for Cu^0, principally appeared just when the reduction started. These observations were similar for all five selected samples and thus the reduction directly to Cu^0 is fast, as also concluded in previous publications [4, 21, 22]. The reduction temperature is, however, strikingly different depending on the ageing time. The two most active samples, 3 and 4, are reduced at lower temperature than the less active samples. In all cases, a small fraction of Cu(I) species (<10%) occurs as intermediate from the beginning of the reduction until its end. This trend that in the more active catalysts copper is easier reduced has also been found for further catalysts in Figure 2. For the most active samples 3 and 4 we observe a higher reduction temperature for the more active sample. This may be due to a change in phase composition and will be investigated in further detail since the copper surface area increases slightly from sample 3 to 4. Note that a too long ageing time results in a catalyst with low activity, as it does for short ageing times. The EXAFS analysis

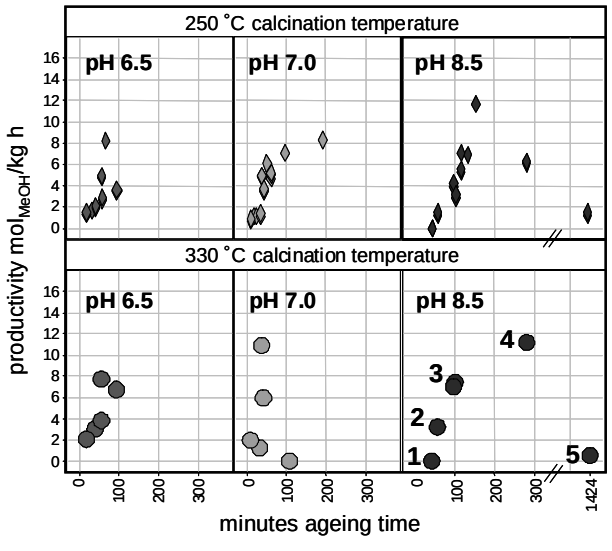

Fig. 2. Effect of ageing time, different starting pH values and calcination temperatures (trapezoid: 250 °C, circle: 330 °C) on catalyst activity dependence. All samples were tested by high throughput screening. Samples of pH 8.5/330 °C were chosen for detailed studies.

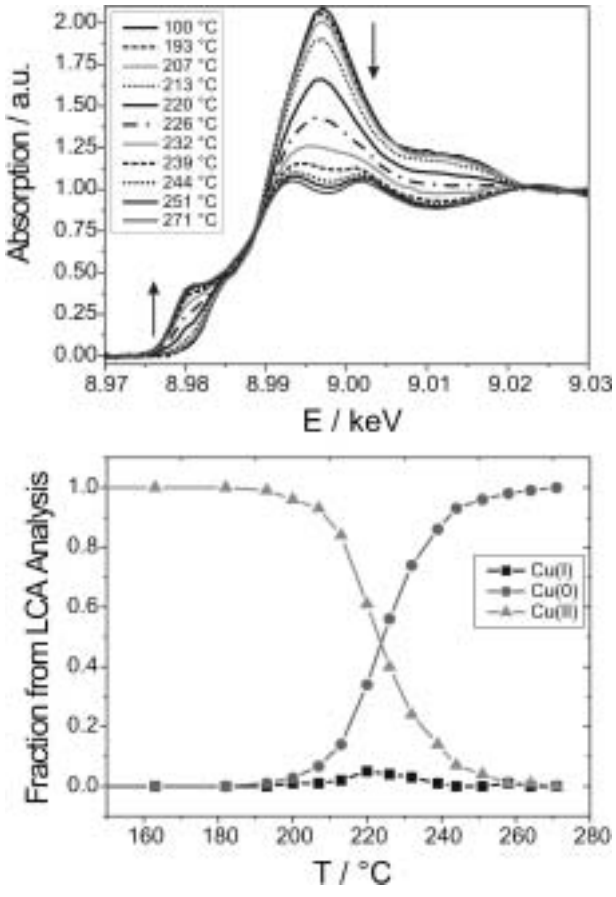

Fig. 3. Reduction of a CuO/ZnO sample monitored by *in situ* EXAFS and the analysis of the copper species by linear combination analysis (LCA).

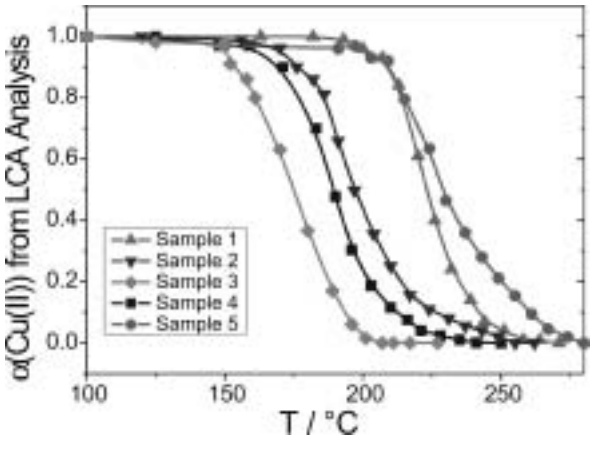

Fig. 4. Reduction behaviour of the 5 selected samples marked in Figure 2 (from starting pH 8.5/330 °C calcination). High activity was found for those samples, which are reduced at low temperature.

of all samples after reduction uncovered the presence of relatively large Cu particles with a coordination number of nearly 12 and a typical Cu-Cu distance of 2.55 Å. This is not surprising, since the copper loading is relatively high (typical for commercial catalysts) in comparison to previous EXAFS studies on Cu/ZnO model catalysts [4]. In previous temperature-programmed reduction experiments it was speculated that ZnO promotes the reduction of CuO [15]. The combined activity/characterization results indicate that the behaviour is more complex. It obviously depends on the phases formed during the ageing process and also the CuO-ZnO interface. Their formation is probably kinetically controlled

during the preparation process [13], i.e. in the beginning the formation of separate copper hydroxide and zinc hydroxide or hydroxycarbonates could be favoured while after longer ageing periods the formation of mixed hydroxides or hydroxycarbonates is preferred. Too long ageing periods probably lead to more crystalline samples that are more difficult to reduce than the amorphous or microcrystalline materials.

4. Conclusions and Outlook

The study shows that the catalytic activity is strongly dependent on different preparation parameters. A systematic approach can only be achieved by thorough catalyst testing and the use of automated synthesis procedures to guarantee reproducibility. The proper characterization of some selected series can lead to a more fundamental understanding. Combination with EXAFS is a useful approach since it can give direct information on the structure and the temperature controlled reduction mechanism. It turned out that a low reduction temperature is beneficial for the final activity, but not the only criterion. Hence, the studies are presently extended by combination with further characterization methods.

Acknowledgements

We gratefully acknowledge beamtime at the Swiss-Norwegian Beamline at ESRF (Grenoble) and at the ANKA-XAS beamline (Karlsruhe). The support by the beamline staff at SNBL (H. Emmerich, W. van Beek) and at ANKA-XAS (J. Göttlicher) is greatfully acknowledged. Moreover, we thank S. Hannemann for help during the EXAFS measurements and ESRF, ETH Zürich and OFG (SFB 558TP B2) for financial support.

Abstract

The local structure around Ni in a nickel phosphide catalyst supported on SiO_2 was investigated by an *in situ* X-ray absorption fine structure (XAFS) method during the reduction process of the catalyst and the hydrodesulfurization (HDS) reaction of thiophene. In the passivated sample, the Ni phosphide was partially oxidized but during the reduction process Ni_2P particles were regenerated. The particles had Ni-P and Ni-Ni distances of 0.220 and 0.259 nm, respectively, corresponding closely to those of bulk Ni_2P. *In situ* XAFS clearly revealed that Ni_2P structure was stable under the reaction conditions at atmospheric pressure and was an active structure for the HDS process.

1. Introduction

Regulations for S content in petroleum feedstock have become increasingly more severe year by year. For this reason there is great interest in the development of highly active hydrodesulfurization (HDS) catalysts. It has recently been found that metal phosphides show high activity for the HDS reaction [1]. A survey of different phosphides shows that Ni_2P is the most active compound for HDS [2]. When the Ni phosphide was supported on SiO_2, the activity and the lifetime were much improved. In this work we investigated the structure of Ni phosphides on a SiO_2 support by *in situ* XAFS spectroscopy during the preparation and the reaction processes.

2. Experimental

The Ni phosphide supported on SiO_2 (Cabosil L90, Cabot corporation, $90\,m^2\,g^{-1}$) was prepared by the reduction of Ni phosphate on SiO_2 [2]. The SiO_2 was impregnated with nickel nitrate and ammonium phosphate, followed by calcination at 773 K for 6 hours to give nickel phosphate. The SiO_2-supported nickel phosphate was reduced to Ni phosphide by means of temperature-programmed reduction (TPR) in H_2 flow using a heating rate of 5 K/min up to 773 K. After the reduction, the catalyst was passivated in 1% O_2/He at room temperature to protect the particle from bulk oxidation and was stored in Ar atmosphere. The passivated sample was then placed in a XAFS measurement cell [3] in a N_2-filled glove box and reduced again to activate the sample. The reduction was carried out in a temperature programmed manner with a ramping speed of 5 K/min up to 723 K under a H_2 flow. The reduction process was monitored by XANES spectroscopy. After the reduction, the sample was cooled down to 323 K and the EXAFS spectrum was measured in order to identify the active structure. The thiophene hydrodesufurization reaction was carried out at 573 K in a H_2 + thiophene mixture. (H_2 flow rate = 42 ml/min, thiophene flow rate = 1.3 ml/min.)

XAFS measurements were carried out at BL9A of Photon Factory (KEK-IMSS-PF) operated at 2.5 GeV and 300 mA. The X-ray was monochromatized by a Si(111) double crystal and focused on the sample using a bent conical mirror. Obtained XAFS data were analyzed by REX2000 (RIGAKU Co.) software [4] using theoretical standards calculated by FEFF 8.2 [5].

3. Results

Fig. 1 shows the EXAFS oscillation and the Fourier transform of a Ni_2P standard compound. The coordination numbers for Ni-O and Ni-Ni were determined to be 2.5 and 7, respectively. Fig. 2 shows the EXAFS oscillation and its Fourier transform of the passivated catalyst before reduction. The EXAFS oscillation is different from that of the Ni_2P standard compound, especially in the low *k*-region. The Fourier transform gives two peaks resembling that of the Ni_2P standard compound but the first peak is shifted to the low *r* side. Curve fitting analysis shows correspondence to a Ni-O bond distance (0.201 nm) in addition to the Ni-P (0.232 nm) and Ni-Ni (0.265 nm) distances. Thus during the passivation process, the Ni phosphide particle on the SiO_2 support was partially oxidized, probably only in the surface region. Fig. 3 shows the XANES spectra of the sample before and after the reduction. The first strong edge peak, indicating the presence of Ni-O, was

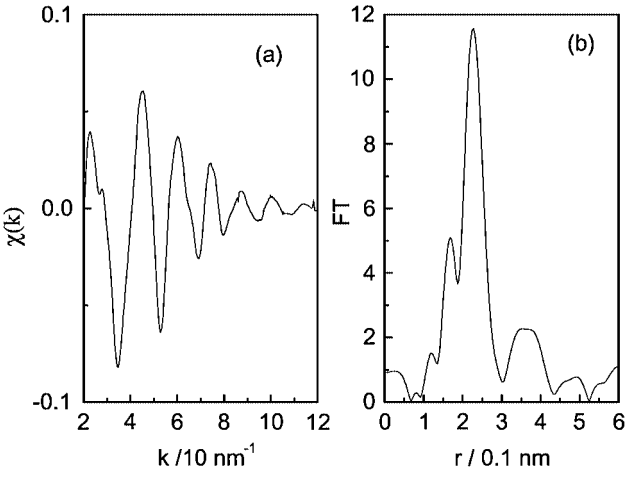

Fig. 1. EXAFS oscillation of Ni_2P powder (a) and its k^3-weighted Fourier transform (b).

completely removed by the reduction process. We followed the reduction process by monitoring the sample with *in situ* XANES. Fig. 4 shows the *in situ* XANES traces in the course of the reduction process. Changes in the XANES traces start at 350 K. The reduction proceeds gradually and is completed at about 500 K. In the passivated sample, only the surface region is oxidized and is reduced easily. Fig. 5 shows the EXAFS oscillation and its Fourier transform of the sample after the reduction, and it can be seen that they are very similar to those of the Ni_2P standard compound shown in Fig. 1, indicating that the Ni_2P structure is generated by the reduction process. Ni-P and Ni-Ni bonds are found at 0.220 nm and 0.260 nm, respectively. The coordination numbers for Ni-P and Ni-Ni are 2.5 and 6.2, respectively. Assuming a spherical

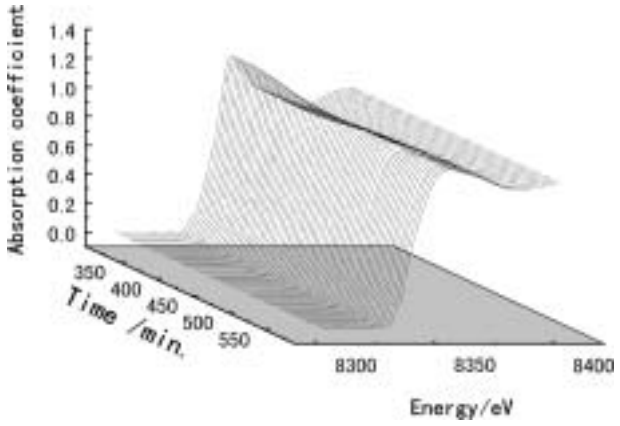

Fig. 4. Series of XANES spectra taken during the reduction process in a quick scan mode. Temperature ramping rate = 5 K/min.

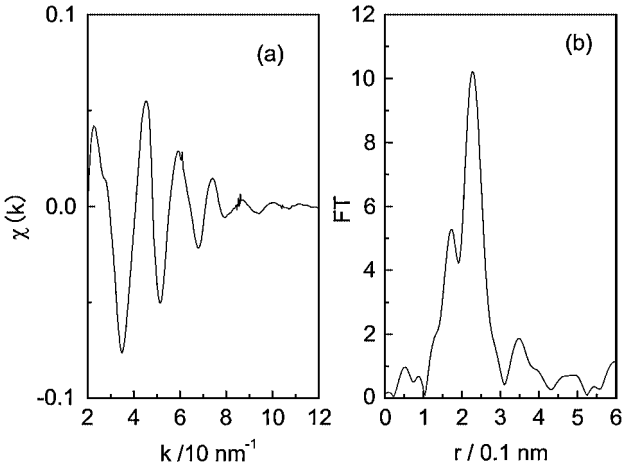

Fig. 5. EXAFS oscillation of Ni phosphide on SiO_2 after reduction (a) and its k^3-weighted Fourier transform (b).

shape of the Ni_2P particle [6], we calculated the particle-size dependence of coordination numbers. Comparing the observed and calculated values, the particle sizes are estimated to be 7.0 nm well corresponding to TEM results (10 nm).

The Ni_2P was heated up to a temperature at 573 K (reaction temperature) and employed in the thiophene HDS reaction. Fig. 6 shows the EXAFS oscillations just before the reaction and 2 hours after the start of reaction. Both XAFS oscillations are reduced

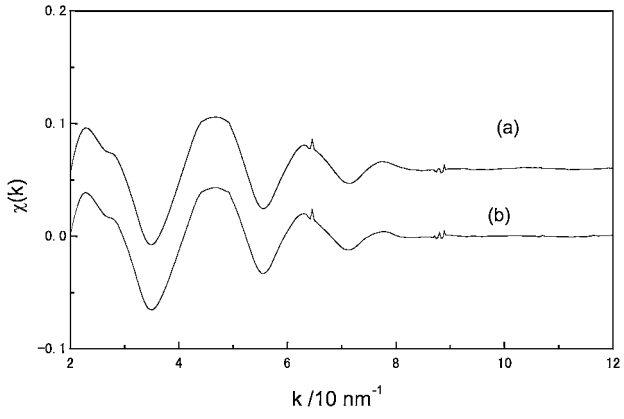

Fig. 6. EXAFS oscillations of Ni phosphide on SiO_2 before the HDS reaction (a) and 2 hours after the start of reaction.

in their amplitude due to the thermal disorder. However, the main features of Ni_2P are maintained after heating to 573 K. We find that little change occurs between the two spectra. Thus the Ni_2P structure is stable during the thiophene HDS reaction.

4. Conclusions

1. Ni phosphides are partially oxidized during the passivation process.
2. The passivated Ni phosphide is easily reduced by H_2 at 350–500 K.
3. The reduced catalyst consists of Ni_2P crystallites with size around 7 nm.
4. The Ni_2P structure is stable during the thiophene HDS reaction.
5. The Ni_2P is an active structure for HDS reaction.

Abstract

Silica supported molybdenum oxide catalysts were prepared from Mo dimer complex ($Mo_2(CH_3CO_2)_4$) by using photochemical anchoring (PCA) method. The local environments of Mo atoms on both attached and oxidized catalysts were investigated by Mo K-edge EXAFS, XANES, Raman spectroscopy and thermal gravimetric analysis. The bond distance between dimeric Mo atoms could be changed depending on the energy of UV irradiation. By using the lower irradiation energy ($\lambda > 350$ nm), the attached structure was close to the original Mo dimer complex. After oxidation of the catalyst, dimeric structure was formed with bridging oxygen and the Mo-(O)-Mo bond distance was 0.316 nm. On the other hand, in the case of higher irradiation energy ($\lambda > 250$ nm), the Raman spectrum of the attached catalyst had bands due to acetate ligands except a band at 405 cm^{-1} due to Mo-Mo skeleton bond. It means that $Mo_2(CH_3CO_2)_4$ is decomposed by UV irradiation. The oxidized form of the higher energy irradiated catalyst showed monomer-pair structure.

1. Introduction

Compounds of group V, VI and VII transition metals, particularly Mo, V, Re and W compounds, are widely used as catalysts for various reactions in industry such as metathesis of hydrocarbons [1–6]. Local structure of metal oxide is one of the most important parameters, which determines the activity. Anchoring metal oxide on support enables to design the local structure around active sites and to increase the number of active sites. Wide varieties of preparation methods, precursors and supports have been investigated in order to control the local structures [7]. For instance, $VOCl_3$ is attached to porous Vycor glass by using UV irradiation. Photo-activated $VOCl_3$ reacts with OH group on the Vycor glass surface. Since this reaction occurs quantitatively at room temperature, vanadium oxides are not aggregated. Vanadium oxides are attached uniformly with high dispersion [8]. Grafting of organometallic di- and tri-nuclear cluster complexes, such as $Mo_2(CH_3CO_2)_4$ and $Mo_3O(CCH_3)(CH_3CO_2)_6(CH_3OH)_3Cl$ to mesoporous FSM-16 generate dimer and trimer structure of Mo oxide, respectively [9, 10].

In this study, light sensitive $Mo_2(CH_3CO_2)_4$ was anchored on silica under UV irradiation. It is expected that the local structures of Mo oxides can be finely designed by controlling the irradiation energy. Local structures of catalysts for each preparation step were determined by using XAFS spectroscopy. Structural difference caused by irradiation energy was compared and discussed.

2. Experimental

5 wt% Mo/SiO_2 catalysts were prepared *in vacuo* by mixing without solvents (solid-solid reaction) in a quartz reactor under UV irradiation (photo-chemical anchoring (PCA) method). The UV irradiation was carried out by a 75 W high pressure Hg lamp through a UV cut-filter ($\lambda > 350$ nm) or without filter ($\lambda > 250$ nm) at room temperature for 1 h. The catalysts were designated with UV irradiation wavelength as PCA35 and PCA25, respectively. PCA35 and PCA25 catalysts were treated with H_2, followed by O_2 at 473 K for 1 h to convert into oxide form denoted as PCA35-ox and PCA25-ox, respectively.

The structures of the catalysts were characterized by X-ray absorption fine structure (XAFS), Raman spectroscopy, and thermal gravimetric analysis (TG). Mo K-edge XAFS measurements were carried out at BL-10B in the IMSS-PF, Tsukuba, Japan (Proposal No. 2000G286). The spectra were collected at room temperature in transmission mode with a Si(311) channel cut monochrometer by using two ion-chambers filled with (50% Ar + 50% N_2) and (100% Ar) for I_0 and I, respectively. The pretreated samples were sealed in an Al cell with Kapton windows in order to protect from contact with air. Coordination number (CN) and atomic distance (r) were evaluated by curve-fitting analysis in k-space using the REX2000 program (Rigaku Co.). Standard reference materials, Mo foil, MoO_3 and K_2MoO_4 were used to extract back scattering amplitude and phase shift function for Mo-Mo, bridging Mo-O and terminal Mo=O bonding, respectively. Raman spectra were taken with the 514.5 nm line of an Ar^+ laser on a JASCO NRS-2100 laser Raman spectrometer, and detected by a CCD cooled at 77 K. Samples were sealed in a quartz cell in order to protect from contact with air.

3. Results and discussions

The Mo K-edge XANES spectra can provide information on the local structural symmetry about X-ray absorbing Mo atoms. The peak positions of Mo K-edge XANES spectra were 20020.5 eV for PCA25, 20021.6 eV for PCA35, and 20022.2 eV for $Mo_2(CH_3CO_2)_4$. The peak position and the near-edge feature of PCA35 were close to those of $Mo_2(CH_3CO_2)_4$. However, the peak position of PCA25 was shifted to lower energy and the near-edge feature was gentler than that of $Mo_2(CH_3CO_2)_4$, suggesting that the average electronic structure and site symmetry around Mo atoms in the PCA25 were different from those in $Mo_2(CH_3CO_2)_4$.

Raman bands due to acetate ligands of $Mo_2(CH_3CO_2)_4$ were observed at 691, 951 and 1434 cm^{-1} [11] in both spectra of PCA25 and PCA35. In addition, a band at 405 cm^{-1} due to the Mo-Mo multiple bond of Mo dimer complex [11] was observed in the PCA35, but not in the PCA25.

The weight loss is 11.7% if all acetate ligands are released from 5 wt% $Mo_2(CH_3CO_2)_4/SiO_2$. The gap between the weight loss of all acetate ligands (11.7 wt%) and the observed weight loss by TG measurements for PCA25 and PCA35 (5.79 and 11.01 wt%, respectively) was assigned to the lost of acetate ligands by photo-decomposition. Thus, the number of acetate

Table I. *Curve-fitting results for $Mo_2(CH_3CO_2)_4$, PCA25 and PCA35.*

compound	coordination	CN	r/nm	DW/nm
PCA25	Mo-O	3.3	0.221	0.0035
	Mo-Mo	0.5	0.239	0.0090
PCA35	Mo-O	3.5	0.219	0.0056
	Mo-Mo	0.9	0.211	0.0068
$Mo_2(CH_3CO_2)_4$	Mo-O	4.0	0.220	0.0066
	Mo-Mo	1.0	0.212	0.0082

ligands remaining on the PCA25 and PCA35 was 0.33 and 3.56, respectively.

The above results of XANES, Raman and TG measurement reveal that the degree of photo-decomposition of $Mo_2(CH_3CO_2)_4$ depends on the energy of UV irradiation. The structure models of PCA25 and PCA35 were proposed as Figure 1(b) and (c). PCA35 kept an original Mo-Mo skeleton with three acetate ligands. On the other hand, most acetate ligands were removed by photo-decomposition with higher UV energy ($\lambda > 250$ nm).The structure of PCA25 is different from $Mo_2(CH_3CO_2)_4$.

Crucial information about bonding properties of the two PCAs and the oxide catalysts were provided by Mo K-edge EXAFS spectroscopy. Figure 2(a), (b) and (c) show the Fourier transforms of the k^3-weighted Mo K-edge EXAFS spectra for the two PCAs and $Mo_2(CH_3CO_2)_4$ obtained from the 40–167 nm^{-1} k-range. A peak at 0.15–0.22 nm was attributed to Mo-O and Mo-Mo pairs [10]. The results of curve-fitting analysis are summarized in Table I. $Mo_2(CH_3CO_2)_4$ contains contributions from Mo-Mo bonds, $r = 0.212$ nm (CN = 1.0), and Mo-O bonds, $r = 0.220$ nm (CN = 4.0). They are in good agreement with the molecular structure of $Mo_2(CH_3CO_2)_4$ as shown in Figure 1(a). The Mo-O bond distances were determined to be 0.219 nm and 0.221 nm for PCA35 and PCA25, respectively. These values are close to that of the original $Mo_2(CH_3CO_2)_4$. The Mo-Mo bond distance for the PCA35 is also similar to that in $Mo_2(CH_3CO_2)_4$. The CN of Mo-O bond for PCA35 is in good agreement with the number of remaining acetate ligands given by TG measurement. On the PCA35 that anchored by irradiation with lower energy ($\lambda > 350$ nm), the Mo_2 initial framework was unchanged and about 3/4 of the acetate ligands remained (Figure 1(c)). On the contrary, the Mo-Mo bond distance for PCA25 is larger than that of $Mo_2(CH_3CO_2)_4$. The Mo_2 initial framework was broken and two Mo atoms were supported apart from each other (Figure 1(b)). The CN for the Mo-O bonds of PCA25 is larger than that expected by TG measurement. PCA25 seems to have two kinds of Mo-O bonds: one bound directly to silica and another bound to acetate ligands. Therefore the local structure of Mo can be controlled by irradiation energy.

Figure 2(d) and (e) show the Fourier transforms of k^3-weighted Mo K-edge EXAFS spectra for Mo/SiO_2 catalysts obtained from the 37–147 nm^{-1} k-range. The peak at about 0.25–0.35 nm in the FTs spectra can be attributed to neighboring Mo atoms. As shown in Table II, PCA35-ox had shorter Mo-(O)-Mo bonds at $r = 0.316$ nm than PCA25-ox ($r = 0.329$ nm). Those Mo-(O)-Mo bond distances reflected photo-chemical anchored Mo structure. The structure of PCA35 was similar to original complex, but in PCA25, the Mo_2 framework was broken down. The peaks observed at about 0.095–0.195 nm could be assigned to Mo-O bonds. A curve-fitting analysis indicated that the Mo species has two kinds of Mo-O bond. The shorter one ($r \sim 0.17$ nm) was attributed to the terminal Mo=O bond and the longer one ($r \sim 0.22$ nm) to the bridged Mo-O bond or to the Mo-O bond directly to the silica surface. The CN of terminal Mo=O bond and Mo-O bond were 1.2 and 0.5 for PCA25-ox and 1.0 and 1.2 for PCA35-ox, respectively. The PCA25-ox had larger CN of Mo=O bond and smaller CN of Mo-O bond than those in the PCA35-ox. Considering that two Mo atoms were supported apart from each other in PCA25, Mo oxide tend to be isolated in the PCA25-ox. The Mo K-edge XANES spectra of MoO_3 and K_2MoO_4 have representative structure for MoO_6 (octahedral coordination) and MoO_4 (tetrahedral coordination), respectively. The XANES spectrum of K_2MoO_4 exhibited a high intensity preedge peak due to the 1s-4d transition. It has been reported that Mo complexes with tetrahedral geometry have strong 1s-4d transition peaks

Table II. *Curve-fitting results for PCA25-ox and PCA35-ox.*

compound	coordination	CN	r/nm	DW/nm
	Mo=O	1.2	0.167	0.0072
PCA25-ox	Mo-O	0.5	0.216	0.0040
	Mo-(O)-Mo	0.4	0.329	0.0069
	Mo=O	1.0	0.165	0.0065
PCA35-ox	Mo-O	1.2	0.216	0.0065
	Mo-(O)-Mo	0.5	0.316	0.0075

[12, 13]. PCA25-ox possessed the strong preedge peak and the near-edge feature was close to that of K_2MoO_4. This suggests that the Mo oxide in the PCA25-ox had mainly tetrahedral geometry and was isolated. The preedge peak intensity of PCA35-ox was weaker than that of PCA25-ox. Thus, the Mo oxide in PCA35-ox was not isolated and made few Mo-(O)-Mo networks. According to the EXAFS and XANES analyses, local structures of Mo/SiO_2 catalysts were proposed as Figure 2(d) and (e). The structure of PCA25-ox was substantially monomer-pair without Mo-(O)-Mo bonding and that of PCA35-ox was dimeric.

4. Conclusion

From the results presented above, we conclude the following:

1. The degree of photo-decomposition of $Mo_2(CH_3CO_2)_4$ could be controlled by the energy of UV irradiation. The acetate ligands of the Mo dimer complex decreased to about 0.33 with higher irradiation energy ($\lambda > 250$ nm). The Mo-Mo bond distance of PCA25 was 0.239 nm. It was much longer than that of $Mo_2(CH_3CO_2)_4$ (0.212 nm). Two Mo atoms were supported apart from each other. On the other hand, about 3/4 of the acetate ligands were left in PCA35, and the Mo-Mo bond distance was 0.211 nm. The structure was close to the original Mo dimer complex. The framework of the Mo dimer complex was maintained.
2. Monomer-pair and dimetric Mo oxide structures were formed by oxidation of PCA25 and PCA35, respectively. PCA25-ox was monomer-pair without Mo-(O)-Mo bonding structure but it was not completely isolated. The Mo-(O)-Mo bond distance for PCA35-ox was 0.316 nm. The local structure of the Mo oxide catalysts was designed by the energy of UV irradiation.

Abstract

In-situ XAFS observation of Pd-Pt catalysts supported on SiO_2, Al_2O_3 and USY was carried out during reduction and sulfidation processes. Under sulfidation conditions, Pd-Pt species on USY was the most seriously sulfided, whereas, no contribution of sulfur was observed in Pt L_{III}-edge EXAFS of sulfided Pd-Pt/SiO_2. Pd-Pt species on Al_2O_3 showed intermediate properties for sulfidation. It is found that Pd and Pt metal species formed relatively uniform alloy particles on SiO_2 and Al_2O_3, whereas, on USY, Pd and Pt atoms were segregated in the alloy particles.

1. Introduction

Supported Pd-Pt catalysts are known as efficient catalysts for deep hydrodearomatization (HDA) of diesel fuel [1, 2]. The activity varies with not only the composition of alloy species but also the kinds of the support [3–5]. In this work, the Pd-Pt alloy species supported on three kinds of supports were investigated: SiO_2, Al_2O_3 and ultra stable Y-type zeolite (USY). The order of total HDA activity was as follows: Pd-Pt/USY $\gg$ Pd-Pt/Al_2O_3 > Pd-Pt/SiO_2 [3]. Though Pd-Pt/USY and Pd-Pt/Al_2O_3 have almost the same number of exposed metal atoms determined by CO adsorption [3], the activity of Pd-Pt/USY was 6 times higher than Pd-Pt/Al_2O_3 [3]. The turn over frequency (TOF) of Pd-Pt/Al_2O_3 was similar to that of Pd-Pt/SiO_2, even though the average size of metal particles on SiO_2 was larger than that on Al_2O_3 [3]. Thus it is strongly suggested that the intrinsic activity of each metal site is different, probably due to difference in surface structure. *In-situ* XAFS (X-ray adsorption fine structure) technique was applied to surface structure analysis of the three catalysts. In the present work, the *in-situ* XAFS observation of the catalysts was carried out during reduction and sulfidation processes and the surface structure is discussed based on the structural change under these conditions.

2. Experimental

2.1. *Sample preparation*

Supported Pd-Pt (molar ratio of Pd/Pt was 4) catalysts were prepared by impregnation method. Al_2O_3 (Catalysts and chemicals Industry), SiO_2 (Fuji Silysia chemical), and an ultra stable Y-type zeolite (USY, $SiO_2/Al_2O_3 = 13.9$, Catalysts and chemicals Industry) were used as supports. The precursors for Pd and Pt were $Pd(NH_3)_4Cl_2 \cdot xH_2O$ and $Pt(NH_3)_4Cl_2 \cdot xH_2O$, respectively. The total metal content was 1.2–2 wt%. The impregnated samples were dried in vacuum at 333 K for 6 h, then calcined at 573 K under oxygen for 3 h. A round disk of 10 mm in diameter was made out of the calcined catalyst (0.2 g) and was set in an *in-situ* cell.

2.2. *XAFS measurements*

In-situ XAFS measurements were carried out at BL7C, 9A and 10 B of the Photon Factory in the Institute of Materials Structure Science, High Energy Accelerator Research Organization (PF-IMSS-KEK) in Japan. A Si(311) channel-cut and Si (111) double crystal monochromators were used for Pd K-edge and Pt L_{III}-edge XAFS measurements, respectively. All the spectra were obtained in transmission mode by using two ionization chambers in front and back of the cell (represented as I_0 and I, respectively). The ionization chambers filled with Ar (for I_0) and Kr (for I) were used in the Pd K-edge energy region, and in the Pt L_{III}-edge energy region, the gases were exchanged with N_2 (for I_0) and 15% Ar/N_2 (for I).

A flow reaction system including an *in-situ* XAFS cell [6, 7] was assembled at the end of the X-ray beam line. All the reaction conditions like temperature, pressure and gas flow rate could be monitored and controlled outside the radiation shield room. The exhaust gas contained H_2S and H_2. H_2S was removed with 20% NaOHaq absorber and H_2 was converted into H_2O with a burner. No toxic and/or flammable gases were detected at the end of the gas flow line.

The sample was initially reduced under a flow of 20%H_2/He. The flow rate was 120 cm^3/min. The temperature was increased stepwise by 50 K from ambient temperature to 573 K and kept for 1 hour at 573 K. After reduction, sulfidation of the sample was done at 553 K under a diluted H_2S (composed of 100 ppm H_2S + 20%H_2/He) at a flow rate of 120 ml/min.

XAFS spectra were observed in-situ in the course of all treatments every 10 min in a step-scanning mode with data accumulation time of 0.5–1 s for each step. XAFS analysis of the obtained data was conducted with commercially available software (REX, Rigaku Co.). Parameters for backscattering amplitudes and phase shift functions were extracted from the oscillations of standard substances (Pd foil, Pt foil, Pd-Pt alloy foil, PdS and PtS_2) observed at reaction temperature in order to exclude influence of thermal oscillations at higher temperature from analysis.

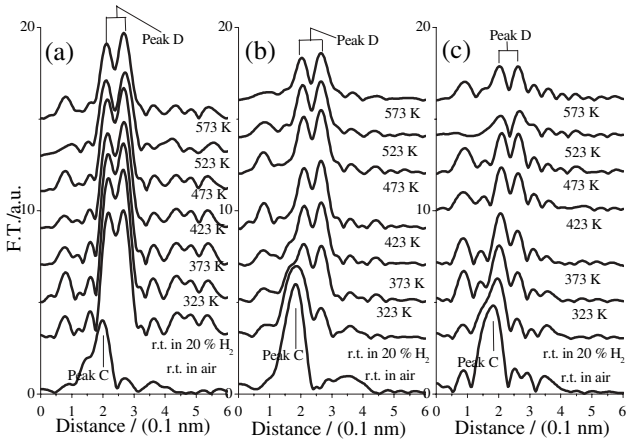

Fig. 2. Fourier transform of Pt L_{III}-edge EXAFS spectra ($k^3\chi(k)$) obtained during reduction under a flow of 20%H_2/He: (a) Pd-Pt/SiO_2, (b) Pd-Pt/Al_2O_3 and (c) Pd-Pt/USY. The bottom function in each figure was obtained in air before reduction in air.

3. Results and Discussion

3.1. *Reduction*

Figure 1 shows Fourier transform of Pd K-edge EXAFS ($k^3\chi(k)$) observed for the three catalysts during reduction under a flow of 20%H_2/He, except for the bottom spectra, which were observed before reduction. Initially, strong bands appeared at 0.18 nm in all catalysts (Peak A), and they were assigned to Pd-O and Pd-Cl scattering. For Pd-Pt/SiO_2, upon introduction of 20%H_2/He, the peak at 0.18 nm completely disappeared and a new peak appeared at 0.26 nm (Peak B), which is assigned to metal-metal scattering: Pd-Pd and Pd-Pt. The Peak B remained almost the same during subsequent reduction upto 573 K. For Pd-Pt/Al_2O_3, the Peak A was weakened by introduction of 20%H_2/He and correspondently the Peak B emerged at 0.26 nm, but contribution by Pd-O or Pd-Cl still remained at 0.18 nm. As the temperature increased, the Peak A became weak and finally disappeared at 373 K, while, the Peak B became intense and dominant. The change of spectra for Pd-Pt/USY was similar to that of Pd-Pt/Al_2O_3. One difference between Pd-Pt/USY and Pd-Pt/Al_2O_3 was that Pd in Pd-Pt/USY was more easily reduced at ambient temperature.

Figure 2 shows the Fourier transform of Pt L_{III}-edge EXAFS ($k^3\chi(k)$) observed under the same conditions as Fig. 1. The change of spectra is almost the same as that of Pd K-edge. Before reduction (the bottom line), a strong band assigned to Pt-O or Pt-Cl appeared at 0.18 nm (Peak C). During reduction, the Peak C decreased, while a new peak appeared near 0.26 nm (Peak D), which is assigned to metal-metal scattering: Pt-Pd and Pt-Pt. Reduction of Pt atoms on SiO_2 completes at ambient temperature as in the case of Pd, whereas, the Pd – (O, Cl) contribution (Peak C) disappeared at 373 K for both Al_2O_3 and USY supported catalysts.

Figure 3 shows the change in coordination numbers (CN) during reduction. The coordination numbers of Pd-Pd and Pt-Pd for Pd-Pt/SiO_2 are larger than those for Pd-Pt/Al_2O_3 and Pd-Pt/USY. This fact indicates that the averaged particle size of metal species on SiO_2 is larger than on Pd-Pt/Al_2O_3 and Pd-Pt/USY. The coordination number of Pt-Pd for Pd-Pt/SiO_2 and Pd-Pt/Al_2O_3 is larger than that of Pd-Pt/USY. A possible explanation for this difference is that the Pd and Pt atoms are relatively uniformly distributed in metal particles in Pd-Pt/SiO_2 and Pd-Pt/Al_2O_3, and segregated in Pd-Pt/USY (Fig. 4). The CN(Pt-Pd) gradually increases with temperature for all catalysts.

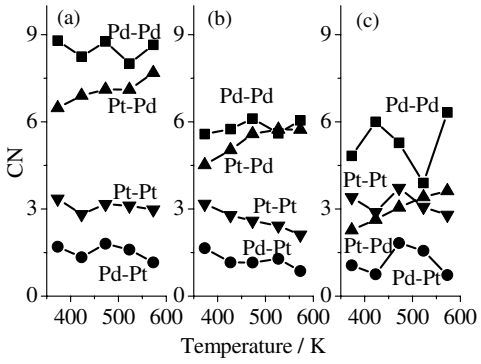

Fig. 3. Change of coordination numbers of metal-metal atomic pairs during reduction under a flow of 20%H_2/He: (a) Pd-Pt/SiO_2, (b) Pd-Pt/Al_2O_3 and (c) Pd-Pt/USY. Squares represent CN(Pd-Pd), circles CN(Pd-Pt), triangles CN(Pt-Pd), and inverted triangles CN(Pt-Pt).

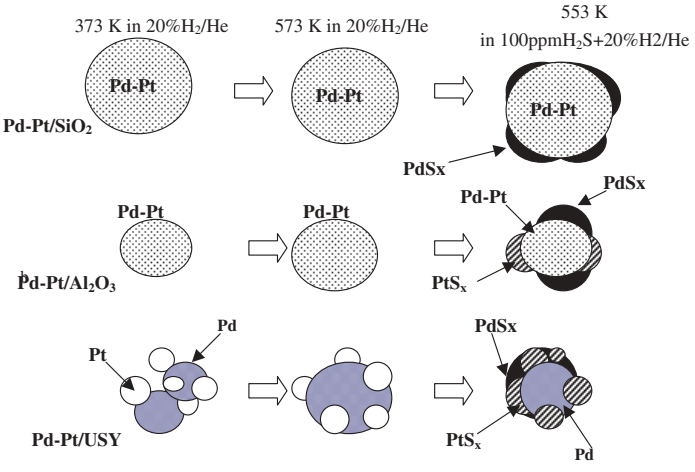

Fig. 4. Proposed structural change of Pd-Pt alloy particles during reduction and sulfidation.

It suggests that the mixing of Pt and Pd atoms increases with temperature.

3.2. *Sulfidation*

After reduction, the catalyst was cooled to 553 K and diluted H_2S (100 ppm H_2S + 20%H_2/He) was introduced. The catalyst was kept at 553 K under diluted H_2S until the sulfidation was

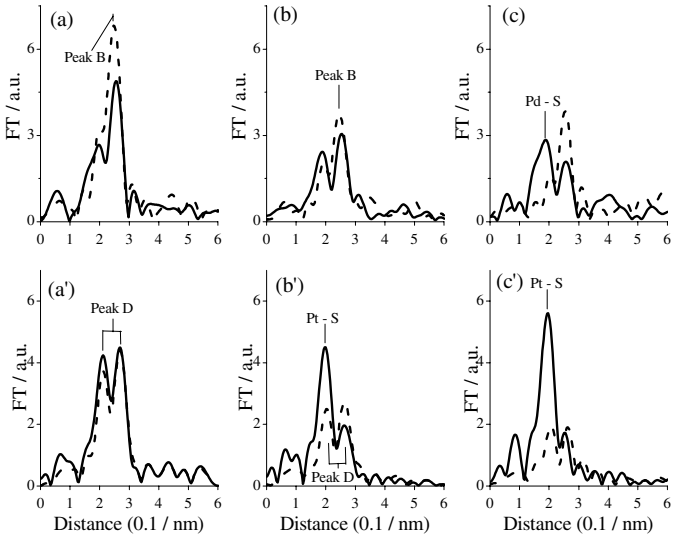

Fig. 5. Fourier transform of Pd K-edge (top figures) and Pt L_{III}-edge (bottom figures) EXAFS spectra ($k^3\chi(k)$) obtained after sulfidation at 553 K under a flow of 100 ppm H_2S + 20% H_2/He (solid lines), compared with those of reduced samples obtained in 20%H_2/He at 573 K (dashed lines) : (a, a′) Pd-Pt/SiO_2, (b, b′) Pd-Pt/Al_2O_3, and (c, c′) Pd-Pt/USY.

completed. Figure 5 shows Fourier transform of Pd K-edge and Pt L_{III}-edge EXAFS ($k^3\chi(k)$) observed after sulfidation at 553 K (solid lines) under diluted H_2S, compared with those obtained after reduction at 573 K (dashed lines). For Pd-Pt/SiO_2, the Peak B decreased in the Pd K-edge spectrum, whereas, in the Pt L_{III}-edge spectrum, the spectrum remained almost unchanged. For Pd-Pt/Al_2O_3, the Peak B decreased as in the case of Pd-Pt/SiO_2, and the Peak D in the Pt L_{III}-edge spectrum also decreased and a new peak due to Pt-S scattering appeared at 0.20 nm. For Pd-Pt/USY, the change was more noticeable than the other catalysts, that is, contribution of Pd-S was observed at 0.20 nm in the Pd K-edge spectrum and the peak of Pt-S scattering became dominant in the Pt L_{III}-edge spectrum after sulfidation. Table I shows curve-fitting (CF) results of reduced and sulfided catalysts. Although CN(Pd-S) was 1.0 in sulfided Pd-Pt/SiO_2, no contribution of Pt-S was found by CF analysis. For Pd-Pt/Al_2O_3, CN(Pd-S) was 0.9 and CN(Pt-S) was 4.2, meaning that higher degree of sulfidation of Pt rather than Pd occurred. For Pd-Pt/USY, sulfidation of the catalyst preceded more deeply, that is, CN(Pd-Pd) decreased from 6.3 to 2.9 and CN(Pt-S) became 6.3, indicating that almost all the Pt atoms were sulfided.

Judging from the contribution of sulfur in EXAFS spectra, it is concluded that sulfidation of metal species occurs favorably in the following order: Pd-Pt/USY > Pd-Pt/Al_2O_3 > Pd-Pt/SiO_2.

Table I. *Coordination numbers determined by curve-fitting analysis of reduced and sulfided catalysts.*

		Coordination Number (CN)					
Sample	Condition	Pd-Pd	Pd-Pt	Pd-S	Pt-Pd	Pt-Pt	Pt-S
Pd-Pt/SiO_2	Reduced*	9.0	1.0		7.7	3.1	
	Sulfided**	5.8	—	1.0	6.8	4.5	—
Pd-Pt/Al_2O_3	Reduced*	6.1	1.3		5.7	2.1	
	Sulfided**	5.0	—	0.9	3.9	—	4.2
Pd-Pt/USY	Reduced*	6.3	0.7		3.6	2.8	
	Sulfided**	2.9	—	1.9	1.9	—	6.3

*After reduction at 573 K for 1 h.
**After sulfidation at 553 K for 4.5 – 6 h.

As mentioned in 3.1, Pt and Pd atoms were segregated in the metal particles in Pd-Pt/USY. If it is assumed that Pt atoms formed small clusters and were mainly located on the outer surface of metal particles, then it is understandable that Pt sulfidation proceeded prior to Pd sulfidation (Fig. 4). On the other hand, in Pd-Pt/SiO_2 and Pd-Pt/Al_2O_3, Pd and Pt atoms were mixed more homogeneously and less Pt atoms were exposed to the outer surface. As a result, sulfidation of Pt was suppressed or limited, compared to Pd-Pt/USY (Fig. 4). In addition to that, it is suggested that Pt and Pd atoms in homogeneous bimetallic alloy are less active toward sulfur compared with pure Pt or Pd, because, according to CO adsorption, Pd-Pt/Al_2O_3 and Pd-Pt/USY have almost the same number of exposed metal atoms, but the number of sulfur adsorbed on Pd and Pt in Pd-Pt/Al_2O_3 was smaller than that in Pd-Pt/USY. The highest sulfur tolerance of Pt in Pd-Pt/SiO_2 might be due to highly homogeneous alloy formation or presence of Pd atoms on the surface, protecting Pt from sulfur.

Ackknowledgement

The XAFS measurements were carried out under the approval of PF PAC (Program Advisory Committee) as projects No. 2002G274 and No. 2000G283.

Abstract

The present paper points out the possibility of investigating solid-solid transformations using time dependent X-ray absorption spectroscopy (QEXAFS) on a second scale. For this purpose, new crystal driving mechanics were developed which enable the measurement of complete X-ray absorption spectra extending over up to 2000 eV with repetition frequencies of up to 40 Hz and the possibility of monitoring a reference sample simultaneously. This permits to detect even very small changes of the edge position – and thus the chemical valency of the species of interest – with a high accuracy. The application of the new set up is demonstrated for the in situ analysis of the thermal decomposition of Co-oxalate-hydrate in different gas atmospheres. The results prove that the details of the decomposition process and the formed reaction products depend sensitively on the composition of the gas atmosphere.

1. Introduction

A number of solid-solid transformations such as decomposition reactions or the reduction/oxidation of heterogeneous catalysts occur relatively fast, i.e. within less than a minute. Time resolved investigations are thus important in order to gain insight into the mechanisms of such solid-solid transformations (e.g. during changes of temperature or gas atmosphere). Since intermediate phases are usually present in an amorphous form, XANES or EXAFS experiments seem to be appropriate methods. In a previous in situ study [1], X-ray absorption near edge spectra were taken in the subsecond scale using the piezo-QEXAFS technique. In many cases full EXAFS spectra are needed for a proper interpretation. Hence, the monochromator needs to be moved over a larger angular range. For this purpose, we developed new crystal driving mechanics making use of a tilt table which is moved by an excenter disc [2]. While the description of this new monochromator will be subject of a forthcoming publication [3], we will report on time resolved investigations of decomposition reactions of inorganic materials and heterogeneous catalysts in this paper. More specifically, we succeeded in monitoring the decomposition of cobalt oxalate at the Co K-edge in different gas atmospheres.

2. Experimental

The experiments described here were performed at the undulator beamline 1-ID at the Advanced Photon Source (Argonne, Illinois, USA) operating with 7 GeV electrons and 100 mA of stored current in the topping up mode [4]. The polychromatic radiation from the X-ray source was monochromatized using a Si(111) channel-cut crystal, which was indirectly cooled via a hollow copper block and liquid nitrogen in a closed cycle [2]. The cooler with the crystal was mounted on a tilt table with two solid state hinges which was driven by an excenter disc. This excenter disc is directly mounted on the shaft of a DC-motor the turning speed of which is controlled by a computer and can be varied from about 0.1 Hz to 40 Hz [2, 3]. Several different excenter discs with different asymmetries enable to modify the angular range of the tilt table from about 0.05° to about 1.52°. Using a Si(111)-crystal in the vicinity of e.g. the Cu K-edge (8980 eV), these values correspond to an available energy range for the EXAFS experiments from about 100 eV to more than 2500 eV. The EXAFS data were obtained in transmission geometry. N_2-filled ionization chambers were used as detectors for the intensity of the incoming and the transmitted radiation. A slit system in front of the first ionization chamber was used for the horizontal and vertical definition of the beam which was typically $(0.3\,\mathrm{mm})^2$. The current signals from the ionisation chambers were converted and amplified by Keithley 428 current-to-voltage amplifiers. Their output signals were directly sampled by a fast A/D converter (4 channels with up to 200 kHz simultaneously) and stored on a PC computer. Further details of this setup are given elsewhere [2, 3].

The *in situ* cell for the experiments (design similar to that used in refs. [5, 6]) consists of a quartz glass capillary tube with 0.5 mm diameter and 10 μm wall thickness, which was loaded with the samples of interest, i.e. Co-oxalate-dihydrate in the present case (diluted with alumina). Different pre-mixed gases from a gas manifold could pass through the capillary reactor cell with a typical gas flow of ca. 5 ml/min. Heating of the *in situ* cell microreactor up to 600 °C was performed by passing a defined flow of hot N_2 gas besides the capillary encapsulated in a shield of Kapton foil (cf. description in [5]).

3. Results and Discussion

Due to their relatively low decomposition temperatures, transition metal oxalates are of high interest e.g. as precursors for the preparation of fine metal or oxide powders of the respective element, as well as for the synthesis of catalyst materials. Furthermore, thermal decomposition of metal oxalates is often used for the preparation of catalytically active solid products (see [7, 8] and references therein). Co-oxalate is of special interest due to its use for the preparation of catalysts for the Fischer-Tropsch-synthesis. We investigated the thermal decomposition of Co-oxalate-dihydrate ($CoC_2O_4 \cdot 2H_2O$) in different gas mixtures *in situ* at the Co K-edge (7709 eV). In Fig. 1(a), the room temperature spectrum of a Co-oxalate-dihydrate sample is shown together with that of the Co metal reference measured simultaneously within about 250 ms (2 Hz oscillation frequency, 10 kHz sampling rate). Besides the different EXAFS structures

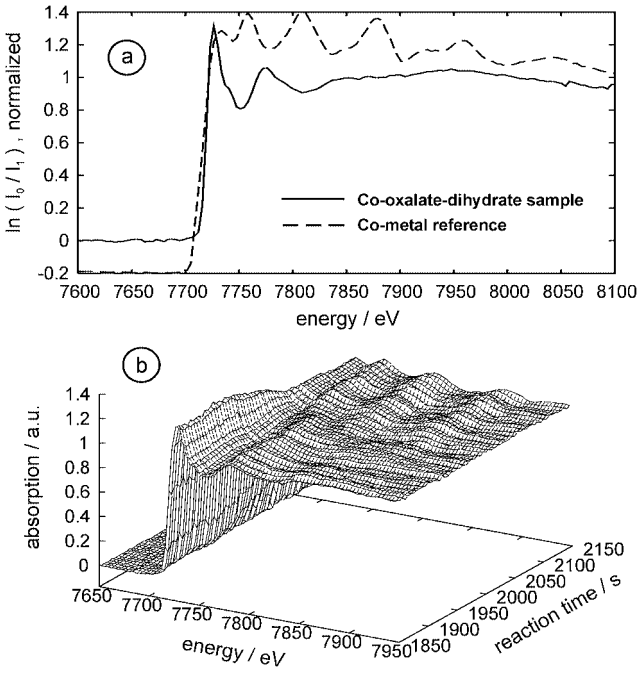

Fig. 1. (a) Co K-edge EXAFS spectrum of $CoC_2O_4{\cdot}2H_2O$ measured *in situ* within 250 ms prior to the initiation of a decomposition reaction together with the Co-metal reference measured simultaneously. (b) *In situ* Co K-edge absorption spectra measured during the thermal decomposition of $CoC_2O_4{\cdot}2H_2O$ in $Ar + 4\%\ H_2$. Each spectrum was measured within 250 ms. The displayed spectra belong to the temperature region between ca. 340 °C and ≈400 °C.

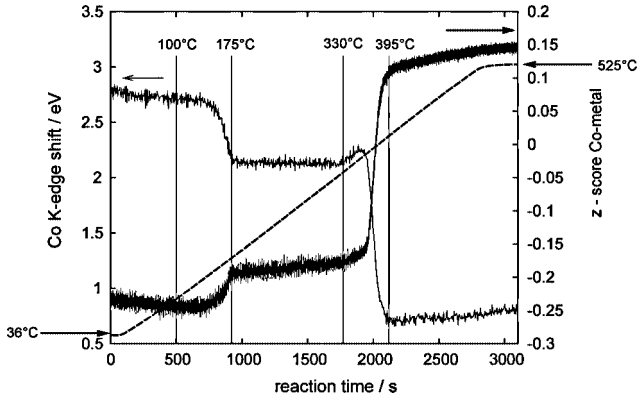

Fig. 2. EXAFS data analysis for the *in situ* decomposition reaction of Co-oxalate-dihydrate in Ar + 4% H_2. The dashed line shows the temperate as a function of time, some essential points are highlighted by vertical lines. The regular line belongs to the observed edge shift of the Co K-edge during the experiment (left ordinate) and the bold line corresponds to the principal component of Co-metal (z-score, right ordinate). Negative and positive values of the z-score belong to small and high Co-metal concentrations, respectively.

above the edge, in particular the small edge shift between both materials is evident – this is one of the big advantages of the set up used. Due to the use of a reference foil even small edge shifts can be very sensitively monitored. Fig. 1(b) depicts EXAFS spectra measured *in situ* in the vicinity of the Co K-edge during the thermal decomposition of Co-oxalate-dihydrate in a mixture of Ar + 4% H_2 in the course of a temperature ramp (10 K/min) from 35 °C to about 530 °C. More than 9000 spectra were measured for each single experiment. The shown spectra belong to the temperature region between ca. 340°C and ≈400 °C.

Obviously, both the structures at the edge and above the edge change dramatically at around 2000 s reaction time: while the white line intensity at the edge decreases significantly, the absorption maximum at about 7770 eV shifts to a lower energy of ca. 7750 eV and further structures appear at around 7900 eV. Besides the determination of accurate values for the edge energy position as a function of the reaction time (and temperature), a principal component analysis [9] was performed using the software package R [10] in order to identify the number and the type of the contributing phases. We found only two contributing principal components during the decomposition which could be identified as the Co-oxalate and Co-metal, i.e. Co(II)oxalate is directly transformed to metallic Co. More detailed results are compiled in Fig. 2. Between about 150 °C and 175 °C, a slight decrease of the absorption edge position to smaller energies by about 0.4 eV was observed. In agreement with previously published data [7, 8], this decrease can be understood in terms of the dehydration of the oxalate-hydrate according to the reaction

$$CoC_2O_4{\cdot}2H_2O \rightarrow CoC_2O_4 + 2H_2O. \quad (1)$$

The small edge shift indicates that the oxalate-hydrate has a slightly increased valence compared to pure CoC_2O_4. In addition, the z-score of Co-metal, which is related to the Co-metal concentration in the sample, shows a slight increase accordingly. It should be noted that the z-score is in general not simply proportional to the concentration, the latter has to be determined from the z-score by means of a target transformation and a least square fit of model compounds [9, 11–13]. However, this is a non-trivial task because of the large number of spectra which are involved in the current experiment. Nevertheless, by comparison with the z-score of the reference compounds (CoC_2O_4 and Co-metal) we can conclude that a negative z-score of the metal corresponds to a high concentration of CoC_2O_4 and positive values belong to a high metal concentration [2].

A further increase of the temperature to about 340 °C results in a steep decrease of the Co K-edge position by about 2.5 eV within a time frame of less than 100 s. At the same time, the Co metal z-score increases from about −0.2 to ca. 0.15 in parallel. Thus it is very likely that the decomposition

$$CoC_2O_4 \rightarrow Co + 2CO_2 \quad (2)$$

occurs in this temperature interval. For comparison, the z-score of metallic Co is 0.16, therefore we can conclude that the decomposition of the oxalate results not only in Co metal, i.e. a small fraction of Co-O species (such as cobalt oxide CoO) is formed.

For comparison, decomposition experiments were also performed in pure Ar atmospheres [2]. These experiments show that course of the reaction is sensitive to the composition of the gas atmosphere, in agreement with recent studies [7]. Our experiments show that the separation of the crystal water according to eqn. (1) occurs for a broader temperature interval compared to the hydrogen containing atmosphere, i.e. it starts at a lower temperature of about 100 °C and is finished at a slightly elevated temperature of ca. 195 °C as can be seen in Fig. 3.

The decomposition of the formed oxalate starts at about 300 °C and is finished at ca. 345 °C, as can be seen in the temperature dependency of the z-score, thus also the decomposition of the oxalate occurs at a lower temperature compared to the H_2-containing Ar atmosphere. However, a closer inspection shows that no shift of the Co K-edge position was observed in this temperature range. In general, the total shift in the Co K-edge position as well as the change in the z-score are smaller compared to the decomposition experiment in Ar + H_2: while the edge shift

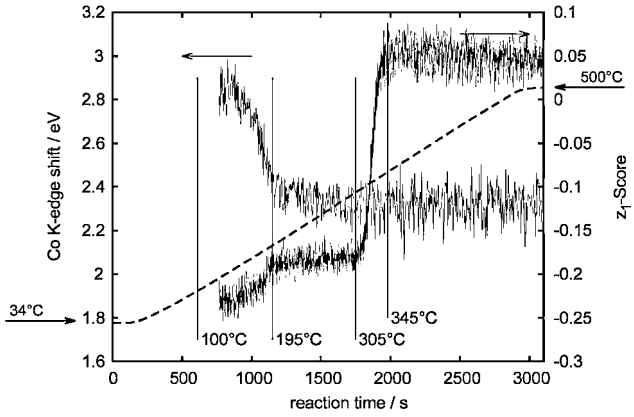

Fig. 3. Analysis of the *in situ* EXAFS data obtained during the decomposition of Co-oxalate-dihydrate in pure Ar. The dashed line shows the temperate as a function of time, some essential points are highlighted by vertical lines. The regular line belongs to the observed edge shift of the Co K-edge during the experiment (left ordinate) and the bold line corresponds to the principal component of Co-metal (z-score, right ordinate).

observed for the decomposition in Ar + H_2 was ≈2 eV, it is only about 0.5 eV in pure Ar. The corresponding changes for the z-score are about 0.3 and 0.4 for the decomposition without and with H_2, respectively. The results indicate that not all Co oxalate is completely decomposed according to eqn. (2) but also some Co-oxide forms directly. This is in agreement with Maciejewski *et al.*, who found about 13% of CoO in samples which were subjected to a decomposition in pure He [7]. Furthermore, the application of the principal component analysis also suggests the presence of three contributing species (i.e. CoC_2O_4, CoO and metallic Co) in the course of the complete experiment, thus it is very likely that the originally existing Co(II)oxalate phase is transformed to Co-metal and Co(II)-oxide. Our experiments suggest that CoO and Co metal exist in equal amounts which may be related to the fact that some residual oxygen in the Ar-atmosphere oxidizes metallic cobalt during the decomposition process. In addition, our samples consisted of Co oxalate diluted with alumina and thus some oxygen exposure may also result from this oxide support. The application of a target transformation is very desirable especially for this experiment to determine accurate values for the respective concentrations (see, e.g. [12, 13]).

Abstract

Zirconium-containing mesoporous silicas Zr-MCM-41 were prepared by two different methods and characterized by XRD, TEM, nitrogen adsorption and EXAFS. In one method, tetraethoxysilane (TEOS) and zirconium tetra-n-propoxide (ZTNP) were mixed and TEOS and ZTNP were hydrolyzed and condensed in aqueous cetyltrimetylammonium bromide solution. EXAFS analysis revealed that zirconium species in Zr-MCM-41 prepared by this method aggregated each other and formed the bonds of Zr-O-Zr. This catalyst had a low catalytic activity for the peroxidative bromination of phenol red. In the other method, $ZrCl_4$ and pure silica MCM-41 were used for impregnation. Zirconium species in this Zr-MCM-41 were highly dispersed as shown in the result of EXAFS analysis. This catalyst exhibited a high catalytic activity for the peroxidative bromination of phenol red. Zirconium species aggregated each other by calcination at 573 K, which caused reduction of catalytic activity.

1. Introduction

Periodic mesoporous silica MCM-41 is a promising material for catalyst support because of its high surface area and uniform pore dimensions [1, 2]. MCM-41 is suitable for transformation of relatively large molecules because the pores of mesoporous materials (2–50 nm diameter) are larger than those of zeolites. Association of transition metals with silica framework of MCM-41 forms catalytic active sites for the reactions. Mesoporous materials containing zirconium have been applied to certain reactions, such as hydroxylation of 1-naphthol [3], photocatalytic generation of hydrogen [4] and chiral alkene polymerization [5]. Tuel *et al.* used zirconium-containing mesoporous silica for the oxidation of large organic molecules using H_2O_2 in the liquid phase [6, 7] and found that it had an acidic character. In this study, we applied this character of Zr-MCM-41 to the peroxidative bromination of phenol red using H_2O_2 as an oxidant [8], according to the following reaction formula:

$$H_2O_2 + Br^- + \text{R-H} + H^+ \rightarrow \text{R-Br} + 2H_2O \quad (1)$$

where R-H and R-Br represent phenol red and bromophenol blue, respectively.

We have synthesized Zr-MCM-41 by two different methods and characterized the product by X-ray diffraction (XRD), transmission electron micrograph (TEM) and extended X-ray absorption fine structure (EXAFS) in order to reveal the effect of local structure of zirconium species on the catalytic activity for the peroxidative bromination of phenol red. EXAFS can provide the interatomic distances and coordination numbers of neighboring atoms for an X-ray absorbing atom in materials with no long-range structural order such as catalysts. O'Brien *et al.* measured Zr K-edge EXAFS in order to characterize organometallic zirconium-grafted siliceous MCM-41 [5] and revealed that the intact ligand existed after immobilization. We present the structural details of zirconium species in zirconium-containing MCM-41 in this article. We found that aggregation of zirconium species occurred by calcination and that it caused reduction of the catalytic activity.

2. Experimental

Zirconium-containing mesoporous silicas, Zr-MCM-41, were prepared by two different methods. In one method, tetraethoxysilane (TEOS) and zirconium tetra-n-propoxide (ZTNP) were used. First, TEOS and ZTNP were mixed in a molar ratio Si/Zr of 49. The mixture was added to an aqueous cetyltrimetylammonium bromide (CTAB) solution, the pH of which was adjusted to 12 by addition of sodium hydroxide. Hydrolysis and condensation of TEOS and ZTNP in the aqueous solution occurred while the mixture was stirred for 1 h and kept for 24 h at ambient temperature with no stirring. The molar ratio of the final gel mixture was 0.12 CTAB : 130 H_2O : 0.5 NaOH : 0.98 TEOS : 0.02 ZTNP. The solid product was filtered, washed with distilled water, and dried at 393 K for 10 h. The product was finally calcined at 773 K for 6 h in air. This product was denoted hereinafter as Zr-MCM-41(mix).

In the other method, zirconium chloride dissolved in ethanol was used as the source of zirconium for impregnation. Only TEOS was added to an aqueous 1.8 wt% CTAB solution, the pH of which was adjusted to 12 by addition of sodium hydroxide. Mesoporous silica without zirconium was obtained in the same way as the first method. Mesoporous silica calcined at 773 K was impregnated with an ethanolic zirconium chloride solution. The molar ratio of the total procedure was 0.12 CTAB : 130 H_2O : 0.5 NaOH : 0.98 SiO_2 : 0.02 $ZrCl_4$. After being dried at 393 K for 3 h, the product was finally calcined at 573, 773, and 1273 K. The product before and after calcination at 573, 773, and 1273 K was denoted hereinafter as Zr-MCM-41-393(imp), Zr-MCM-41-573(imp), Zr-MCM-41-773(imp) and Zr-MCM-41-1273(imp), respectively. The amount of zirconium in Zr-MCM-41(mix) and Zr-MCM-41-X(imp) samples were determined to be ca. 49 in Si/Zr by X-ray fluorescence technique.
